# 19 Heart Disease

---

Peter A. Shapiro, M.D.

**CARDIOVASCULAR DISEASE IS** the cause of death for one-third of American adults, and it is the leading cause of death in the developed world. Although some patients experience sudden fatal illness, many have a disease with chronic course that has a marked impact on their life. The relationships between psychiatry and cardiovascular disease are complex, including both the effects of psychosocial factors on the heart and vascular system and the effects of cardiovascular system changes on mental states. Many psychological states and traits have been identified as contributing to risk for the development or exacerbation of heart disease, including anxiety, anger, type A behavior pattern, depression, stress, and, recently, sleep disorders. Behavioral disorders such as overeating, smoking, and alcohol abuse also add to the risk of heart disease. Conversely, the experience of heart disease seems to contribute to risk for numerous psychiatric problems, especially depression, anxiety, and cognitive disorders. Not only are the psychological effects of dealing with cardiac illness complicated and profound, but the medications and other treatments for heart diseases also often have psychiatric effects. Because heart disease is so common, psychiatrists must expect to deal with the effects of cardiovascular comorbidity in the care of their patients, evaluating the role of medical factors in their mental health and recognizing the potential impact of psychiatric interventions on the cardiovascular system.

## Coronary Artery Disease

---

Aggressive attention to primary prevention measures has reduced the incidence of coronary artery disease (CAD) in the United States over the past 20 years. Traditional CAD risk factors include hypertension, smoking, hypercholesterolemia, diabetes, male sex, and family history. National campaigns to raise awareness about modifiable coronary risk factors and promote treatment have re-

sulted in reduction in the prevalence of some of these factors. Nevertheless, the incidence of acute myocardial infarction (MI) is about 500,000 cases per year in the United States (Rosamond et al. 1998). One-third of patients die within the first hour after the onset of symptoms, before receiving any treatment. Aggressive use of thrombolysis and revascularization procedures, beta-adrenergic blockers, angiotensin-converting enzyme (ACE) inhibitors, statins, and antiplatelet agents has reduced mortality in those who survive long enough to receive acute care. Estimated 28-day survival after acute MI for patients who survive to hospital admission is about 91% (Rosamond et al. 1998).

## Congestive Heart Failure

---

The point prevalence of congestive heart failure (CHF) in the United States is over 2%—a figure essentially unchanged over the past 2 decades. In individuals older than 65 years, the incidence of heart failure approaches 1% per year. By and large, heart failure is characterized by an inexorable if gradual downhill course. The 5-year mortality of congestive heart failure is 50%, generally within 1 year after the onset of symptoms. The primary modes of death in heart failure are pump failure and cardiac arrhythmias (Jessup and Brozena 2003). Treatment with beta-adrenergic blockers, ACE inhibitors, angiotensin<sub>2</sub> receptor blockers, spironolactone, and implantable cardiac defibrillators reduces the risk of death, whereas inotropic agents have largely failed to do so, although they improve functional status in severely ill patients (Cohn 1996; Jessup and Brozena 2003). New treatments in heart failure include the use of biventricular pacing and long-term ventricular assist devices, which hold the promise of improving survival and quality of life (Jessup and Brozena 2003; Lazeau et al. 2001; Rose et al. 2001).

## Psychiatric Disorders in Heart Disease

The development of cardiac disease in a previously well individual is associated with a variety of psychological reactions. Perhaps most fundamentally, it is difficult to maintain denial about one's mortality after a cardiac event. Viewing oneself as having heart disease has effects at every level of psychological development: increasing concerns about dependency, autonomy, control, and ability to provide for others; provoking loss of self-esteem and concern about loss of love; and inciting fears about vitality, sexuality, and mortality. The maintenance of denial has been associated with mental well-being (Levenson et al. 1989; Levine et al. 1987) and may be manifest as minimizing the severity of the event ("I just had a small attack") or attributing symptoms to a noncardiac source ("gas pains"), but excessive denial can be detrimental to health because of the failure to accept the need to maintain a treatment regimen or a delay in seeking treatment (Cassem 1985). In contrast, inadequate denial or exaggeration of the illness can lead to invalidism or mental disorder in the cardiac patient.

Attention to one's heartbeat, conscious experience of twinges of chest pain or palpitations, and other preoccupations with minor physical symptoms may result in hypochondriacal avoidance of activity and increased visits to the doctor and emergency room. Research with hypochondriacal, somatizing, and panic patients, who make up a large portion of patients presenting to emergency rooms with noncardiac chest pain, has demonstrated the high level of somatic awareness common in such patients (Barsky 1992; Barsky et al. 1994a, 1996).

### Depression

#### *Depression in Coronary Artery Disease*

Depression appears to be the most common psychiatric disorder in CAD patients (Glassman and Shapiro 1998). Numerous surveys of patients with established coronary disease, acute MI, and unstable angina indicate a point prevalence of depression consistently in the range of 15%–20% (Shapiro et al. 1997). In a study of 200 patients interviewed after diagnostic coronary angiography confirmed a diagnosis of CAD, 16% met the criteria for major depressive disorder, and 17% met the criteria for minor depression. Most patients with major depression and about half of those with minor depression were found to have major depression at 1-year follow-up (Hance et al. 1996). Studies in post-MI patients in Europe, Canada, and the United States also converge on a point prevalence

of depression of about 15% (Frasure-Smith et al. 1993; Ladwig et al. 1991; Schleifer et al. 1989). This figure is remarkable in light of national surveys indicating a lifetime prevalence of depression of approximately 16% in the general population (Kessler et al. 2003). Three studies of patients following coronary artery bypass graft surgery also demonstrate a point prevalence of depression in the range of 20%–30% (Blumenthal et al. 2003; Connerney et al. 2001; Shapiro et al. 1998). Elevated symptom scores on depression rating scales such as the Beck Depression Inventory (BDI) are even more common and may predict subsequent major depression (Frasure-Smith et al. 1995a, 1995b).

Many studies indicate the failure to diagnose and treat depression in CAD patients (Frasure-Smith 1993; Luutonen et al. 2002). In a Finnish study (Luutonen et al. 2002) of 85 consecutive post-MI patients with 18-month follow-up, the prevalence of BDI scores of 10 or greater was 21% in hospital, 30% at 6 months, and 33.9% at 18 months. Only 6 patients received mental health treatment; 2 received benzodiazepines; none received adequate antidepressant therapy (Luutonen et al. 2002). In the Montreal Heart Institute sample, none of 35 patients identified with major depression by research interviews in the post-MI hospital stay received antidepressants (Frasure-Smith et al. 1993). In another study of patients with newly diagnosed CAD, one-sixth of the sample met the criteria for major depression; at 1-year follow-up, only one-sixth of those who were depressed had received treatment (Hance et al. 1996). The availability of good social support reduces the likelihood of persistent depression after an acute coronary event (Frasure-Smith et al. 1995b, 2000).

#### *Depression in Congestive Heart Failure*

Fewer studies have examined the prevalence of depression in patients with CHF, but as in patients with coronary disease, a point prevalence of depression approaching 20% is suggested by available data (Faris et al. 2002; Freedland et al. 1998; Jiang et al. 2001). A recent study of 347 hospitalized CHF patients demonstrated a 14% point prevalence for major depression, and 35% of patients had a BDI score over 10, commonly regarded as a threshold of significant depressive symptoms (Jiang et al. 2001). Other studies have estimated a prevalence of significant depressive symptoms in 20%–30% of CHF patients. In the REMATCH trial, a study comparing left ventricular assist device (LVAD) implantation with medical therapy for patients with chronic, end-stage congestive heart failure, the mean baseline BDI score was over 16, and more than two-thirds of patients had a score over 10 (Rose et al. 2001).

## Anxiety

### *Anxiety in Coronary Artery Disease*

The prevalence of anxiety disorders in CAD has not been as well studied as that of depression, but anxiety symptoms are clearly elevated in patients with acute coronary disease and in 5%–10% of patients with chronic heart disease (Sullivan et al. 2000). Many patients with coronary disease have a family history of death of the parent of the same sex as a result of the same illness. This history is often associated with the conscious fantasy that the patient's death at the age at which the parent died is inevitable, leading to considerable vigilance, avoidance, and other anxiety behaviors.

### *Anxiety in Congestive Heart Failure*

There is a marked absence of studies on the frequency of anxiety disorders in CHF patients (MacMahon and Lip 2002). In a survey of ambulatory outpatients with dilated cardiomyopathy, anxiety symptoms rated by the Hospital Anxiety and Depression Scale were significantly increased in comparison to population norms, suggesting a substantial prevalence of anxiety disorders, but no diagnostic information was obtained (Steptoe et al. 2000).

### *Panic and Mitral Valve Prolapse*

An association of mitral valve prolapse with panic was proposed in the past on the basis of symptoms associated with prolapse (fluttering or palpitation experiences) in patients with panic disorder and echocardiographic findings of prolapse (Carney et al. 1990; Gorman et al. 1988). Depending on the echocardiographic criteria employed, 5%–20% or more of patients with panic disorder have mitral valve prolapse (Dager et al. 1986; Libberthson et al. 1986; Margraf et al. 1988). Individuals with mitral valve prolapse may be asymptomatic or may experience occasional palpitations or “fluttering” sensations in the precordium, and it has been proposed that these sensations give rise to catastrophic cognitions that stimulate panic attacks in predisposed individuals (Barlow 1988). The nature of the link between panic and mitral valve prolapse has been questioned, however, because panic does not occur at higher-than-expected rates in patients with echocardiographic mitral valve prolapse and because mitral valve prolapse occurs in many other psychiatric disorder populations. Confusion has been created by varying criteria for mitral valve prolapse, small sample sizes, and poorly controlled studies. A possible link, in at least some cases, comes from recent genetic studies in panic disorder

that have identified a syndrome of joint hyperlaxity, bladder and renal abnormalities, mitral valve prolapse, and panic that is linked to chromosome 13 (Hamilton et al. 2003; Martin-Santos et al. 1998).

### *Anxiety and Automatic Implantable Cardioverter-Defibrillators*

Malignant ventricular arrhythmias account for a substantial fraction of fatal events in patients with ischemic heart disease and CHF. The use of automatic implantable cardioverter-defibrillators (AICDs) reduces mortality (DiMarco 2003), but the experience of defibrillation is unpleasant, likened to being “kicked in the chest.” Implantable defibrillator discharges are associated with iatrogenic anxiety, particularly in patients who experience repetitive, frequent, or early discharges after device implantation (Heller et al. 1998). Early experience indicated a 50% incidence of psychiatric disorders after AICD implant (adjustment disorders, major depression, and panic disorder) (Morris et al. 1991), but the incidence of psychopathology has apparently diminished over time (Crow et al. 1998). In the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, patients who reported shocks during the follow-up period had reduced mental well-being and physical functioning and more anxiety than patients who did not receive shocks (Schron et al. 2002). In the Canadian Implantable Defibrillator Study (CIDS), adverse effects on quality of life were observed in patients who had received four or more shocks. Patients who did not receive shocks reported quality of life equal or superior to that of arrhythmia patients being treated with drug therapy who did not complain of side effects of the drug therapy (Irvine et al. 2002). Although full-fledged post-traumatic stress disorder appears to occur in fewer than 5% of AICD patients, symptoms of the disorder such as avoidance, hypervigilance, and reexperiencing are common, especially if patients experience multiple sequential shocks while conscious, which they endure with a sense of helplessness. A variety of other reactions to implanted defibrillators have been described, including feelings of invulnerability, dependency, and withdrawal (Fricchione et al. 1989). Nevertheless, most patients with implanted defibrillators report satisfaction with their experience with the device.

A recent trial of defibrillator-delivered pacing and shock therapy for atrial fibrillation found improvement in quality of life at a 6-month follow-up to implantation. In patients in whom the device fired during the follow-up period, there was no decrement in quality of life compared with that of patients who did not experience defibrillator discharges (D.M. Newman et al. 2003).

### *Anxiety and Supraventricular Tachycardia*

Patients with supraventricular tachycardias often experience anxiety, especially with paroxysmal arrhythmias (e.g., paroxysmal supraventricular tachycardia—see the section “Diagnostic Issues” later in this chapter).

### Delirium and Neurocognitive Dysfunction

In the cardiac surgery intensive care unit (ICU), delirium, like beauty, is very much in the eye of the beholder. After coronary bypass graft surgery and open-heart procedures, it is evident that many patients have altered mental status with impaired level of consciousness for some days. Whether these patients are identified as experiencing delirium appears to depend on the sensitivity of the observer and on the degree to which the patient's obtundation or agitation interferes with the clinical management of the postoperative state. Pioneering studies in the 1960s of the psychiatric aspects of heart disease included observations of the psychiatric complications of mitral commissurotomy and mitral and aortic valve replacement (Kornfeld et al. 1965). These studies documented a high prevalence of delirium in early open-heart surgery patients, which led to changes in ICU design and attention to preservation of sleep-wake cycles and appropriate use of narcotic analgesia in open-heart surgery. Studies demonstrating the importance of emboli from valvular structures or intracardiac thrombus, and from the cardiopulmonary bypass circuit, for subsequent cognitive impairment led to alterations of surgical technique and bypass circuit filters (S. Newman 1989; S. Newman et al. 1988; Willner and Rodewald 1991).

Frequency of adverse cerebral effects after coronary-artery bypass graft (CABG) was estimated at 6% at hospi-

tal discharge in a multicenter study of 2,104 patients, with about half of these events being focal neurological events; other problems included persistent cognitive impairment, diminished level of consciousness, and seizures (Roach 1996). Risk factors included advanced age, history of alcohol abuse, systolic hypertension, pulmonary disease, and aortic arch atherosclerosis. A longitudinal study of 261 patients found that 53% of post-CABG patients demonstrated neurocognitive impairment 1 week after surgery; the prevalence of impairment fell to 24% at 6 months (M.F. Newman et al. 2001). Predictors of delirium after open-heart surgery include older age, cerebrovascular disease, prolonged sedation, and narcotic use. Off-pump coronary bypass surgery has been studied as a means of reducing delirium and neuropsychological impairment after surgery (Diegeler et al. 2000). Avoidance of the heart-lung bypass machine reduces the production of inflammatory cytokines and reduces emboli to the brain; these factors appear to correlate with modestly improved neuropsychological outcome (Lee et al. 2003; Van Dijk et al. 2002).

### Psychiatric Side Effects of Cardiac Drugs

A few cardiac medications have psychiatric side effects. These include digoxin, ACE inhibitors, amiodarone, lidocaine, and beta-blockers. Beta-blockers are frequently blamed for depression, fatigue, and sexual dysfunction; however, a recent analysis demonstrated that fatigue, but not depression, is likely to be exacerbated by beta-blockers (Ko et al. 2002). An exhaustive review is available (Brown and Stoudemire 1998) (see Table 19–1).

**TABLE 19–1. Selected psychiatric side effects of cardiac drugs**

<b>Drug/Class</b>	<b>Effects</b>
Digoxin	Visual hallucinations (classically, yellow rings around objects); delirium; depression
Beta-blockers	Fatigue, sexual dysfunction more common than depression per se; possibly less effect with atenolol
Alpha-blockers	Depression
Lidocaine	Agitation, delirium
Carvedilol	Fatigue, insomnia
Methyl dopa	Depression, confusion, insomnia
Reserpine	Depression
Clonidine	Depression
ACE inhibitors	Mood elevation or depression (rare)
Pressors (dobutamine, milrinone, dopamine)	Rarely cause psychiatric effects
Angiotensin II receptor blockers	Rarely cause psychiatric effects
Amiodarone	Mood disorders secondary to thyroid effects
Diuretics	Hypokalemia, hyponatremia can result in anorexia, weakness, apathy

*Note.* ACE=angiotensin-converting enzyme.

## Cardiac Neurosis

Development of cardiac neurosis can occur after a patient experiences symptoms attributed to heart disease, whether or not actual heart disease exists. In some patients, apparent clinging to symptoms of disease, and the resulting disability, serve as an unconscious, face-saving means to escape otherwise intolerable life stress related to work, troubled intimate relationships, or other demands. Remaining in the sick role provides respite from negative affects related to one's previous psychosocial role. Such patients may have a previous history of hard work; denial of dependent needs; and relatively poor capacity for introspection, psychological insight, and verbalization of affects (alexithymia). In other patients preexisting hypochondriasis, somatization, or panic is directed toward awareness of cardiac symptoms after an initial episode of symptoms. Less commonly, a patient with depression or a chronic psychosis becomes fixated and delusional about cardiac disease. Factitious illness and malingering must also be considered in the differential diagnosis for patients who appear to cling to cardiac disability.

## Sexual Dysfunction

Sexual dysfunction after the onset of heart disease occurs as a consequence of both physical and psychological factors. Physical factors include medications, comorbid medical conditions such as peripheral vascular disease and diabetes mellitus, and low cardiac output. Psychological factors include depression, anxiety, and fear of inducing a heart attack. Coital angina makes up 5% of angina attacks, but it is rare in patients who do not have angina during strenuous physical exertion. The metabolic demand of coitus is about 2–4 metabolic equivalents in men age 33 years, about equal to the demand of walking 2–3 miles/hour. The metabolic demand may be less in older men (DeBusk 2003) (see Chapter 17, "Sexual Disorders").

## Effects of Psychological Factors on the Heart and Heart Disease Risk

---

### Depression and Risk of Coronary Heart Disease

Community prospective studies of several different populations demonstrate that a history of depressive disorder or elevated symptoms of depression as evaluated by questionnaire ratings is associated with increased risk for the subsequent development of ischemic heart disease and for coronary disease death. In studies of American, Danish,

and Swedish populations, the estimated magnitude of the risk of incident disease associated with depression is 1.5- to 2.0-fold (Anda et al. 1993; Barefoot and Schroll 1996; Barefoot et al. 1996). In patients with preexisting CAD, the risk of death for patients with depression is three- to fourfold higher than that for nondepressed coronary patients (Carney et al. 2003; Frasure-Smith et al. 1993, 1995a; Ladwig et al. 1991).

Following CABG surgery, depression predicts recurrent cardiac events at 12 months (Connerney et al. 2001), and a recent study with 817 patients showed that moderate to severe depression symptoms on the day before surgery or even mild depression persisting from baseline to 6-month follow-up after surgery was a predictor of mortality over mean follow-up of 5.2 years, with hazard ratios of more than 2.0 (Blumenthal et al. 2003).

Depression clearly adversely affects patients' perceptions of their heart disease status and quality of life. A recent study (Ruo et al. 2003) examined 1,024 patients with stable CAD to evaluate the contributions of depressive symptoms and objective measures of cardiac function to their health status. The patients who had depressive symptoms (20%) were more likely to report coronary disease symptom burden, physical limitations, diminished quality of life, and fair to poor health. In multivariate analyses, depression symptoms had significant independent association with these health status outcomes. In contrast to exercise capacity, left ventricular ejection fraction and myocardial ischemia (measured by stress echocardiography) were not related to worse health status. These findings suggest that efforts to improve subjective health status in coronary disease patients should address depression symptoms.

### *Mechanisms Linking Depression and Coronary Artery Disease*

Candidate psychophysiological mechanisms linking depression to adverse coronary disease outcomes include platelet dysfunction, autonomic dysfunction, and abnormalities of inflammation (Carney et al. 2002). Persons with depression have increased platelet reactivity to orthostatic challenge (Musselman et al. 1996) and heightened circulating levels of beta-thromboglobulin and platelet factor 4, two markers of platelet activation (Laghriissi-Thode et al. 1997; Pollock et al. 2000). This implies that depressed patients have increased likelihood of thrombus formation in response to thrombogenic stimuli. Serotonin is stored in platelets, and serotonin release is a crucial intermediate step in platelet aggregation and thrombus formation. Serotonin storage in platelets is dependent on a serotonin transporter protein on the platelet cell membrane. Serotonin reuptake inhibitors may reduce the ca-

capacity of platelets to store serotonin, and thereby reduce their capacity to initiate thrombus formation. A large case-control study of first MI patients demonstrated that use of serotonergic antidepressants with high affinity for the serotonin transporter protein reduced the risk of MI in comparison to the risk for those using other antidepressant agents (Sauer et al. 2003).

Several measures of cardiac autonomic control, derived from time series or power spectral analyses of heart rate variability, are also deranged in depression. These measures indicate elevated sympathetic activation, suppression of vagal tone, and increased propensity to cardiac arrhythmias (Carney et al. 2001; Stein et al. 2000). Similar changes in heart rate variability have been described as common in CAD patients and predict mortality after MI (Bigger et al. 1992, 1993).

Inflammation has only recently been widely recognized as another process involved in the development of atherosclerosis and acute coronary events (Libby et al. 2002). Inflammatory cytokines are elevated in coronary disease patients, and the extent of elevation of specific markers such as interleukin-6 (IL-6), tumor necrosis factor- $\alpha$ , and C reactive protein (CRP), predicts coronary and cerebrovascular disease events and progression of heart failure (Cesari et al. 2003). Depression has been shown to be associated with increases in circulating levels of IL-6 and CRP (Miller et al. 2002).

Depression may also exert a negative effect on cardiovascular outcomes through its negative effects on adherence to treatment recommendations. Demonstrated effects of depression in coronary disease patients include lower rates of smoking cessation, exercise, dietary modification, and adherence to medication regimen (Glassman 1993; Ziegelstein et al. 2000). However, the magnitude of the adherence effects does not appear sufficiently large to account for the differential effect of depression on survival and morbidity in cardiac patients.

### ***The ENRICHD and SADHART Trials***

If depression exerts a negative effect on cardiac outcomes in coronary disease, a natural and important question is whether treatment of depression improves coronary disease outcomes. Two recent trials have investigated this subject—in particular, in patients with depression after MI. In the SADHART trial (Glassman et al. 2002), 369 patients with major depression after hospitalization for unstable angina or acute MI were randomized in a double-blind study to receive treatment with sertraline, 50–200 mg/day, or placebo. The primary goal of the trial was to assess the safety of sertraline treatment, but a secondary goal was to obtain an estimate of the effect on cardiac outcomes. Although the trial was not powered to ade-

quately test an effect on morbidity or mortality (i.e., only seven deaths occurred during the follow-up period), sertraline was superior in absolute numerical terms to placebo in the rate of recurrent MI, mortality, heart failure, and angina, suggesting that a larger study of treatment effects on mortality would be worthwhile.

Concurrent with the SADHART trial, the ENRICHD (Enhancing Recovery in Coronary Heart Disease) trial was directed primarily at addressing the effects of treatment on mortality in post-MI patients (Writing Committee for the ENRICHD Investigators 2003). In ENRICHD, patients with low social support or depression after MI were enrolled in usual care or a cognitive-behavioral therapy (CBT) intervention group. Patients in the intervention group received 6–10 sessions of treatment over 6 months following acute MI. Mortality was assessed at 30-month follow-up. A confounding element of the trial was the use of antidepressants, usually sertraline, in both arms of the trial in patients with more severe depressive symptoms. The CBT intervention was not effective in reducing mortality, and subgroup analyses did not demonstrate an effect of the intervention even in the depression subgroup. Although the use of sertraline was not randomized, it was notable that all-cause mortality in the sertraline-treated patients was only 7.4%, compared with 15.3% and 10.6% in patients who did not receive drug therapy and patients treated with tricyclic antidepressants, respectively. However, sertraline did not reduce the risk of recurrent nonfatal MI.

Suggestive convergent evidence of a possible benefit of selective serotonin reuptake inhibitor (SSRI) treatment of depression on cardiovascular disease outcomes in cardiovascular disease patients comes from a study of prophylaxis of depression after stroke (Rasmussen et al. 2003). In this study, 137 patients with acute ischemic stroke who were not depressed at screening assessment within 4 weeks of the index stroke were randomized to placebo or sertraline treatment for 12 months. The study demonstrated a strong prophylactic effect of sertraline on the incidence of depression, and cardiovascular adverse events during the 12-month follow-up were reduced by two-thirds in the sertraline group, compared with the patients receiving placebo.

### **Depression Effects on CHF Outcome**

Depression also appears to carry increased mortality risk in patients with CHF. In one cohort, major depression more than doubled the risk of 3-month and 1-year mortality (Jiang et al. 2001), although the effect did not quite achieve the level of statistical significance after adjustment for other medical variables associated with mortality

risk. Depression did continue in multivariate analyses to predict hospital readmissions at 1-year follow-up. "Mild depression," defined as a BDI score of 10 or greater in the absence of a major depressive disorder, did not confer an increased risk of mortality or readmission. A retrospective assessment in an English center, with 5-year follow-up of 396 patients with congestive heart failure caused by nonischemic dilated cardiomyopathy, found that 21% of the patients were clinically depressed; of these, 60% were receiving antidepressants. Mortality at 5 years was 36% in depressed versus 16% in nondepressed patients, yielding a significant hazard ratio of 3.0 (Faris et al. 2002).

A multicenter study of 460 outpatients with CHF showed that, compared with nondepressed patients, patients with significant depression symptoms had both worse health status at baseline and more deterioration in health status over short-term follow-up. Depression predicted worsening of heart failure symptoms, physical and social functioning, and quality of life. Depression symptoms were the strongest predictor of decline in health status (Rumsfeld et al. 2003).

### Anxiety and CAD Risk

There is little evidence in nonclinical samples that anxiety symptoms increase the risk of coronary disease or heart-disease-related mortality, with the exception of sudden cardiac death. Two prospective epidemiological studies do demonstrate an association of anxiety with sudden cardiac death. In a study involving 33,999 male, middle-aged health professionals with 2-year follow-up, there were 168 new cases of coronary heart disease, including 40 fatal and 128 nonfatal events. Nonfatal events were not associated with anxiety, but the risk of fatal CHD increased with the level of phobic anxiety, and high phobic anxiety carried a threefold increased relative risk of fatality compared with the risk in subjects with low anxiety; the excess risk was limited to cases of sudden cardiac death, with a sixfold increased risk associated with high anxiety (Kawachi et al. 1994a). The second study assessed 2,280 men free of chronic disease at baseline, with 32-year follow-up. Subjects completed an anxiety symptom rating scale at baseline. During the follow-up, there were 26 sudden cardiac deaths and 105 nonsudden CHD deaths. In multivariate analysis, after adjustment for potential confounding variables, men with anxiety scores above the ninety-eighth percentile had a 4.46-fold increased risk of sudden cardiac death, and a 1.94-fold increased risk of fatal coronary heart disease, but no excess risk for angina or nonfatal MI. These hazard ratios are strongly suggestive of an association of anxiety and sudden cardiac death (Kawachi et al. 1994b).

In a clinical study of hospitalized acute MI patients, scores above the median on the anxiety subscale of the Brief Symptom Inventory were associated with a more than twofold increased risk of death during the hospitalization (Moser and Dracup 1996). In the long run after MI, anxiety does confer mortality risk independently of depression in some studies (Frasure-Smith et al. 1995b; Strik et al. 2003), but some reviewers have expressed concern that inadequate adjustment for confounding medical disease severity accounts for these positive findings (Lane et al. 2003).

Panic disorder was associated with increased cardiovascular morbidity (MI and stroke) in a community sample using a subset of the Epidemiologic Catchment Area Study data, but the study had significant methodological limitations, including retrospective self-report of cardiovascular outcomes without external validation (Weissman et al. 1990). In an anxiety disorders clinic sample, panic disorder was associated with an excess of cardiovascular deaths in men, but not in women, and the total number of deaths was too small to provide reliable estimates (Coryell 1988; Coryell et al. 1986).

### Anger, Type A Behavior, and Hostility

Type A behavior pattern—characterized by anger, impatience, aggravation, and irritability—was linked to incident coronary disease in men in the 1970s. The Western Collaborative Group Study of more than 3,000 middle-aged men demonstrated that type A behavior was associated with a more than twofold increased risk of incident MI and of fatal coronary events (Rosenman et al. 1975). One of the few large-scale clinical trials in psychosomatic cardiology, the Recurrent Coronary Prevention Project, examined the effect of group counseling to reduce type A behavior pattern on mortality and recurrent infarction. Patients were survivors of an acute MI and were randomized to usual care or added type A behavior modification groups. Follow-up in 4.5 years demonstrated a significant reduction in recurrent infarction in those assigned to type A counseling (Friedman et al. 1986). Subsequent studies of type A behavior pattern and CAD have been inconclusive or negative, perhaps because of the difficulty in measuring type A behavior or changes in cardiovascular therapeutics, especially the widespread use of beta-adrenergic blockers in patients with coronary disease (Booth-Kewley and Friedman 1987).

Anger and hostility, considered as "toxic components" within the type A concept, have also been studied as risk factors for coronary disease but with mixed results in longitudinal observations (Barefoot et al. 1994, 1995). Low hostility is protective against incident coronary disease

(Shekelle et al. 1983), but high anger and high hostility are less clearly linked to increased cardiovascular risk. In the Normative Aging Study analysis, anger predicted the incidence of a combined endpoint of coronary death, non-fatal MI, and angina, but it did not predict coronary death or nonfatal MI to a statistically significant degree (Kawachi et al. 1996).

## Acute Mental Stress

George Engel, who championed the biopsychosocial model in medicine, provided vivid examples from the news media of acute mental stress preceding acute coronary events (Engel 1976), and epidemiological studies of disasters have helped to confirm the relationship of acute stress to risk for sudden cardiac death (Leor et al. 1996). In animal experimental models of sudden cardiac death, acute mental stress has been one of the most studied psychosomatic factors. Animals conditioned to anticipate unpleasant restraint experience increased ventricular ectopy and ventricular tachycardia-fibrillation when exposed to the threat of restraint. Interestingly, this effect depends on the presence of myocardial ischemia and can be disrupted by the use of intracerebral  $\beta$ -adrenergic blockade (DeSilva 1983, 1993; Lown 1990; Lown et al. 1980; Skinner 1985; Skinner et al. 1975, 1981). The Northridge, California, earthquake in 1994 caused a surge in sudden cardiac deaths over the subsequent 2 days in individuals who were not physically endangered by the earthquake but resided in the immediate area (Leor et al. 1996). A preliminary, similar finding has been reported in the aftermath of the destruction of the World Trade Center in New York in 2001 (Qureshi et al. 2003). Acute stress in the laboratory, provoked by standardized tasks such as mirror-drawing, the Stroop color word test, mental arithmetic, video games, and public speaking, results in elevation in heart rate and blood pressure and alteration in indices of cardiac autonomic regulation, with diminished parasympathetic and elevated sympathetic activation, in both healthy volunteers and patients with CAD (Blumenthal et al. 1995; Manuck and Krantz 1986; Rozanski et al. 1988, 1999; Sheps et al. 2002). In addition, coronary vasospasm appears to be a mechanism of mental stress-induced ischemia in at least some cases (Yeung et al. 1991). One-third to one-half of patients with CAD experience ischemia during mental stress testing, and ischemia occurs at lower levels of rate-pressure product elevation during mental stress than during exercise stress. Most patients with mental stress-induced ischemia also have exercise-induced ischemia. Wall motion abnormality appears to be a more sensitive indicator of ischemia than ST segment depression, for unknown reasons (Strike and Step-

toe 2003). Mental stress-induced ischemia is usually silent (Blumenthal et al. 1995; Rozanski et al. 1988, 1999). The technique of ecological momentary assessment has been used to demonstrate that emotional arousal, and especially anger during daily events, is associated with similar alterations in hemodynamic and autonomic state, and it has been estimated that acute emotional stress is a trigger for up to 20%–30% of acute coronary events (Muller et al. 1994). In patients with coronary disease, mental stress-induced ischemia, indicated by wall motion abnormalities on radionuclide ventriculography or echocardiography, is associated with increased risk of death, even after adjusting for other prognostic variables (Jiang et al. 1996; Sheps et al. 2002).

## Sleep Apnea

Sleep apnea is associated with hypertension and CHF (Bradley and Floras 2003a, 2003b). Two studies of chronic heart failure patients found the prevalence of obstructive sleep apnea to range from 11% to 37%, and the presence of sleep apnea increases the risk of developing heart failure. Obstructive apnea results in hypoxia, elevated intrathoracic pressure, and sympathetic nervous system activation, with increases in heart rate and blood pressure. These physiological derangements may contribute to the development of heart failure, ischemic events, and arrhythmias (Shamsuzzaman et al. 2003). A recent randomized trial showed that continuous positive airway pressure for 1 month leads to improvement in the number of apneas, systolic blood pressure, heart rate, left ventricular end-systolic dimension, and left ventricular ejection fraction (Kaneko et al. 2003). Central sleep apnea does not severely exacerbate negative intrathoracic pressure, but it does produce periodic sympathetic arousals and increased afterload and myocardial work (Bradley and Floras 2003b) (see also Chapter 16, "Sleep Disorders").

## Stress Management and Health Education Interventions in CAD Patients

---

A large meta-analysis of a variety of health-education and stress-reduction interventions in patients with CAD concluded that these interventions reduce the incidence of recurrent MI (29% reduction) and death (34% reduction) at 2- to 10-year follow-up. The mechanism of the effect is unclear; these analyses do not consistently demonstrate a reduction in mental symptoms (i.e., anxiety and depression ratings are not reduced) (Dusseldorp et al. 1999).

Psychoeducational programs may include varying components of health education, stress management, and supervised exercise training; and many individual reports fail to give specific details of the interventions. Successful effects on proximal targets such as systolic blood pressure, cholesterol, body weight, smoking behavior, physical exercise, and emotional distress or some combination of these mediate the beneficial effects for mortality. For recurrent MI, protective effects of psychoeducational intervention were associated with beneficial effects on systolic blood pressure, smoking behavior, physical exercise, and emotional distress. Patients who participate in psychoeducational programs are three times more likely to be successful in quitting smoking (Dusseldorp et al. 1999). Longer intervention programs with more hours of intervention and more tailoring of program content to individual needs appear to have greater long-term effect on cardiac outcomes (Linden 2000; Linden et al. 1996).

## Diagnostic Issues

---

Most psychiatric diagnoses are reached in a straightforward fashion in patients with heart disease, but confusion may arise because of the overlap of symptoms of heart disease with symptoms of psychiatric disorder and because treatments for heart disease may cause psychiatric side effects. The most frequent problem in psychiatric diagnosis is the attribution of symptoms of depression to the underlying cardiac disease or to a “normal” reaction to the illness, with the resultant underdiagnosis of depression. Generally in practice, however, an inclusive approach is appropriate, counting symptoms such as fatigue and poor sleep toward a diagnosis of depression even if the symptoms might also be attributable to the patient’s cardiac condition (Cohen-Cole and Kauffman 1993) (see also Chapter 9, “Depression”). In an analysis of the 222 acute MI patients included in the landmark Montreal Heart Institute depression-mortality study, the investigators considered the specificity of various symptoms from the depression criteria set for a diagnosis of depression. Sleep disturbance and appetite disturbance did not help to distinguish between patients who met criteria for depressive episode and those who did not (i.e., these symptoms were common in both depressed and nondepressed patients), but fatigue and especially sadness and loss of pleasure occurred almost exclusively in patients who met criteria for a major depressive episode (Lesperance et al. 1996). This suggests that patients reporting somatic symptoms of depression should be evaluated for the presence of the cardinal mood and interest symptoms, and they should be considered depressed if these symptoms are also present.

Patients with advanced heart failure often develop appetite loss and cachexia, but in the absence of loss of self-esteem, interest in ordinarily interesting events, or depressed mood, these patients should not be diagnosed with a depressive disorder.

Paroxysmal supraventricular tachycardia (PSVT) occurs in young and middle-aged adults and may manifest with symptoms of shortness of breath, chest discomfort, and apprehension. Because these features may overlap with those of generalized anxiety symptoms and panic attacks, there is a significant risk of misdiagnosis. In a retrospective study of 107 patients with PSVT, DSM-IV criteria for panic disorder were met in 59 patients (67%) (American Psychiatric Association 1994); PSVT had been unrecognized after initial medical evaluation in 55% and remained unrecognized for a median of 3.3 years. Prior to the eventual identification of PSVT, nonpsychiatric physicians attributed symptoms to panic, anxiety, or stress in 32 (54%) of the 59 patients (Lessmeier et al. 1997). Of course, some patients may have both PSVT and an anxiety disorder, with symptomatic attacks including elements of each.

## Atypical Chest Pain and Palpitations

Typical anginal chest pain in CAD occurs with exertion or after eating; is not exacerbated by palpation of the chest or inspiration; is described as dull, pressurelike, or burning rather than sharp or stabbing; and is experienced across the precordium rather than in a pinpoint area of the left side of the chest. Many patients present for evaluation of atypical chest pain. While atypical features do not rule out a diagnosis of CAD, 40%–70% of patients with no history of documented CAD and few CAD risk factors have panic disorder, somatoform disorders, or depression (Alexander et al. 1994; Fleet et al. 2000). In the absence of CAD, characteristics of chest pain patients predicting panic disorder include female sex, atypical chest pain quality, younger age, lower education and income, and high self-reported anxiety (Dammen et al. 1999; Huffman and Pollack 2003). A study of 199 outpatient cardiology clinic chest pain patients found that a three-item questionnaire (Table 19–2), with a cutoff score of 5 points, correctly identified 74% of patients with panic disorder with a sensitivity of 55% and a specificity of 86%. Panic disorder is twice as likely in chest pain patients without CAD as in patients with CAD (Dammen et al. 1999; Fleet et al. 2000).

Psychiatric disorders are also common in patients complaining of palpitations. In one study using structured diagnostic interviews and self-report questionnaires for patients undergoing ambulatory electrocardiogram (ECG)

**TABLE 19-2. Screening questions for panic disorder in patients with atypical chest pain**

When nervous or frightened, patient thinks he or she will pass out.	(never = 1, always = 5)
In past 7 days, patient has been bothered by pain in the heart or chest.	(not at all = 0, extremely = 4)
Pain is experienced as tiring or exhausting.	(no = 0, severe = 3)

*Note.* A cutoff score of 5 correctly identifies 74% of patients with panic disorder in the outpatient setting.

*Source.* Dammen et al. 1999.

monitoring, the lifetime prevalence of any disorder was 45%, and 25% of the patients had a current disorder. The lifetime prevalence of panic disorder and major depression was 27% and 21%, respectively. Current prevalence of panic disorder was 19% (Barsky et al. 1994b). These rates are probably somewhat higher than in the general population, because they derive from a tertiary care clinic setting.

## Special Issues

### Heart Transplantation

Heart transplantation has been the treatment of last resort for patients with severe heart failure, and occasionally for patients with intractable recurrent myocardial ischemia or ventricular arrhythmias, for the past 2 decades (see also Chapter 31, "Organ Transplantation"). Because of donor scarcity, the number of heart transplants performed annually in the United States has reached a plateau of approximately 3,000/year. Patients eligible for heart transplantation typically have an expected survival of less than 2 years unless they receive a transplant. With transplantation, expected 5-year survival is now better than 75%. Complications can occur, and the care regimen for heart transplant patients is complicated, especially in the first few months after surgery, so transplant programs generally screen patients and exclude from candidacy those with absolute contraindications or excessive relative contraindications.

These facts provide the context for the "normal" psychological experience of patients entering the process. Patients generally fear that they are close to death, or will experience a sudden catastrophic deterioration in the future, and believe that a transplant is their best hope for survival. Although they may be anxious about the dangers of transplantation, they are even more often anxious about being excluded from candidacy. Consequently, the evaluation period is a time of heightened concern, and pa-

tients meeting with a psychiatrist as part of the evaluation process wonder whether they will "pass" this examination. Patients awaiting transplantation often experience depression symptoms, because they perceive themselves as helpless to fundamentally affect their own chances of survival. During the waiting period, depression is often enhanced by a sense of guilt over wishes for the death of a suitable donor. Patients sometimes describe a kind of psychological ambulance chasing, hearing a siren and wondering whether this might signal the availability of a donor. Before, at the time of evaluation, and up to the time of receiving a transplant, patients may also display variable levels of denial of the seriousness of their illness and ambivalence about undergoing transplant surgery. This minimization or denial of illness can fluctuate and coexist with other emotional responses, including fear, depression, and anxiety. Patients who come to heart transplantation after an acute catastrophic cardiac event, without a prior chronic heart failure syndrome, are especially prone to experience a combination of denial, shock, anger, and fear all at the same time, as they must rapidly assimilate an altered view of their health status, appreciate the associated risks, and appraise the possible risks and benefits of transplantation, before having much opportunity to mourn the loss of their previous health and associated social role. If they are sedated or in a state of altered consciousness because of cardiogenic shock, medication, or metabolic disarray, their capacity to psychologically adjust is further reduced, with more adaptation forced on them after the fact.

Following heart transplant surgery, patients receive multiple immunosuppressive antirejection medications, along with vitamins; minerals; antibacterial, antifungal, and antiviral medications; and treatments as needed for hypertension, arrhythmias, fluid retention, or other conditions. Most patients are hospitalized for 10–20 days after surgery, undergoing surveillance for allograft rejection as the immunosuppressive medication doses are adjusted. (These medications are discussed in Chapter 31, "Organ Transplantation.") High doses of intravenous and then oral corticosteroids are the rule in the initial weeks after transplant surgery, and predictably they induce increased appetite, fluid retention, and mood lability. Most patients experience an initial euphoria at awakening from surgery, knowing that they have now been delivered from end-stage heart failure, but the emotional reaction depends in part on the patient's previous expectations in comparison with the state of subjective well-being in the early days after surgery. Positive feelings tend to subside as complications occur and as the patient settles into the work of rehabilitation and adjustment to the new medication regimen. One or more episodes of rejection are not

uncommon in the early period after surgery; if transient corticosteroid dose increases are employed to treat rejection episodes, a medication-exacerbated emotional roller coaster may ensue.

Psychiatric complications after heart transplantation are fairly common. In addition to postoperative delirium, steroid-induced mood disorders and depression not attributable to steroids occur in perhaps 20%–40% of patients in the first year after surgery. Many cases occur in the setting of medical complications, but role transitions are often difficult for the recovering patient, and stressors such as increased demand for autonomous function or the need to provide for others in the family, difficulty negotiating return to work, or financial concerns that were previously ignored often stimulate increased emotional distress (Shapiro 1990; Shapiro and Kornfeld 1989). Some heart transplant patients experience transplantation-related posttraumatic stress disorder following particularly frightening or troubling episodes during their care, appear psychologically fixated on these events and subjectively distressed, and are impaired in their daily functioning long after the transplant (Dew et al. 2001).

## Left Ventricular Assist Devices

The shortage of available donors of hearts for transplantation and the large number of patients dying of congestive heart failure provided impetus even early in the era of heart transplantation for the development of artificial heart technology (Goldstein and Oz 2000). In addition to attempting to devise a total artificial heart, researchers have developed and tested a variety of ventricular assist pumps over the past decade. To date, experience with total artificial hearts has been characterized by limited success—limited patient survival compromised by stroke, infection, and poor quality of life. Ventricular assist devices, however, have been more successful and are in widespread use as rescue devices—that is, bridges to heart transplantation or in some cases bridges to recovery after acute myocardial injury (Goldstein and Oz 2000). Early experience with use of left ventricular assist devices (LVADs) designed to be used for periods of weeks to months as a bridge to transplantation indicated that significant neuropsychiatric issues were delirium, stroke, cognitive impairment, pain, and depressed mood. Depression seemed especially linked to frustration with ongoing limitations in function as a result of tethering to the device, and cerebrovascular and cognitive problems were associated with a history of even minor or transient cerebrovascular disease symptoms before LVAD surgery (Shapiro et al. 1996). For most patients, quality of life with LVADs was superior to that while they were in severe heart failure (Dew et al. 1998,

1999a, 1999b). Ongoing improvements in device design have reduced the mechanical problems of attachment to an external device to a considerable degree and are likely to continue to do so (Goldstein and Oz 2000).

The success of LVAD use as a bridge to transplantation led to study of permanent (“destination”) LVAD treatment for patients with end-stage heart failure who could not receive a heart transplant (Rose et al. 1999). The REMATCH trial, a randomized clinical trial providing either optimized medical therapy or LVAD therapy for patients with severe chronic heart failure, demonstrated a substantial survival benefit associated with LVADs, along with improved quality of life outcomes (Rose et al. 2001). Interestingly, somatic dimensions of quality of life were substantially better in LVAD recipients, but mental-emotional components did not differ from those of medically treated heart failure patients (Shapiro et al. 2002). Postoperative delirium was the most important psychiatric problem seen in the LVAD patients in this study (Lazar et al. 2004). The success of LVAD treatment in extending survival without worsening quality of life in the REMATCH trial led to approval by the U.S. Food and Drug Administration of destination LVAD therapy for nonexperimental use in the United States in 2002. Although issues of cost, patient selection, and criteria for approval of cardiac surgical centers by regulatory agencies continue to limit availability, it is likely that destination ventricular assist device therapy will become more widespread in the next several years. Continuous device modifications make it difficult to extrapolate the neuropsychiatric and quality-of-life implications from past data.

## Hypertension

The relationship of psychological factors to the development of hypertension has been a subject of controversy, with mixed findings in large-scale observational studies.

In a cross-sectional correlation of psychological variables with mild hypertension measured in clinic visits or by ambulatory monitoring in 283 middle-aged men, there were no significant differences between normotensive and hypertensive men in any of the psychological variables assessed, including type A behavior, state and trait anger, anger expression, anxiety, psychological distress, locus of control, or attributional style (Friedman et al. 2001). In one study that noted an increased prevalence of panic disorder in patients with hypertension compared with normotensive comparison primary care patients, the onset of panic occurred after the diagnosis of hypertension in most cases. Thus the study does not support the idea that panic gives rise to hypertension (Davies et al. 1999).

A 15-year prospective study of psychosocial risk factors for hypertension based on a follow-up of over 3,000 young white and black adults from four metropolitan areas of the United States used multivariate analysis, including age, sex, gender, body mass index, race, and baseline blood pressure, and found that two components of type A behavior—namely, “time urgency–impatience” and “hostility”—were each associated with almost double the rate of incident hypertension at 15-year follow-up. In contrast, anxiety symptoms, depression symptoms, and “achievement–striving–competitiveness” (another type A component) did not predict hypertension (Yan et al. 2003). In another large longitudinal study, however, results differed.

A population-based cohort of 3310 normotensive persons without chronic diseases from the NHANES I Epidemiologic Follow-up Study was followed for four waves, up to 22 years. Using Cox proportional hazards regression analysis, controlling for baseline blood pressure (BP), age, sex, race, education, smoking, alcohol use, body mass index (BMI), and change in BMI over time, and using combined symptoms of depression and anxiety (“negative affect”) as the primary independent variable, increased negative affect was associated with increased risk for hypertension. The risk for treated hypertension was increased in both men and women and was most pronounced (over threefold) in black women (Jonas and Lando 2000).

In addition to these individual large-scale studies, a recent review (Rutledge and Hogan 2002) examined 15 prospective studies of psychological traits affecting the development of hypertension. These studies included samples of 78 to 4,650 subjects, and most cohorts were primarily male- and white-dominated. The length of follow-up varied from 2.5 to 21 years. Psychological variables included anger, anxiety, depression, defensiveness, neuroticism, and “psychopathology.” Small but significant effects were observed for anger, anxiety, depression, and other variables, with an overall magnitude of effect suggesting an 8% increase in prospective hypertension risk associated with a high level of one or more of the psychological variables. A smaller number of studies separately reported the effect of psychological factors on hypertension in African Americans and in women. In African Americans the same psychological predictors appeared to be associated with hypertension. In women, the results were equivocal.

The main psychiatric consequence of hypertension seems to be long-term neurocognitive impairment and increased risk of dementia (Frishman 2002). Treatment that successfully controls blood pressure reduces the risk (Forette et al. 2002; Guo et al. 1999; Launer et al. 1995). The data demonstrate that dihydropyridine calcium chan-

nel blockers reduce the risk of dementia of probable Alzheimer’s disease, as well as vascular or mixed dementia, and improve or maintain cognitive function in patients with impaired cognition.

## Congenital Heart Disease

The prevalence of psychiatric disorders in adult survivors of congenital heart disease is unknown. The existence of this clinical population depends largely on advances in pediatric cardiac surgery over the past 3 decades, and adult survivors have not been systematically studied from a psychiatric standpoint. Clinical experience suggests that although many patients appear to have excellent psychological adjustment, anxiety is common.

Some studies have examined children and adolescents. One evaluated 243 children, age 5 years, who had been treated for congenital heart defects. Full-Scale IQ, Verbal IQ, and Performance IQ were all in the normal range. Lower socioeconomic status and velocardiofacial syndrome predicted lower Full-Scale IQ. Single ventricle diagnosis, longer ICU stay, and duration of hypothermic circulatory arrest showed trends toward association with lower Full-Scale IQ (Forbess et al. 2002). For cyanotic conditions, but not for acyanotic lesions, delayed repair appears to exacerbate intellectual impairment (Newburger et al. 1984). Other common psychological problems for children and young adults with congenital heart disease include concerns about exclusion from participation in peer-group activities such as sports and gym class, problems with appearance (short stature, cyanosis, drug side effects on appearance), concerns about attractiveness, capacity to develop intimate relationships, exclusion from work, and fears about mortality (Kendall et al. 2001).

## Treatment Issues

---

### Psychotherapy

Psychological reactions to the experience of heart disease include feelings of anxiety and sadness and concerns about survival, well-being, and effects on social roles, relationships, and the impact on loved ones. Denial is nearly universal as an initial reaction to illness, and it can be helpful in staving off depressed and anxious mood or hurtful because of nonadherence to the treatment program. Conversely, preoccupation with disease can lead to abnormal illness behavior, unnecessary disability, and impaired quality of life. Few systematic studies of psychotherapy have been reported that specifically targeted psychological symptoms or psychiatric disorders in heart

patients. As was described previously, a larger number of studies have described stress management or health education effects on cardiac outcomes in cardiac rehabilitation settings; meta-analyses of these studies do show beneficial effects on cardiac outcomes and suggest that reducing emotional distress may be correlated with better cardiac disease outcomes (Dusseldorp et al. 1999; Linden et al. 1996).

The ENRICHD trial tested the effects of a CBT intervention versus usual care in patients who had a recent MI and either low social support and/or major depression or minor depression with a history of prior major depression in a randomized trial. Patients in the intervention arm participated in either individual or group therapy sessions; treatment was manualized; and therapist adherence to treatment methods was assessed during the trial. Most patients received 6–10 therapy sessions. The trial demonstrated a modest benefit of the CBT intervention on measures of social support and depression. However, the improvement on these measures seen in the usual-care group was higher than expected, so that the effect of treatment, although statistically significant, was of small magnitude (Writing Committee for the ENRICHD Investigators 2003).

As described previously, the Recurrent Coronary Prevention Project tested the effect of group type A behavior modification on the extent of type A behavior in a cohort of post-MI patients on recurrent coronary events (Friedman et al. 1986). In retrospect, although the term was not used at the time, this was clearly a cognitive-behavioral psychotherapy intervention. The intervention had a strong beneficial effect on type A behavior as rated using a videotaped structured interview for the assessment of type A behavior.

*Interpersonal psychotherapy* (IPT) of depression focuses on present-day interpersonal problems linked to de-

pressed mood, such as interpersonal disputes, grief after object loss, interpersonal deficits, and social role transitions. One such role transition may occur with the change in social role imposed by development of a chronic or acute medical illness (Klerman et al. 1984). Therefore IPT would seem to be readily applicable to the treatment of patients who experience depression after the onset or exacerbation of heart disease. Although a case has been reported (Stuart and Cole 1996), controlled trials of IPT in heart disease patients have not appeared.

## Psychopharmacological Treatment

Common adverse cardiac effects of psychiatric drugs are shown in Table 19–3 (see also Chapter 37, “Psychopharmacology”).

### *Antidepressants*

Antidepressants must be used in therapeutically effective doses in cardiac patients with depression, and it is counterproductive to use inadequate doses out of fear of side effects or prolongation of metabolism. Unless the patient has severe right heart failure resulting in hepatic congestion, ascites, and jaundice, it is unlikely that metabolism of oral psychotropic medication (except for lithium) will be substantially impaired because of heart disease.

Tricyclic antidepressants (TCAs) cause orthostatic hypotension, cardiac conduction delay (bundle branch block or complete AV nodal block), and, in overdose, ventricular arrhythmias (ventricular premature depolarization, ventricular tachycardia, and ventricular fibrillation). QRS interval prolongation results from interference with phase 1 depolarization (slow Na<sup>+</sup> channel activity) of the action potential across the membrane of the specialized conduction tissue of the ventricle. Prolongation of the QT interval is predominantly caused by prolongation of the

**TABLE 19–3. Selected cardiac side effects of psychotropic drugs**

Drug	Cardiac effects
Lithium	Sinus node dysfunction and arrest
SSRIs	Slowing of heart rate; occasional sinus bradycardia or sinus arrest
TCAs	Orthostatic hypotension; atrioventricular conduction disturbance; type IA antiarrhythmic effect; proarrhythmia in overdose and in setting of ischemia
MAOIs	Orthostatic hypotension
Phenothiazines	Orthostatic hypotension, QT interval prolongation; rare instances of torsade de pointes
Second-generation antipsychotics	Variable; QT interval prolongation
Carbamazepine	Type IA antiarrhythmic effects; AV block
Cholinesterase inhibitors	Decreased heart rate

Note. AV=atrioventricular; MAOI=monoamine oxidase inhibitor; SSRI=selective serotonin reuptake inhibitor; TCA=tricyclic antidepressant.

QRS interval, and ventricular tachycardia or fibrillation can occur if marked prolongation of the QT interval (over 500 msec) results in the R-on-T phenomenon. Nortriptyline and desipramine tend to cause less orthostatic hypotension than tertiary-amine tricyclic drugs and are better tolerated by patients with cardiac disease (Roose and Glassman 1989; Roose et al. 1986, 1987, 1989). Cardiac pacemakers can obviate the risk of heart block associated with TCAs. More commonly problematic, however, is orthostatic hypotension, which can result in syncope and falls.

TCAs have quinidine-like effects on cardiac conduction and are classified as type 1A antiarrhythmic agents. Drugs of this class have been shown to increase rather than decrease mortality in post-MI patients with premature ventricular contractions (CAST Investigators 1989; CAST II Investigators 1992; Morganroth and Goin 1991), an effect believed to be mediated by episodic myocardial ischemia (Lynch et al. 1987). Consequently, TCAs should generally not be used as first-line agents for treatment of depression in ischemic heart disease patients. This is not to say that they should never be used, however, because their efficacy may offset the risk for selected patients. Consideration should be given to the totality of the clinical situation, including the severity of depression, past treatment responses, concomitant medications, and ECG (Glassman et al. 1993).

SSRIs have little to no cardiac effect in healthy subjects. The most commonly observed effect is slowing of heart rate, generally by a clinically insignificant 1–2 beats/minute. Occasional cases of sinus bradycardia or sinus arrest, with lightheadedness or syncope, have been reported (Roose et al. 1994, 1998a, 1998b). The combination of beta-adrenergic blockade and serotonin reuptake inhibitors may result in additive effects on slowing of heart rate with increased risk of symptoms. In addition, some SSRIs (fluoxetine, paroxetine, fluvoxamine) inhibit metabolism through the cytochrome P450 2D6 pathway responsible for metabolism of many beta-blockers. Therefore, the blood level and effect of beta-adrenergic blockers may be increased.

In patients with preexisting heart disease, the effects of SSRIs on cardiac function have been evaluated in several studies (Sheline et al. 1997). Some studies using fluoxetine and paroxetine in mixed groups of stable patients with ischemic and nonischemic heart disease demonstrate that ejection fraction may actually improve to a small extent in patients with preexisting ventricular dysfunction. The effects on heart rate are similar to those seen in patients who are free of cardiac disease, and no blood pressure, cardiac conduction, or arrhythmia effects have been noted (Roose et al. 1994, 1998a, 1998b). The SADHART

study, as described previously, was a double-blind, placebo-controlled, randomized trial examining the effect of sertraline in patients with major depression immediately after an acute coronary syndrome. Sertraline had no effect on heart rate, blood pressure, arrhythmias, ejection fraction, or cardiac conduction, and adverse events were rare. All patients in SADHART began medication within 30 days of the index acute coronary event (Glassman et al. 2002). Sertraline was effective for treatment of depression in those patients with a prior history of depression, but it did not differ from placebo in response rate for those patients with no prior history of depression.

The cardiovascular effects of other antidepressants have been less fully studied, especially in patients with cardiac disease. Bupropion appears to have few cardiovascular effects in small studies but may cause hypertension in some patients (Roose et al. 1991). The serotonin-norepinephrine reuptake inhibitor venlafaxine behaves as an SSRI at low doses and displays a noradrenergic effect at higher doses. The main cardiovascular effect of this dual action is a tendency to increase blood pressure in a dose-dependent fashion at a dosage of 150 mg/day or higher. There may be a diminution of this hypertensive effect of venlafaxine with its extended-release formulation. The effect on patients with preexisting heart disease or hypertension has not been evaluated. Clinical experience with mirtazapine in patients with hypertension has also demonstrated instances of worsening hypertension, but the frequency of this adverse effect is unknown. Monoamine oxidase inhibitors (MAOIs) cause hypotension and orthostatic hypotension; dietary indiscretions resulting in high circulating levels of tyramine cause hypertensive crises. Consequently, there has been little interest in use of MAOIs in patients with heart disease. Sympathomimetic agents increase blood pressure in patients on MAOIs, though hypertensive crises are actually infrequent. Caution with the use of intravenous pressors (epinephrine, isoproterenol, norepinephrine, dopamine, dobutamine) is required (Krishnan 1995).

### *Antipsychotics*

Antipsychotics are used in cardiac disease patients in cases of comorbid schizophrenia or other psychotic disorders and in the management of delirium in acute cardiac care settings, such as after cardiac surgery or in ICU management of pulmonary edema, arrhythmias, or acute MI. Although first-generation antipsychotic medications are losing primacy as agents of choice for management of chronic psychosis because of their extrapyramidal side effects, they continue to play a role in management of acute psychotic symptoms in delirium. In part this is because of the availability of parenteral formulations for haloperidol,

few cardiovascular effects, and extensive experience with use of intravenous haloperidol in the critically ill (see Chapter 6, "Delirium").

For chronically psychotic patients with heart disease, the choice of antipsychotic is based on side-effect profile. The principal cardiovascular effects of antipsychotic agents are orthostatic hypotension and QT interval prolongation. Orthostatic hypotension secondary to antipsychotic drugs is related to their  $\alpha$ -adrenergic receptor blocking effect, seen especially with the low-potency antipsychotic agents such as chlorpromazine and often accompanied by sedative effects. There are few data about the frequency or clinical significance of orthostatic effects of antipsychotic drugs in patients with heart disease. More attention has been paid to the less common but much more dramatic and dangerous side effect of cardiac arrest secondary to ventricular tachyarrhythmias in patients on antipsychotic drugs. The characteristic tachyarrhythmia is *torsade de pointes*, a polymorphic tachycardia with the appearance of "twisting of the points" of the QRS complex. Risk factors for torsade include QT interval prolongation of more than 500 msec, family history of sudden death, female sex, hypokalemia, hypomagnesemia, and low ejection fraction. QT prolongation as a result of antipsychotic agents, unlike that caused by TCAs, appears to be an effect of impaired repolarization of the ventricular conduction tissue at the end of systole, specifically an effect on the so-called potassium rectifier channel. The QT interval normally is less than 450 msec. Because the normal QT interval is dependent on heart rate, evaluation customarily adjusts for heart rate to yield a corrected QT interval (QTc). Thioridazine is the agent most commonly associated with torsade and sudden cardiac death, and sertindole was withdrawn in the United States because of its QT prolongation effects and the rate of sudden cardiac deaths observed overseas. Intravenous haloperidol is frequently employed in delirious open-heart surgery patients, and although it does have the potential to prolong the QT interval, its use in dosages up to 1,000 mg/24 hours has been reported without complications (Tesar et al. 1985). Clearly, electrocardiographic monitoring is important in ICU settings, and patients with a QTc interval greater than 450 msec should be closely monitored. A QTc interval over 500 msec is generally considered a contraindication to use of haloperidol and other QT-prolonging agents.

Not all antipsychotic drugs have been associated with sudden cardiac death or QT prolongation, and the correlation of QT interval prolongation with risk of sudden death is not exact. For example, ziprasidone prolongs the QT interval but has not been associated with sudden death. Olanzapine, risperidone, and quetiapine have not

been associated with QT prolongation or sudden death. In considering the use of drugs that may prolong the QT interval, factors to be reviewed in the history include familial long QT syndrome; family or personal history of sudden cardiac death, syncope, or unexplained seizure; arrhythmias; personal history of hypertension; medications that prolong the QT interval; medications that may interfere with metabolism of other QT-prolonging agents; valvular heart disease; and bradycardia. Laboratory values of particular importance are magnesium and potassium levels. Class IA and III antiarrhythmic drugs, dolasetron, droperidol, tacrolimus, levomethadyl acetate, other antipsychotic agents, many antibiotics ("floxacin"), and antifungal agents may increase the risk of torsade de pointes (Al-Khatib 2003; Glassman and Bigger 2001; Moss 2003).

### *Anxiolytics*

Benzodiazepines have no specific cardiac effects. Reduction of anxiety tends to reduce sympathetic nervous system activation and, therefore, to slow heart rate, reduce myocardial work, and reduce myocardial irritability. Before the introduction of beta-blockers to acute coronary care, benzodiazepines were widely used for prophylaxis of infarct extension and arrhythmias in acute coronary syndrome patients, but this practice has largely been abandoned. Lorazepam can be given by intramuscular (or intravenous) injection; for most other benzodiazepines this route should be avoided because of poor absorption. Buspirone has no cardiovascular effects.

### *Stimulants*

Stimulants are often useful for treating of depressed, medically ill patients, particularly those with pronounced apathy, fatigue, or psychomotor slowing. At dosages of 5–30 mg/day, dextroamphetamine and methylphenidate are well tolerated by heart disease patients, including patients with cardiac arrhythmias and angina (Masand and Tesar 1996), and have no effects on heart rate and blood pressure. Clinical response generally occurs within days rather than weeks.

### *Lithium*

Lithium occasionally causes sinus node dysfunction and even sinus arrest (Mitchell and Mackenzie 1982). There are no studies of the use of lithium in patients with heart disease. Generally, even in patients with heart disease with reduced cardiac output, lithium can be safely used by adjusting the dosage downward. Because renal function is sometimes impaired in advanced heart failure, lithium dosing requires further reduction. Caution is necessary

for patients taking diuretics, especially thiazides, and those on salt-restricted diets. In patients with acute congestive heart failure exacerbations and acute coronary syndromes, rapid electrolyte and fluid balance shifts can occur; lithium is best avoided during such episodes because of the difficulty managing fluctuations in lithium level as cardiac therapy is adjusted.

### *Other Mood Stabilizers*

Valproic acid and lamotrigine have no cardiovascular effects. Carbamazepine resembles TCAs in having a quinidine-like type IA antiarrhythmic effect and may cause atrioventricular conduction disturbances.

### *Cholinesterase Inhibitors and NMDA Receptor Antagonists*

The elderly are prone to co-occurrence of dementia and heart disease, and relatively new treatments for dementia, including cholinesterase inhibitors (donepezil, rivastigmine, galantamine) and NMDA inhibitors (memantine), are likely to be used increasingly in patients with concurrent heart disease. The procholinergic effect of cholinesterase inhibitors may cause vagotonic effects, including bradycardia or heart block. For memantine, hypertension is the only cardiac effect described by the manufacturer on the basis of premarketing controlled trials.

### *Electroconvulsive Therapy*

Electroconvulsive therapy (ECT) leads to an initial sympathetic discharge, with tachycardia and hypertension, followed by a parasympathetic reflex response, with instances of bradycardia and arrhythmia. Asystole can occur rarely but can be prevented by premedication with atropine. Excessive sympathetic response may evoke myocardial ischemia; for the elderly or those with known coronary disease, monitoring the ECG is essential, and

treatment with intravenous beta-blockers is sometimes required. Cardiac effects of ECT are discussed in Chapter 39, "Electroconvulsive Therapy". ECT has been used safely in patients with ischemic heart disease, heart failure, and heart transplants. Acute MI or recent malignant tachyarrhythmias are relatively strong contraindications.

### Cardiac–Psychiatric Drug Interactions

A few drug interactions between psychotropic and cardiovascular drugs are worth noting (see Table 19–4). Many psychotropic drugs lower blood pressure; their interaction with antihypertensive medications, vasodilators, and diuretics may potentiate hypotension. TCAs and antipsychotic drugs that prolong the QT interval may interact with antiarrhythmic agents such as quinidine, procainamide, moricizine, and amiodarone and result in further QT prolongation or atrioventricular block.

### Drug Interactions: Cytochrome P450 Issues

Cytochrome P450 2D6 is responsible for the metabolism of many beta-blockers, carvedilol, and antiarrhythmic agents; this metabolic pathway is inhibited by haloperidol, fluoxetine, and paroxetine, with resulting elevation of blood levels of 2D6 substrates. Conversely, amiodarone is a 2D6 inhibitor and can elevate blood levels of amitriptyline, nortriptyline, clomipramine, codeine, desipramine, fluoxetine, and risperidone. Cytochrome P450 3A4 is responsible for metabolism of alprazolam, midazolam, triazolam, zolpidem, buspirone, carbamazepine, and haloperidol and of calcium channel blockers, cyclosporine, many statin agents, and tacrolimus. The 3A4 system is inhibited by amiodarone, diltiazem, verapamil, grapefruit juice, and nefazodone, and to a lesser degree by fluoxetine and sertraline. The combination of nefazodone

**TABLE 19–4. Selected psychotropic drug interactions with cardiovascular drugs**

Psychotropic agent	Cardiovascular agent	Effect
SSRIs	Beta-blockers	Additive bradycardic effects
SSRIs	Warfarin	Increased bleeding risk, despite little effect on INR
MAOIs	Epinephrine, dopamine	Hypertension
Lithium	Thiazide diuretics	Increased lithium level
TCAs	Guanethidine	Reduced antihypertensive efficacy of guanethidine
TCAs	Type IA antiarrhythmic agents, amiodarone	Prolong QT interval, increase AV block
Lithium	ACE inhibitors	Increase lithium level
Phenothiazines	Beta-blockers	Hypotension

*Note.* ACE=angiotensin-converting enzyme; AV=atrioventricular; INR=international normalized ratio; MAOI=monoamine oxidase inhibitor; SSRI=selective serotonin reuptake inhibitor; TCA=tricyclic antidepressant.

and haloperidol might increase the risk of ventricular arrhythmias, because increased haloperidol levels may result in greater QT prolongation. Carbamazepine and St. John's wort are inducers of 3A4 activity. An evolving reference listing for P450 interactions is available on the World Wide Web (Flockhart 2003), and these interactions are also reviewed in Chapter 37, "Psychopharmacology".

# 20 Lung Disease

---

Kathy Coffman, M.D.

James L. Levenson, M.D.

**IN THIS CHAPTER**, we review psychiatric aspects of the major pulmonary disorders, as well as lung transplantation and the use of psychiatric drugs in pulmonary patients. Diseases affecting the lungs occur across the life span. Asthma and cystic fibrosis usually have an early onset; sarcoidosis may begin in early to midlife; and emphysema, chronic bronchitis, and pulmonary fibrosis are usually diagnosed in midlife to senescence. Tuberculosis, hyperventilation syndrome, and vocal cord dysfunction may affect people of any age. For end-stage patients who are not candidates for lung transplantation, terminal weaning may be considered. Despite the large number of people with lung disease, many conditions have not been well studied from the psychosomatic standpoint.

## Common Pulmonary Disorders

---

### Asthma

Asthma is now the most common chronic disease in the United States, affecting 5%–7% of the population, or roughly 17 million people (American Lung Association 2000; Barnes and Woolcock 1998). This chapter focuses on asthma in adults (see Chapter 34, “Pediatrics,” for discussion of asthma in children). Mortality has risen steadily since the early 1980s. Age-adjusted mortality of asthma varies among ethnic groups: Puerto Ricans, 40.9 per million; non-Hispanic blacks, 38.1 per million; Cuban Americans, 15.8 per million; non-Hispanic whites, 14.7 per million; and Mexican Americans, 9.2 per million (National Center for Health Statistics 2000).

### *Comorbidity With Psychiatric Disorders*

Asthma symptoms overlapping with those of other disorders can complicate diagnosis. Asthma may be misdiag-

nosed as an anxiety disorder, and some anxiety disorders (panic, social anxiety) may be mislabeled as asthma. In one study, 31% of patients who had been given an asthma diagnosis had a negative methacholine inhalation challenge test, indicating no airway hyperresponsiveness. Social anxiety symptoms were a strong predictor of mislabeling the patient as asthmatic. Among patients without bronchial reactivity, social phobia was 10 times more common than in patients who actually had asthma (Schmalig et al. 1999). Therefore, clinicians should ask whether symptoms only occur in certain circumstances such as social settings. Methacholine inhalation challenge was useful in identifying three cases of factitious asthma (Downing et al. 1982).

Of course, patients may frequently have both asthma and anxiety. Anxiety is increased by sudden and unexpected attacks of asthma, anticipation of attacks in response to certain triggers, and side effects of medications for treatment of asthma. Anxiety can affect the patient's response to an attack, as well as use of medications and quality of life (ten Thoren and Petermann 2000).

Some have reported a high comorbidity between asthma and panic disorder and other anxiety disorders. Those with asthma and panic disorder have more perceived breathlessness after an inhalation challenge test than those without panic disorder. Perceived discomfort, rather than actual bronchoconstriction, predicts use of bronchodilators (Schmalig et al. 1999). Several recent studies have indicated that anxiety and depression are more common in asthma patients than in the general population, particularly in women and those with less education (Centanni et al. 2000). A study of 230 outpatients with asthma revealed that almost half had a positive screen for depressive symptoms (Mancuso et al. 2000). Most recently, Goodwin and colleagues (2003) systematically screened a general adult population sample of more than 13,000 Germans for asthma

and DSM-IV mental disorders. They found that current asthma and lifetime history of severe asthma were each associated with significantly elevated odds ratios of anxiety disorders, including panic, social phobia, generalized anxiety, and specific phobias.

### *Psychological Factors in Asthma*

Psychosomatic theories about asthma were proposed by French and Alexander in 1939–1941, based on the hypothesis that a central conflict revolved around unconscious dependency issues with the mother and fear of separation. However, these theories have little empirical support (Greenberg et al. 1996).

Few prospective studies of the relationship of psychosocial variables to pulmonary function in patients with asthma have been reported. One small study showed that 50% of subjects had significant associations between pulmonary function and a variety of psychosocial factors (Schmaling et al. 2002).

Asthma is a primary respiratory disease with varying immunological and autonomic pathophysiological changes. No particular personality type is more susceptible to development of asthma. Asthma was once regarded as a classic psychosomatic disorder, and it is still widely believed that psychological factors (particularly anxiety) play an important role in the precipitation and aggravation of asthma. However, respiratory distress itself may be misinterpreted as anxiety and can also cause anxiety symptoms (panic attacks, generalized and anticipatory anxiety, phobic avoidance). In addition, most of the drugs used to treat asthma can cause anxiety. *Brittle* asthma patients, like brittle diabetic patients, are more likely to have current or past psychiatric disorders, particularly anxiety disorders, than other asthma patients are; but which comes first has not been established (Garden and Ayres 1993). Anxiety and depression are associated with more respiratory symptom complaints in asthma patients but with no differences in objective measures of respiratory function (Janson et al. 1994; Rietveld et al. 1999).

Similar to panic disorder, those with asthma have a tendency to hold catastrophic beliefs. In a study of 50 subjects and their partners, there was a significant association between catastrophic cognitions and more asthma symptoms such as irritability, panic and fear, and rapid breathing even when severity of asthma was considered (Giardino et al. 2002).

Asthma attacks have long been thought to be provoked by psychological distress. There was a 27% increase in severity of asthma symptoms in patients surveyed in New York City 5–9 weeks after the September 11, 2001, terrorist attacks (Centers for Disease Control and Prevention 2002), and PTSD was a significant pre-

dictor of asthma symptom severity (Fagan et al. 2003).

Psychological factors and psychosocial problems in hospitalized asthma patients were a more powerful predictor of which patients required intubation than any other examined variable (e.g., smoking, infection, prior hospitalization) (LeSon and Gershwin 1996). Several psychological factors in asthma patients may be associated with asthma deaths. A case-control study involving 533 cases showed an increased risk of death associated with health behaviors such as poor adherence with follow-up visits and poor inhaler technique. Three independent psychosocial factors appeared to increase the odds of death: psychosis, financial problems, and learning difficulties. Two factors associated with reduced risk were sexual problems and prescription of antidepressant drugs. Surprisingly, factors such as bereavement, domestic abuse, family problems, and social isolation did not correlate with risk of asthma death (Sturdy et al. 2002).

By what mechanisms might psychological factors affect asthma? From a physiological perspective, the vagus nerve is thought to mediate airway reactivity to emotion (Isenberg et al. 1992). The upper airways innervated by cholinergic neurons may be affected more by suggestion and emotion than smaller airways (Lehrer et al. 1986). Recent research has shown that various emotions and types of stress can increase respiratory resistance in asthma (Ritz et al. 2000).

Psychological factors may also influence asthma through behavioral mechanisms. Noncompliance with medications is common among asthma patients and may increase likelihood of hospitalization. Psychological morbidity is associated with high levels of denial and delays in seeking medical care, which may be life-threatening in severe asthma (D.A. Campbell et al. 1995; Miles et al. 1997), as well as less medication adherence and consequently poorer control of asthma (Cluley and Cochrane 2001). Not surprisingly, then, psychopathology in persons with severe asthma is associated with increased health care utilization, including hospitalizations and outpatient and emergency room (ER) visits, independent of asthma severity (ten Brinke et al. 2001). One study of 85 asthma patients showed higher prevalence of self-reported noncompliance with treatment among those who were ever hospitalized than those that had never been hospitalized. Emotional distress associated with disease and treatment was related to noncompliance (Put et al. 2000).

### *Interventions With Asthma Patients*

Adjuvant forms of treatment for asthma may involve psychological interventions such as biofeedback, education programs, hypnosis, stress management, symptom perception, and yoga (Lehrer et al. 2002). Patient education pro-

grams can reduce anxiety and improve self-management. Problem checklists and patient diaries of asthma attacks can be useful in determining signs of an attack, triggers of attacks, helpful steps for the patient or others to take during an attack, and the impact of the illness on social and academic development and family life (Weiss 1994).

Whether behavioral interventions can affect asthma morbidity was investigated in a randomized, controlled study of 16 young, non-steroid-dependent asthma patients who participated in biofeedback-assisted relaxation. This small study found that the intervention produced improvement in FEV1/FVC (ratio of forced expiratory volume after 1 second to forced vital capacity) at posttest and decreased severity of asthma and bronchodilator usage with changes in white blood cell populations over time, suggesting decreased inflammation (Kern-Buell et al. 2000).

## Cystic Fibrosis

In the United States, cystic fibrosis (CF) affects over 18,000 children under the age of 18 (1 in 2,500 births). CF is the most common hereditary disease in white children, and it is also seen in other races. The disease typically results in chronic progressive lung disease and pancreatic insufficiency. Survival improved from a median age of 12 years in 1966 to 40 years by 2001 (Jaffe and Bush 2001), so adults living with CF are a relatively recent and growing population. (See Chapter 34, "Pediatrics," for information on CF in children.)

The regimen of therapy necessary to maintain health in patients with cystic fibrosis is extremely time-consuming and may involve the whole family, especially in early childhood. Treatment includes a nebulizer with bronchodilators followed by physiotherapy three times a day, frequent antibiotic treatment via portacath, pancreatic enzyme replacement, inhalers, and, in cases of severe malnutrition, gastrostomy tubes with a kangaroo pump (Llewellyn 1998).

### *Psychological Factors in Cystic Fibrosis*

Several authors have described growing up with CF from a child's perspective. Different issues arise during various stages of psychological development. In adolescence, for example, teens may come to grips with the illness, put it into a new perspective because of their growing cognitive abilities, and hopefully assume responsibility for their health care. Knowing the key issues involved can enhance effectiveness of therapeutic interventions (Christian and D'Auria 1997; Hains et al. 1997; Llewellyn 1998).

One recent study looked at the impact of recent pulmonary exacerbations on quality of life in patients ages 5–45

with mild-to-moderate CF. Among the 162 patients who participated, recent exacerbations had an impact on health-related quality of life that was not accounted for by lung function, nutritional status, or demographic factors (Britto et al. 2002).

There are few studies of psychological functioning in adults with CF. One recent study included 34 adults with CF who completed the Minnesota Multiphasic Personality Inventory–2, Beck Depression Inventory (BDI), and State-Trait Anxiety Inventory; the patients did not display significant levels of depression, anxiety, or any other psychopathology. Males reported higher depression and anxiety scores than females. Lower anxiety correlated with better pulmonary function (D.L. Anderson et al. 2001).

Coping responses and reasons for nonadherence to medical regimens in 60 adult CF patients were systematically explored. Four ways of coping with CF were described: optimistic acceptance, hopefulness, distraction, and avoidance. Not surprisingly, the adherent patients scored higher on the optimistic acceptance and hopefulness scales, whereas the nonadherent patients used avoidant strategies significantly more often. Those patients who relied heavily on distraction fell in the middle regarding adherence (Abbott et al. 2001).

A comparison of pre-lung transplant quality of life in 58 patients with CF versus 52 patients with other types of end-stage lung disease revealed some interesting differences. The CF patients had lower levels of anxiety, were more likely to be working, and used more functional coping methods. This suggests that adults with CF had developed better adaptation to their illness than had those with other chronic lung disease (Burker et al. 2000).

However, other investigators found psychiatric problems, mainly related to anxiety, in 50%–60% of CF patients (Hains et al. 1997). Increases in depressive symptoms have been seen in older teenagers and young adults (Benner 1993). Noncompliance with the medical regimen has been estimated to be at least 35% (Czajkowski and Koocher 1987).

## Chronic Obstructive Pulmonary Disease

Almost 16 million Americans have chronic obstructive pulmonary disease (COPD): 14 million with chronic bronchitis and 2 million with emphysema. COPD ranks fourth as a cause of death in the United States after heart disease, cancer, and stroke. Whereas many other types of lung disease affect minority groups disproportionately, COPD shows a higher age-adjusted death rate for whites (21.9 per 100,000) than blacks (17.7 per 100,000). Cigarette smokers are 10 times as likely to die of COPD as non-smokers.

COPD results in progressive and usually irreversible declines in arterial oxygen, with carbon dioxide increasing late in the course of the disease. Hypoxia causes confusion, disorientation, altered consciousness, muscle twitching, tremor, and seizures. Mild hypoxia can be accompanied by irritability, mental slowing, and impairment of memory with poor reasoning and perseveration. Prolonged hypoxia can result in permanent memory deficits or dementia, that is, hypoxic encephalopathy (Lishman 1987). Chronic or severe hypoxia can lead to extrapyramidal symptoms, pseudobulbar palsy, or visual agnosia. If hypoxia is accompanied by hypercapnia and respiratory acidosis, as in chronic bronchitis or status asthmaticus, patients may be lethargic and have auditory and visual hallucinations (Lishman 1987).

### *Comorbidity With Psychiatric Disorders*

Nicotine dependence is the most commonly associated psychiatric condition in COPD patients. More than 80% of COPD cases are associated with tobacco smoking (Tashkin et al. 2001). Alcohol abuse aggravates COPD, in part because of a higher rate of severe community-acquired pneumonia, particularly aspiration pneumonia (Ewig and Torres 1999).

Sexual dysfunction is also common in COPD. In a study of Spanish male COPD patients on long-term oxygen, 67% of the patients and 94% of their wives said they had sexual problems, including lack of desire and impotence (Ibanez et al. 2001). There are intriguing reports of decreased dyspnea and improvement in spirometry after sildenafil for treatment of erectile dysfunction (Charan 2001).

Major depression is also very common in patients with COPD, although this finding is in part a result of its increased prevalence in smokers (Aydin and Ulasahin 2001; Withers et al. 1999; Yohannes et al. 2000). In one recent study, clinical depression was found in 42% of the patients, of whom 30% were mildly depressed; 68%, moderately depressed; and 2%, severely depressed (Yohannes et al. 2000). Only about one-fifth of COPD patients with major depression are treated with antidepressants. Depression not only may adversely impact rehabilitation but also may contribute to difficulty ceasing tobacco use, and the depression may recur when tobacco is discontinued (Borson et al. 1998).

Anxiety is also common in COPD (Aydin and Ulasahin 2001; Withers et al. 1999; Yohannes et al. 2000). The prevalence of panic disorder in COPD patients remains controversial, because some groups claim a higher rate among COPD patients, and others dispute this finding. Many studies mention panic attacks without stating whether the patients met DSM or ICD criteria for panic disorder.

In one study, 37% of COPD patients reported having had a panic attack. These patients also reported significantly more agoraphobic cognitions and more concern with bodily sensations than those who did not have panic (Porzeli et al. 1992). Another study found that COPD patients had symptoms similar to those of agoraphobic patients, though not as intense (Klonoff and Kleinhenz 1993).

Cognitive dysfunction is also very common in COPD, because of hypoxemia, and is improved by supplemental oxygen. Two decades ago, it was demonstrated that 42% of COPD patients with neuropsychological deficits showed modest improvement after 6 months of oxygen therapy. Those receiving continuous oxygen treatment (COT) had better neuropsychological performance and survival at 12 months than did those receiving nocturnal oxygen treatment only (Heaton et al. 1983). Rates of neuropsychological impairment rose from 27% in those with mild hypoxemia to 61% in those with severe hypoxemia (Grant et al. 1987). Higher scores on the Benton Visual Motor Retention Test and Digit Symbol subtest of the Wechsler Adult Intelligence Scale (associated with better oxygenation) predicted significantly better survival (Fix et al. 1985). More recent studies have shown slower reaction times, (Della Sala et al. 1992) and decreased visual attention related to the nadir of nocturnal saturation of oxygen (Vos et al. 1995). About 30% of COPD patients showed immediate memory impairment (Fioravanti et al. 1995). Of the COPD patients tested at discharge after a first episode of acute respiratory failure requiring mechanical ventilation, 47% showed Mini-Mental Status Examination (MMSE) scores below 24, compared with 3% of stable COPD control subjects receiving continuous oxygen treatment. Retesting 6 months later showed that 17% of the hospitalized patients still scored below 24 on the MMSE versus 5% of the comparison group (Ambrosino et al. 2002). Anterior cerebral hypoperfusion has been demonstrated on SPECT in hypoxemic COPD patients, with below-normal scoring on verbal attainment, attention, and deductive reasoning, which could presage frontal-type cognitive decline with worsening hypoxemia (Antonelli Incalzi et al. 2003).

### *Psychological Factors in COPD*

As with other medical illnesses, measurement of physical symptoms in COPD may be confounded by psychological symptoms, and vice versa. Psychological distress in COPD amplifies dyspnea, usually without causing changes in objective pulmonary functions. One study of COPD patients showed that patients with more severe physical symptoms had more negative mood symptoms. In particular, fatigue was found to account for 28% of the variance on the Neg-

ative Mood Scale. Surprisingly, dyspnea, congestion, and peripheral-sensory disturbances did not factor into the equation for negative mood in this study (Small and Graydon 1992).

Results have not been consistent in correlating quality of life and various measures of pulmonary function. A recent study found that quality of life was related to perceived self-efficacy with functional activities in COPD rather than strictly to pulmonary function (Kohler et al. 2002). Those with higher levels of positive social support had better quality of life with less depression and anxiety. Lower quality of life was seen when catastrophic withdrawal coping strategies were employed by the patients (McCathie et al. 2002).

Depression and anxiety in COPD patients have led to lower exercise tolerance (Withers et al. 1999), noncompliance with treatment (Bosley et al. 1996), and increased disability (Aydin and Ulusahin 2001). Psychological factors may predict whether a patient with obstructive pulmonary disease is at higher risk of relapse after emergency treatment. In one study, those with anxiety or depression had a higher rate of relapse within 1 month (53%) compared with those in the group without anxiety or depression (19%) (Dahlen and Janson 2002).

On the basis of clinical experience, Dudley et al. (1985) observed that when patients and physicians face COPD, they may feel helpless. The patient may be viewed by others as weak and lacking motivation. The physician may feel impotent when a patient cannot be cured. The patient and family may be angry and frustrated that this illness cannot be fixed. The patients may feel guilty if smoking resulted in the disease, and he or she may feel like a burden to spouse and family. The patient may avoid emotional expression because it exacerbates his or her sense of dyspnea. Denial, suppression of affect, repression, and isolation are frequently used as coping strategies in COPD patients (Dudley et al. 1985). Consequently, the patient's spouse or family may feel that the patient is emotionally distant and unavailable. This may perpetuate a cycle of confrontation and avoidance, leading to unresolved anger and despair as neither the needs of the patient nor those of the family are met. Patients may fear loss of control or loss of independence. Other losses may include loss of job, social status, role in the family, and changes in appearance because of steroids. Chronic steroid use may also exacerbate depression, emotional lability, or irritability, which in turn further strains interpersonal relationships.

Dependence on supplemental oxygen can be socially stigmatizing and make the patient feel unattractive. The oxygen tank may or is feared to be a liability in the patient's occupation. Some cannot accept the need for oxy-

gen because of denial about the illness. Others become psychologically dependent on oxygen, exceeding the amount prescribed, posing a risk of carbon dioxide retention, which leads to lethargy.

The Veterans Administration Normative Aging Study found that optimism in older men with COPD predicted higher levels of pulmonary function and a slower rate of pulmonary function decline (independent of smoking status). Significantly higher forced expiratory volume in 1 second (FEV<sub>1</sub>) and forced vital capacity (both  $P < 0.01$ ) were found in those with more optimism, measured 8 years earlier (Kubzansky et al. 2002).

### *Interventions With COPD Patients*

Psychotherapeutic, psychopharmacological, and rehabilitation intervention trials in COPD have been recently reviewed in detail elsewhere (Brenes 2003). The first priority in the rehabilitation of patients with COPD is smoking cessation. Other interventions include pharmacotherapy, physical therapy, psychosocial interventions, nutritional therapy, and, for those who are hypoxemic, long-term oxygen therapy surgery. A small fraction of patients may benefit from bilateral lung volume reduction surgery (Wurtemberger and Hutter 2001).

COPD is a chronic debilitating disease that limits lifestyle and progressively compromises quality of life. The goals of treatment are to relieve symptoms, improve physical functioning via rehabilitation, and improve patients' coping skills (Small and Graydon 1992). Patients may interpret dyspnea as a signal to avoid all activity and thus become homebound and isolated. Exercise may allow patients to build endurance, improve their range of activities, and learn to pace themselves. Some patients avoid exercise groups so as to avoid confronting their illness or seeing others who may be sicker, foreshadowing their own eventual decline. These patients may do better with individual physical therapy. Through participating in a structured exercise program, the patient may gain control and learn that mild dyspnea is not necessarily life-threatening. A treatment plan with realistic and attainable goals and rewards can counteract helplessness (Dudley et al. 1985).

A meta-analysis of 23 randomized, controlled trials of pulmonary rehabilitation for COPD concluded that pulmonary rehabilitation significantly decreased dyspnea and fatigue, although the improvement in exercise capacity was modest (Lacasse et al. 2002).

Pulmonary rehabilitation may decrease dyspnea and anxiety symptoms significantly and increase global quality of life (Buchi et al. 2000). An uncontrolled study of the impact of inpatient pulmonary rehabilitation found 29.2% of patients with significant anxiety on admission

and 15% with significant depression. Scores for both anxiety and depression were significantly lower after pulmonary rehabilitation and at 6-month follow-up. Those with high initial anxiety scores made significantly greater improvement in exercise capacity than those with low initial scores (Withers et al. 1999). Pulmonary rehabilitation can increase patients' sense of control over COPD, a key issue in this progressive chronic illness (Lacasse et al. 2002).

Predictors of nonadherence with an outpatient pulmonary rehabilitation program were investigated by Young et al. (1999). Noncompleters were more likely to be currently smoking, divorced, living alone in rented accommodations, and less likely to use inhaled corticosteroids. In this study, noncompleters were not more anxious, depressed, or prone to hyperventilation or worse quality of life, and were not more physiologically impaired (Young et al. 1999).

Rose et al. (2002) reviewed 25 published studies of psychological treatments for reduction of anxiety in patients with COPD. Only 6 were randomized, and methodological limitations across all studies led the authors to conclude that there is an insufficient evidence base to recommend a specific psychological treatment for anxiety in COPD. However, some clinicians have found relaxation techniques useful in motivated patients, and there seems to be no reason to believe that psychological interventions for anxiety would be harmful in COPD (Rose et al. 2002). Pharmacological treatment of anxiety is discussed later in this chapter.

## Sarcoidosis

Although sarcoidosis was first reported by Jonathan Hutchinson in 1872 (Scadding 1967), its etiology is still undetermined. Sarcoidosis is characterized by noncaseating granulomatous involvement of lymph nodes, lymphatic channels in the lung and other tissues. Sarcoidosis affects black patients more than whites in the United States (40 per 100,000 vs. 5 per 100,000). In Europe, Swedes and Danes have high prevalence rates (American Lung Association 2000). Onset of the illness is usually between ages 20 and 40. Diagnosis may be delayed by failure to recognize the slowly progressive symptoms until characteristic findings are recognized on a chest X ray. The disease often follows a relapsing and remitting course, with recovery in 80% of patients, but about 5% die from sarcoidosis. Patients may be asymptomatic, but often they have a dry cough, shortness of breath, fatigue, and weight loss. Lesions can affect the skin, bones, joints, skeletal muscles, and heart. Fatal complications include progressive respiratory impairment, infection, cardiac disease, and renal failure.

## *Central Nervous System Sarcoidosis*

Sarcoidosis affects the central nervous system (CNS) in as many as 5% of patients. Neurosarcoidosis may cause brain lesions, involve cranial nerves (especially VII), and cause peripheral neuropathies (and rarely choreoathetosis). In as many as 30% of cases, the cerebrospinal fluid may be normal, and the diagnosis is made on clinical grounds (Stou-demire et al. 1983). Arachnoiditis may cause increased intracranial pressure and hydrocephalus, and meningitis can cause headache. Hypothalamic involvement can cause obesity, hyperthermia, memory dysfunction, personality changes, and somnolence. Pituitary involvement may result in diabetes insipidus, or conversely syndrome of inappropriate antidiuretic hormone secretion (SIADH) with hyponatremia, hypercalcemia, hyperprolactinemia, menstrual cycle changes, or hypogonadism (see Bullman et al. 2000; Delaney 1977; Mino et al. 2000; Sharma 1975).

CNS disease may cause disturbance of orientation, sensorium, memory, and cognitive functions (Mathews 1965; Silverstein et al. 1965). Various psychiatric symptoms, such as apathy, dementia, hallucinosis, irritability, and neglect, have been noted (Hook 1954). CNS sarcoidosis can mimic depressive stupor, Wernicke-Korsakoff psychosis, classic paranoid psychosis, and schizophreniform disorder (Hook 1954; Sabaawi et al. 1992; Suchenwirth and Dold 1969; Zerman 1952). Psychotic symptoms rapidly remit with steroids. Patients with CNS sarcoidosis may also present with seizures (Thompson and Checkley 1981).

## *Psychological Factors in Sarcoidosis*

Sarcoidosis has been rarely investigated from the psychological standpoint. One small study found that increased life stress predicted subsequent impairment of lung function. The only psychological variable that consistently correlated with lung function was the mean score for day-to-day hassles, suggesting the potential benefit of relaxation exercises and stress management (Klonoff and Kleinhenz 1993). Some patients ultimately diagnosed with sarcoidosis have been mistakenly labeled as having somatization disorder, which can happen with any occult multisystem disease (DeGruy et al. 1987).

Hoitsma et al. (2003) studied pain in 821 Dutch patients with sarcoidosis without other medical comorbidity. They found that 72% of patients had pain, including arthralgia (53.8%), muscle pain (40.2%), headache (28%), and chest pain (26.9%), suggesting that psychological and pharmacological pain management may also be beneficial. Wirnsberger et al. (1998) found that sarcoidosis has considerable impact on quality of life, especially via fa-

tigue, although fatigue was not related to any measured psychological variable.

## Pulmonary Fibrosis

The etiology of idiopathic pulmonary fibrosis (IPF) is unknown, but the prevalence is roughly 3–5 per 100,000. Pulmonary fibrosis also may be caused by inhalation of a variety of agents (especially via occupational exposure), radiation, and rheumatological disorders, especially systemic sclerosis. Patients with IPF develop gradual progressive loss of lung function and declining exercise tolerance.

Psychological factors have received surprisingly little attention in IPF. Dyspnea is the most important factor in determining quality of life in IPF. Dyspnea correlated with quality-of-life variables, as did some pulmonary parameters (Martinez et al. 2000). DeVries et al. (2001) studied patients with IPF, comparing them with control subjects, and found that the subjective sense of breathlessness appeared related to depressive symptoms and quality of life.

## Tuberculosis

The incidence of tuberculosis (TB) had been declining for more than 70 years but began to rise again over the last decade in the United States, Western Europe, Asia, and Africa. Causes for this trend include the rise of AIDS and increasing homelessness, as well as the failure to fund public health systems to provide treatment. The World Health Organization estimates there are 2.9 million deaths per year and nearly 8 million new cases per year in the world. About one-third of the world's population is infected with *Mycobacterium tuberculosis* and at risk for the disease. Roughly one-fifth of all adult deaths in developing nations are caused by tuberculosis (Bloom et al. 1996). See Chapter 27, "Infectious Diseases," for a discussion of CNS tuberculosis.

Psychiatrists may be asked to make capacity determinations in patients who are nonadherent with TB treatment and need to be confined for treatment of TB (O'Dowd et al. 1998). One survey of TB detainees showed that 81% had drug or alcohol abuse, 46% were homeless, and 28% had mental illness (Oscherwitz et al. 1997). The prevalence of mental illness in the homeless ranges from 25%–33% in Ireland and Spain to 80%–95% in the United States, Australia, Canada, Norway, and Germany (Martens 2001). Screening of the homeless in Spain showed that 75% were infected with TB, 14% had radiographic evidence of inactive pulmonary TB, and 1% had active pulmonary TB (Solsona et al. 2001). In San Francisco,

homeless patients showed an incidence of TB of 270 per 100,000 associated with older age, less education, HIV infection, and nonwhite ethnicity (Moss et al. 2000). Positive purified protein derivative (PPD) tests were found in 17% of the severely mentally ill in New York City, but none had active TB (McQuiston et al. 1997). In New Orleans, PPD screening of homeless men with psychotic disorders showed a relative risk of 4.48 compared with the general population. It is very difficult to effectively treat TB in homeless, infected individuals with severe chronic mental illness, particularly in the absence of adequate mental health treatment and social and residential resources (Sakai et al. 1998).

Alcoholic patients are more susceptible to TB (Sternbach 1990), and drug dependence is also a risk factor (Reichman et al. 1979). Thus, access to adequate substance abuse treatment may be essential to achieving recovery from TB and preventing relapse. Measures to control TB in homeless, mentally ill, alcoholic, or drug-addicted persons include screening in clinics, hotels, and shelters; directly observed therapy; and incentive programs (Malotte et al. 1999).

Psychiatrists must also be attuned to the possibility of iatrogenic neuropsychiatric symptoms during treatment with isoniazid, such as mania and psychosis (Alao and Yolles 1998), probably related to its being a weak inhibitor of monoamine oxidase. Predisposing factors identified include alcoholism, diabetes, hepatic insufficiency, old age, slow acetylation, and family and personal history of mental illness (Djibo and Lawan 2001). Pyridoxine deficiency may also play a role in the etiology of isoniazid-related psychosis. Acute overdose with isoniazid, causing convulsions (controlled by giving pyridoxine), has been reported (Ebadi et al. 1982). Pellagra encephalopathy has also been seen, especially with poor nutrition, because isoniazid inhibits conversion of tryptophan to niacin. Clinicians should suspect pellagra if TB patients taking isoniazid show gastrointestinal, mental, or neurological symptoms (Ishii and Nishihara 1985).

## Hyperventilation

A syndrome of hyperventilation was first recognized in 1871 by DaCosta. Hyperventilation is a common presenting complaint in ERs leading to psychiatric consultation (Nguyen et al. 1992). These patients experience an increase in the rate and depth of breathing briefly for a few minutes and may have dizziness or syncope from the respiratory alkalosis and cerebral vasoconstriction that result. Accompanying symptoms of carpopedal spasm, myoclonic jerks, or paresthesias may frighten the patient or relatives and result in an ER visit.

Hyperventilation syndrome (HVS) has been defined by three criteria: the patient hyperventilates and has a low  $p\text{CO}_2$ , somatic diseases causing hyperventilation have been ruled out, and the patient has somatic complaints because of hypocapnia (Folgering 1999). HVS occurs across the life span, from children to the elderly (Hodgens et al. 1988; Teramoto et al. 1997). The incidence of HVS may be as high as 6%–11% of the general population (Lachman et al. 1992). In one Japanese study, HVS attacks recurred in half of patients and continued to recur over 3 years in 10% (Hirokawa et al. 1995). Differential diagnosis for hyperventilation includes medical and psychiatric disorders. Evaluation in the ER, to avoid mislabeling patients as having HVS, may include a chest X ray, blood chemistries, a complete blood count, and thyroid functions (Saisch et al. 1996).

Medical illnesses that can cause hyperventilation and be confused with HVS include angina, arrhythmia, asthma (Demeter and Cordasco 1986), carbon monoxide poisoning (Skorodin et al. 1986), diabetic ketoacidosis (Treasure et al. 1987), pulmonary emboli (Hoegholm et al. 1987), epilepsy, hypoglycemia, ingestion of salicylates (Rognum et al. 1987), Meniere disease, tetany (Hehrmann 1996), and vasovagal syncope. In HVS patients, unilateral neurological symptoms, often left-sided, may mimic a cerebral vascular accident; and loss of consciousness and pseudoseizures caused by hyperventilation may be misdiagnosed as epilepsy (North et al. 1990; Perkin and Joseph 1986). However, there have also been reports of neurological causes of hyperventilation, including thalamic infarct (Scialdone 1990), Cheyne-Stokes breathing (Liippo et al. 1992), and traumatic vestibular hyperreactivity after whiplash injury (Fisher et al. 1995).

Hyperventilation syndrome may be present in many patients with cardiac chest pain (Castro et al. 2000; Freeman and Nixon 1985; Hegel et al. 1989). Hyperventilation syndrome and medical disorders are not mutually exclusive; they frequently occur together both because some disorders promote hyperventilation physically *and* psychologically (i.e., asthma, angina, pulmonary embolism), and because the metabolic consequences of hyperventilation may precipitate pathological events (i.e., arrhythmia, seizures, muscle spasm). Medications reported to cause central hyperventilation include carbamazepine, salicylates, and topiramate. Central hyperventilation resolves promptly within a day or two after discontinuation of these drugs (Lasky and Brody 2000; Mizukami et al. 1990).

Psychiatric disorders to consider in HVS include conversion disorder, histrionic personality disorder, panic disorder, phobic disorders, hypochondriasis, and substance abuse. Hyperventilation syndrome has also occurred as part of mass psychogenic illness (Araki and Honma

1986). Estimates of the overlap between HVS and panic disorder are between 35% and 50%, and in one study 83% of the patients had panic disorder with agoraphobia, and 82% had generalized anxiety disorder (Cowley and Roy-Byrne 1987; deRuiter et al. 1989; Hoes et al. 1987). The relationship between HVS and panic disorder is controversial. Bass has argued that the concept of a discrete hyperventilation syndrome is no longer tenable and that there is no evidence to support the view that panic attacks and hyperventilation are synonymous (Bass 1997). Patients with HVS may benefit from exploration of stressful life events, relationships, and self-esteem (Hanna et al. 1986; Robinson et al. 1988; Roncevic et al. 1994).

Various treatments for HVS have been employed over the years. Some methods are anecdotal, such as use of antidepressants (Saarijarvi and Lehtinen 1987), intravenous sedatives (Hirokawa et al. 1995), group therapy (Fensterheim and Wiegand 1991), and resolution of grief through individual psychotherapy (Paulley 1990). Methods with some evidence of effectiveness include beta-blockers (Van De Ven et al. 1995), breathing retraining (DeGuire et al. 1992, 1996; Pinney et al. 1987), and hypnosis (Conway et al. 1988).

Although having patients with acute hyperventilation rebreathe into a brown paper bag is a traditional technique used in the ER, there may be some hazards associated with its use. Death resulted in three cases where this treatment was mistakenly applied to patients with hypoxia or myocardial ischemia. A study of the effects of paper bag rebreathing in normally breathing volunteers showed that a few subjects reached  $\text{CO}_2$  levels as high as 50, (though many never reached 40), and the mean maximal drop in  $\text{O}_2$  was 26 mmHg (Callaham 1989). A small study showed that  $\text{CO}_2$  restoration during a paper bag rebreathing paradigm for HVS is subject to the effects of expectation and suggestion (Van den Hout et al. 1988). A large nonrandomized outcome study showed that half of the HVS patients recovered without treatment, while the others recovered with either paper bag rebreathing or intravenous sedatives (Hirokawa et al. 1995).

## Vocal Cord Dysfunction

Vocal cord dysfunction (VCD) is a respiratory syndrome often confused with asthma, although they often occur together (Neman et al. 1995). It is not unusual for VCD to be misdiagnosed as steroid-resistant asthma (Thomas et al. 1999). VCD may also co-occur with HVS. The syndromal picture of VCD was first described 200 years ago by Osler (Brugman 2003), yet it is still not well understood. VCD has been called by many different names—for example, episodic laryngeal dyskinesia, paradoxical

vocal cord motion, hysterical croup, adductor spastic dysphonia, factitious asthma, and functional upper airway obstruction. The disorder may present in childhood, adolescence, or adulthood. Patients may appear in severe respiratory distress yet have relatively normal blood gas levels, or respiratory alkalosis from hyperventilation, only rarely presenting with hypoxemia. In contrast to asthma, in VCD wheezing will be loudest over the larynx and more pronounced in the inspiratory phase, but the chest is otherwise clear. Also unlike asthma, VCD attacks typically have rapid onset and equally rapid resolution. VCD may lead to frequent ER visits and hospitalizations, high doses of (ineffective) asthma medications, and unnecessary intubation (Bahrainwala and Simon 2001). The differential diagnosis of VCD includes asthma, HVS, neurological disorders (e.g., spasmodic dysphonia and laryngeal nerve injury), and angioedema (Brugman 2003).

For many years, VCD was considered a conversion disorder, but VCD should be considered as a symptom. In most patients, VCD appears not to be a primary psychiatric disorder but rather a conditioned response or functional disorder, which may result in secondary anxiety, which then further aggravates the condition. The onset of VCD is typically preceded by allergy, asthma, reflux, irritant exposure (Perkner et al. 1998), or a dyspneic episode in athletes (Newsham et al. 2002). The psychiatric literature reflects referral bias but nevertheless captures part of the VCD spectrum. Case reports and retrospective case series noted strong dependency needs and fears of separation in patients with VCD and its acute precipitation following psychosocial stress. One study of tertiary care VCD patients found that the majority had a history of childhood sexual abuse (Freedman et al. 1991), but this has not been substantiated (Brugman 2003). There is only one prospective controlled blinded study using standardized measurements, comparing adolescent patients with VCD to matched asthma patients without VCD (Gavin et al. 1998). Anxiety disorders and depression were much more common in VCD patients. Psychiatrists are most likely to see those patients with VCD who develop panic attacks and phobic symptoms. Wamboldt et al. (in press) note the considerable overlap among VCD, HVS, and panic disorder, and they postulate that VCD is linked to Klein's "faulty suffocation alarm" (Klein 1993). Other referred cases of VCD may represent conversion disorder, posttraumatic stress disorder, somatization disorder, factitious illness, or another psychiatric disorder.

There is no empirically proven treatment for VCD. Most patients with uncomplicated VCD respond well to speech therapy alone (Brugman 2003). Those with associated psychopathology should receive treatment appropriate to their psychiatric diagnosis, for example, psycho-

therapy or antipanic pharmacotherapy. Biofeedback has recently been reported as helpful (Earles et al. 2003).

## Lung Cancer

Lung cancer is the most common cause of cancer death in the United States and the world. Smoking tobacco is the primary cause of most lung cancers (Strauss 1998).

A review of quality of life in lung cancer patients from 1970 to 1995 noted that over 80% of lung cancer patients died within a year of diagnosis, because many were diagnosed late (Montazeri et al. 1998). More than 50 instruments have been used to measure quality of life in patients with lung cancer. Psychological distress and lower quality of life have been correlated with even moderate weight loss (Ovesen et al. 1993). Symptoms of psychological distress are common in lung cancer. One study showed that newly diagnosed lung cancer patients had frequent insomnia (52%), loss of libido (48%), loss of interest or ability to work (33%), concerns about their families (29%), and poor concentration (19%) (Ginsburg et al. 1995). Another study found that predictors of psychological distress in ambulatory lung cancer patients included being female, living alone, having no children as confidants, relying on nursing staff as confidants, and having a helpless or hopeless coping style (Akechi et al. 1998).

A study of newly diagnosed patients with unresectable non-small cell cancer of the lung described the most common psychiatric diagnoses as nicotine dependence (67%), adjustment disorders (14%), alcohol dependence (13%), and major depression (5%). Depression did not increase over the course of the illness. Pain management was key in relieving depression (Akechi et al. 2001). Uchitomi et al. (2003) also studied non-small cell lung cancer patients ( $n = 212$ ) and found that the prevalence of depression in the year after curative resection did not significantly decrease, suggesting that ongoing psychosocial support is needed even after curative resection of non-small cell cancer of the lung. Type of lung cancer may influence the rate of depression. In one study, the rate of depression was nearly three times higher in those with small-cell cancer (25%) than in those with non-small cell cancer (9%). The most important risk factor for depression was functional impairment (Hopwood and Stephens 2000).

Fatigue is more common at diagnosis with lung cancer than most other cancers: 50% of those with inoperable non-small cell cancer reported severe fatigue. Key factors contributing to fatigue include disease burden, dyspnea, pain, and psychological distress (Stone et al. 2000). Adaptive behaviors can reduce fatigue even with low hemoglobin levels. Lung or colon cancer subjects who used nonadaptive routines—namely, disorganization,

inertia, and overexertion—reported more fatigue (Olson et al. 2002).

Tanaka et al. (2002) found that dyspnea, very common in advanced lung cancer, was significantly correlated with cough, pain, and psychological distress. Given the high rate of dyspnea in lung cancer patients, one might expect that many patients would cease tobacco use. However, this is not the case, despite evidence that continued smoking after lung cancer diagnosis decreases treatment efficacy, increases complications, increases risk of recurrence and occurrence of another primary tumor, and decreases survival time. Schnoll et al. (2002) noted that in 74 cancer patients decreased readiness to quit smoking was associated with emotional distress, fatalistic beliefs, greater nicotine dependence, less self-efficacy, and having relatives at home who also smoke.

Do psychological factors alter the course of lung cancer? One study of lung cancer patients found that self-report of depressive coping was an independent predictor of decreased survival time at 8- and 10-year follow-up (Faller and Bulzebruck 2002; Faller et al. 1997). Psychological factors may also influence response to treatment in other ways. For example, one small study concluded that anxiety or depression predicted increased nausea scores after chemotherapy (Takatsuki et al. 1998).

Little has been written on coping in lung cancer. One study noted four common coping strategies among 50 patients with stages III and IV adenocarcinoma of the lung: seeking social support, problem solving, self-control, and positive reappraisal. There was no correlation between coping, mood, or perceived stress and the side effects of chemotherapy (Chernecky 1999).

## Lung Transplantation

### *Indications and Contraindications*

The first lung transplant was performed in 1963, but it was 20 years before the first successful operation in 1983 (Ochoa and Richardson 1999) (see also Chapter 31, “Organ Transplantation”). The most common indication is COPD (including alpha-I-antitrypsin deficiency), which accounts for about 45% of lung transplants (Hosenpud et al. 1998). Transplants are also performed for those with CF, IPF, Eisenmenger syndrome, primary pulmonary hypertension, and a number of other pulmonary diseases (Etienne et al. 1997). Patients are generally listed when their quality of life has declined and transplant would confer a survival benefit, given the waiting time of up to 2 years once the patient is listed for transplant (Maurer et al. 1998).

Exclusion criteria vary from one transplant center to another. Absolute contraindications typically include seri-

ous cardiac, renal, or hepatic insufficiency; cancer; chronic infections (e.g., cytomegalovirus, hepatitis B virus, or hepatitis C virus); or weight less than 70% or greater than 130% of ideal body weight. Psychiatric factors that are considered to be absolute contraindications to lung transplantation include active alcoholism, drug abuse or cigarette use, severe psychiatric illness, and noncompliance with treatment (Aris et al. 1997; Paradowski 1997; Snell et al. 1993).

Generally, lungs are allocated differently than hearts and livers. Presently in the United States, only waiting time, not severity of disease, is considered, but a prioritization scheme is currently being developed (Hauptman and O'Connor 1997). There are four main approaches to lung transplantation, including single-lung transplantation (the type most commonly performed), bilateral sequential transplantation, heart-lung transplantation, and single-lobe donation from living donors (Arcasoy and Kotloff 1999). Living donor donation has been controversial because of the uncertainty regarding risks to the donor. An analysis of one series of 120 donors reported four serious complications requiring return to surgery but no deaths. Loss of one lobe only decreased the lung volume by 15%, because the remaining lung expands to compensate, which does not impact long-term function in the donor (Barr et al. 1998).

### *Medical and Surgical Outcome*

Patient survival in the United States at 1 year and 3 years after lung transplant is currently 77% and 58%, respectively. Median survival is 3.7 years. For comparison, the corresponding survival figures after heart transplant are 85% and 77% (United Network for Organ Sharing 2003). For patients with CF and IPF, there appears to be increased survival relative to the natural history of the underlying illness. However, for patients with COPD, no survival advantage has been demonstrated, although transplant does appear to improve quality of life and functional ability. Exercise capacity improves, with about 80% of recipients reporting no limitations in activity within 1 year of transplant. Only 4% of lung recipients require total care at 1 year posttransplant. Quality of life remains stable for the first few years if the course is uncomplicated, but those who develop bronchiolitis obliterans show a sharp decline in quality of life. Despite improvements in exercise tolerance and quality of life, 40% or fewer of lung transplant recipients return to work. This finding may be a result of employer bias, a fear of losing health insurance or disability benefits, or a change in priorities after a life-threatening illness (Paris et al. 1998).

Early complications after lung transplantation include primary graft failure, stenosis of the anastomosis, and a

higher rate of infectious complications than in other solid organ transplantation, including bacterial pneumonia, cytomegalovirus pneumonitis, and complications of infection by *Aspergillus* and other pathogens (Christie et al. 1998; Kramer et al. 1993).

The incidence of acute rejection is greatest in the first 100 days after transplantation and declines over the first year (Bando et al. 1995). Chronic rejection is more common in lung transplant recipients, resulting in bronchiolitis obliterans (fibrotic obliteration of small airways) (Estenne and Hertz 2002).

### *Psychological Factors and Quality of Life*

Until recently, there were few studies in this area because of the small numbers of lung transplants being performed and the dearth of long-term survivors to study. All available studies are limited by small size. Cohen et al. (1998) described 32 recipients reporting better quality of life posttransplant. No pretransplant psychological variables were found to be associated with the length of survival posttransplant. Pretransplant trait anxiety did predict posttransplant quality of life. Those with higher levels of pretransplant trait anxiety had poorer mental health as well as more state anxiety, subjective sleep disturbances, and cardiac and pulmonary symptoms posttransplant (Cohen et al. 1998).

Stilley et al. (1999) studied 36 lung recipients and 14 heart–lung recipients, noting no differences in psychological data between the two transplant types. Recipients showed lower hostility than a normative sample. On the Hopkins Symptom Checklist–90 (SCL-90), recipients had about double the rates of depression and anxiety compared with the control group, with lung recipients having higher rates than heart–lung recipients. Lower global quality of life was more often seen in those recipients with low caregiver support, lower educational level, and higher level of health-related concerns when other variables were controlled (Stilley et al. 1999).

Limbos et al. observed that although many lung transplant recipients continued to have impaired psychological functioning posttransplant, most reported significant improvement in general health, self-esteem, social functioning, quality of life, anxiety, and depression. They noted no significant differences in sexual functioning between pretransplant and posttransplant subjects (Limbos et al. 2000).

A group in the Netherlands followed 28 lung transplant recipients for at least 55 months. Until about 43 months after transplant, there were significant improvements in anxiety, depression, quality of life, and activities of daily living, but after that time there was a decline in all of these measures (Vermeulen et al. 2003).

### *Psychological Interventions*

Napolitano et al. (2002) tested the efficacy of inexpensive telephone-based supportive and cognitive behavioral therapy for lung transplant candidates. The telephone-intervention group reported significantly higher general well-being, general quality of life, disease-specific quality of life, and levels of social support.

Teichman et al. (2000) studied adherence to treatment regimens after lung transplant and found that the level of family support was significantly correlated with self-reported compliance. Patients became less compliant the further from the time of transplant, suggesting that periodic reeducation after transplantation may improve adherence.

### Terminal Weaning

Patients with end-stage pulmonary disease caused by amyotrophic lateral sclerosis, COPD, CF, IPF, lung cancer, or other diseases may request terminal weaning to avoid futile interventions. The term *terminal weaning* has been viewed by some as an oxymoron for several reasons. *Terminal* implies that the withdrawal of ventilator support will inevitably end in death, yet *weaning* carries the implication of achieving independence from the ventilator. Another problem with the term is that patients do not always die shortly after discontinuation of ventilatory support. In one study, 8% of patients survived and were discharged (M.L. Campbell 1994). In the Karen Quinlan case, the U.S. Supreme Court supported her parents' right to have her ventilator withdrawn. Physician experts for both sides testified that she would die shortly afterward, but she lived 10 years after extubation. The phrase "discontinuation of ventilator support" or "withdrawal of mechanical ventilation" may be used when talking with the patient, family, and staff caring for the patient (Apelgren 2000; Daly et al. 1993).

Ethicists and legal experts concur that competent patients have the right to refuse treatment, regardless of whether it is "life saving," and that there is no moral difference between not initiating treatment and withdrawing treatment in response to the patient's request. However, physicians and nurses find withdrawing treatment, especially a ventilator, more difficult because this is viewed as a more active intervention, which may cause a greater sense of culpability. The patient must be aware that death is the most likely outcome when ventilator support is discontinued (although not every patient dies) and make the decision after due deliberation. The patient may view mechanical ventilation as an intolerable intrusion that diminishes the quality of life and renders death the preferred option (Daly et al. 1993).

The patient's goals should guide the process of withdrawing ventilator support (J. Anderson and O'Brien 1995). If the patient shows ambivalence about terminal weaning, or it is unclear whether the patient has sufficient mental capacity to make a well-thought-out decision, consultation from a psychiatrist should be obtained. The first step in evaluation is to explore why the patient has requested discontinuation of ventilator support. Some patients may be depressed and will agree to a trial of antidepressants prior to finalizing the decision for terminal weaning. Some have concluded (often correctly) that they can never be weaned successfully and prefer death to spending whatever is left of their lives on a ventilator in the hospital. Some are delirious, and their request is inconsistent and confused. Some are worried about burdening their families with hospital bills. Others may be struggling with whether giving up on the ventilator violates their religion's prohibition of suicide. Those health care workers caring for the patient should have an opportunity to discuss the decision as a team. In difficult cases, in addition to the psychiatrist, involvement of the hospital's ethics committee, chaplain, social worker, and legal counsel may be helpful. A brief delay after the decision has been made to withdraw ventilator support may reassure staff and family that the patient made a decision that was not based on temporary frustration or discomfort.

Patients should be told that the weaning process may be stopped at any time if they wish and that they may decide who will be present during the weaning process. Family members should be asked if they want to be present if the patient is incompetent or unresponsive. Withdrawal of the ventilator may follow the withdrawal of pressors, antibiotics, and enteral feeding (Brody et al. 1997). In a comatose patient whose family does not wish to be present, the physician may opt for extubation. In a conscious patient, a gradual decrease in  $FIO_2$ , with decreased positive end-expiratory pressure (PEEP) and decrease in respiratory rate over several hours has been advocated (Grenvik 1983).

No matter which method is used, adjunctive medication may alleviate distress. Opiates have been used for pain relief and to decrease gasping, coughing, or the sensation of shortness of breath; to provide sedation; and to decrease anxiety in the patient. Documentation of the physician's intent in administering opiates is important to show that the medication is being used as a comfort measure and not to hasten death. One protocol suggests giving a bolus of 5–10 mg morphine intravenously followed by a drip of 2.5–5.0 mg per hour of morphine. Benzodiazepines may decrease anxiety and prevent myoclonus or twitching that may be unsettling to the family (Faber-Langendoen 1994). Phenobarbital may control twitching not relieved by benzodiazepines. Low-dose haloperidol may

be used intravenously for anxiety not relieved by benzodiazepines or if the patient is delirious.

The family should be educated prior to the procedure that although the patient may have reflexive gasping or twitching, the medications used will prevent the patient from having awareness of these bodily events, and they may induce euphoria. Although patients in a persistent vegetative state may grimace when extubated, without higher cortical function there is no awareness of discomfort.

Use of paralytic agents is discouraged because they may prevent the patient from signaling if there is any distress. In patients who retain carbon dioxide, decreasing tidal volume or respiratory rate on intermittent mechanical ventilation may allow the  $CO_2$  to gradually rise, resulting in drowsiness, at which point mechanical ventilation may be stopped. The process should take place over just a few hours, preventing a prolonged bedside vigil that is exhausting for the family. The comfort of the family should be considered, for example, by providing ample seating and tissues, dimming the lights if desired, and turning off patient monitors if the family finds constantly beeping alarms disruptive or the electrocardiogram (ECG) readout upsetting. Staff members should remain at the bedside in a supportive, unobtrusive way, to attend to the patient and provide comfort to the family. Expressions of concern about how the withdrawal of ventilator support is affecting family members are appropriate. Physicians should take cues from the family and may step out to allow privacy or for religious ceremonies to be performed without interference (Benner 1993; Daly et al. 1993).

## Psychopharmacology in Pulmonary Disease

---

### Anxiety

Anxiety in pulmonary patients may be caused by symptoms of lung disease such as breathlessness, bronchospasm, excessive secretions, or hypoxia, so the first step in treatment of anxiety is optimization of management of the patient's respiratory illness. Many drugs used to treat pulmonary disease may themselves cause anxiety (Table 20–1). Theophylline, a methylxanthine, can cause anxiety, nausea, tremor, and restlessness, especially at higher doses. Beta-adrenergic bronchodilators used in treatment of asthma or other obstructive lung disease can cause marked anxiety, tachycardia, and tremor, particularly in patients who overuse their inhalers. Nonprescription asthma preparations contain nonselective sympathomimetics, which are even more likely to cause anxiety. At high doses, they may cause psychosis and seizures.

**TABLE 20-1. Psychiatric side effects of common pulmonary drugs**

Anticholinergics	Auditory and visual hallucinations, anxiety, confusion, delirium, depersonalization, amnesia, paranoia
Antileukotrienes	Anxiety
Beta-agonists (selective)	Anxiety in susceptible patients
Beta-agonists (nonselective)	Anxiety, psychosis
Corticosteroids (inhaled)	None
Corticosteroids (systemic)	Depression, mania
Cromolyn	Irritability
Cycloserine	Agoraphobia, anxiety, depression, psychosis
Isoniazid	Amnesia, anxiety, depression, hallucinations, mania, psychosis
Theophylline	Anxiety, delirium, insomnia, mutism, restlessness, tremor

Source. Adapted from *The Medical Letter* 1998, 2002.

In anxious pulmonary patients with hypercapnia, buspirone is preferred for treatment of anxiety, but it may have a slow onset of action (Craven and Sutherland 1991). Buspirone may improve exercise tolerance and dyspnea, can be used safely in patients with sleep apnea (Mendelson et al. 1991), and can be combined with theophylline and terbutaline (Kiev and Domantay 1988).

In COPD patients who do not retain carbon dioxide, prudent doses of benzodiazepines may decrease breathlessness. In elderly or debilitated patients, shorter-acting benzodiazepines with no active metabolites, such as alprazolam, lorazepam, and oxazepam, are preferred. Zolpidem does not alter respiratory drive in COPD patients, but rebound insomnia or withdrawal similar to triazolam may result. Diazepam has no effect on breathlessness and may decrease exercise tolerance. Although some have advocated promethazine to decrease breathlessness and increase exercise tolerance in COPD, this drug is a phenothiazine and has the same spectrum of adverse effects as chlorpromazine. Selective serotonin reuptake inhibitors (SSRIs) may also be helpful in treating panic symptoms and do not have pulmonary side effects. If panic does not respond to these measures, then neuroleptics may be effective in low doses. Beta-blockers should not be used for anxiety in asthma patients, because of resulting bronchoconstriction.

## Depression

When choosing an antidepressant, the side-effect profile and cytochrome P450 interactions with pulmonary drugs should be considered. Generally, SSRIs other than fluvoxamine are effective and have few drug interactions that are problematic in pulmonary patients, and SSRIs may decrease dyspnea and even increase arterial oxygen concentration in some patients (Ciraulo and Shader 1990; Smoller et al. 1998).

Many pulmonary patients are elderly with comorbid conditions and may be on other medications that can prob-

long the QT interval, so reviewing the ECG is prudent when considering treatment with a tricyclic antidepressant. In elderly patients or in patients with COPD or sleep apnea, nortriptyline or desipramine is preferred over the more sedating tertiary amines, which may cause delirium or hypotension. Protriptyline may be helpful in sleep apnea by increasing respiratory drive, but the half-life is very long (54–92 hours), three to four times longer than that of nortriptyline, and there is no evidence that protriptyline is more effective than other tricyclics for sleep apnea (DeVane 1998). Doxepin may be a mild bronchodilator because of its anticholinergic qualities (Cooper 1988).

## Psychosis

Pulmonary patients may have primary psychotic disorders, such as bipolar disorder or schizophrenia, or may become psychotic because of medications such as beta-agonists, cycloserine, isoniazid, or corticosteroids. The incidence of steroid psychosis is dose-related, seen in less than 1% of patients taking 40 mg or less of prednisone per day versus 28% taking 80 mg daily (Boston Collaborative Drug Surveillance Program 1972).

Typical neuroleptics such as haloperidol at high doses may cause laryngospasm, akathisia, and paradoxical intercostal muscle movements that, in turn, may cause restlessness and interfere with breathing. Tardive dyskinesia sometimes affects the diaphragm and other muscles used in breathing, and in severe cases, this effect can result in respiratory insufficiency. For chronic treatment, newer drugs with lower incidence of extrapyramidal side effects may be preferred.

## Drug Interactions Between Psychotropic and Pulmonary Drugs

The psychiatrist should consider potential interactions when prescribing psychotropic medications to patients with pulmonary disease (Table 20-2). Theophylline levels

**TABLE 20-2. Drug interactions**

Pulmonary drug	Psychotropic drug	Adverse effect
Isoniazid	TCA's	MAOI effect of isoniazid
Rifampin	Donepezil	Decreased donepezil effect
Rifampin	Diazepam	Induced diazepam metabolism
Rifampin	Valproate	Decreased valproate level
Rifampin	TCA's, MAOIs	Induced TCA, MAOI metabolism
Sympathomimetic drugs <sup>a</sup>	TCA's, MAOIs	Hypertensive crisis
Theophylline	Alprazolam	Decreased benzodiazepine effect
Theophylline	Carbamazepine	Decreased carbamazepine level
Theophylline	Clozapine	Increased theophylline level
Theophylline	Fluvoxamine	Increased theophylline level
Theophylline	Lithium	Reduced lithium level 20%–30%

*Note.* MAOI=monoamine oxidase inhibitor; TCA=tricyclic antidepressant.

<sup>a</sup>Epinephrine, ephedrine, pseudoephedrine.

*Source.* Adapted from Cozza KL, Armstrong SC, Oesterheld JR: *Drug Interaction Principles Pocket Guide*. Washington, DC, American Psychiatric Publishing, 2003.

may be reduced from 50%–80% by tobacco smoking. Nicotine gum does not have this effect. Alcohol can reduce clearance of theophylline as much as 30% for up to 24 hours. Most pulmonary medications do not affect lithium levels, except theophylline, which can lower lithium levels by 20%–30%. Patients with chronic pulmonary disease may develop right-sided heart failure, and they may receive diuretics that raise or lower lithium levels depending on choice of diuretic. Theophylline preparations administered concurrently with electroconvulsive therapy can prolong seizure duration, especially if the theophylline level is above the accepted therapeutic range, even if the level is below that typically associated with seizures (Peters et al. 1984).

Rifampin is a cytochrome P450 3A4 substrate and so may compete with many psychotropic drugs, including the antidepressants amitriptyline, imipramine, fluoxetine, sertraline, bupropion, venlafaxine, and trazodone. Rifampin may compete through the same site with anticonvulsants (e.g., carbamazepine, tiagabine, and valproate) and with benzodiazepines, zolpidem, and haloperidol. Montelukast sodium may have similar interactions to those of rifampin, because of metabolism via 3A4 and 2C9.

## Gastrointestinal Disorders

---

Francis Creed, M.D., F.R.C.P.C., F.R.C.Psych., F.Med.Sci.

Kevin W. Olden, M.D.

**THE CLOSE RELATIONSHIP** between the gut and the psyche means that there are many examples of biopsychosocial relationships in the patient population seen by gastroenterologists. The consulting psychiatrist can expect to see a large number of patients with functional gastroenterological disorders, such as functional dyspepsia and irritable bowel syndrome. Functional disorders like these compose approximately half of all patients seen by gastroenterologists (Thompson et al. 2000). Life stressors and mood disorders are thought to play a large part in the symptoms, presentation, and course of the disorders. Psychiatrists in medical settings can also expect to see patients with organic diseases, such as liver disease and inflammatory bowel disease, where the relationship with stress is less clear but where psychiatric disorders can influence management and outcome. Some patients are seen routinely by psychiatrists prior to liver transplant (see Chapter 31, “Organ Transplantation”) or before commencing interferon treatment for chronic hepatitis C.

### Functional Gastrointestinal Disorders

---

The broad categorization of disorders into *functional* and *organic* (or *structural*) has some advantages and many disadvantages. The distinction has helped to facilitate research into the psychological factors that are important in the etiology, presentation, and outcome of the so-called functional disorders. This research has been multidisciplinary, with gastroenterologists, physiologists, psychiatrists, and psychologists working to understand underlying mechanisms. This has led to a useful adaptation of the biopsychosocial model in gastroenterology (Drossman 1998; Drossman et al. 1999).

The most prominent disadvantage of the functional and organic terminology is the reinforcement of dualistic thinking—the separation of mind and body. Thus, peptic ulcer was previously regarded as a psychosomatic condition until the importance of *Helicobacter pylori* was discovered and then interest in the psychological aspects of peptic ulcers waned (Levenstein 2000). Another problem is that some gastroenterologists falsely equate *functional* with *psychiatric*, which leads them to ignore psychiatric disorders in patients with organic disease.

For convenience, the term *functional gastrointestinal disorder* will be used in this chapter. However, a multifactorial view of illness should be maintained. Therefore, readers should bear in mind the frequent comorbidity of psychiatric disorders with all gastrointestinal (GI) disorders.

In clinical practice, the identification and treatment of psychiatric disorders in patients with GI disorders can be very rewarding. Many patients with functional GI disorders may experience considerable improvement in their symptoms when a concurrent psychiatric disorder is successfully identified and treated. In structural (organic) disorders, the GI symptoms may not change as dramatically when coexisting depression or anxiety is treated, but patients may experience substantial improvement in their health-related quality of life—that is, they can cope with their symptoms, treatment, and lifestyle changes much more successfully.

### Epidemiology of Psychiatric Disorders and Their Relationship With Gastrointestinal Diseases

---

Our understanding of the relationship between psychiatric and GI disorders has developed considerably over the

last 2 decades, as more refined clinical studies have used better diagnostic systems. The development of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM; American Psychiatric Association 1980, 1994, 2000) has been mirrored by a similar symptom-based classification of the functional GI disorders, the so-called Rome criteria. (Drossman et al. 2000a). Such a classification has caused much discussion among gastroenterologists, who are used to making diagnoses on the basis of observable structural abnormalities. This has implications for clinical practice because some gastroenterologists may give the impression to patients that complaints based on structural abnormalities of the gut are “real,” whereas complaints without any abnormalities seen on endoscopy or imaging studies may be dismissed as they turn out to be “only” functional. When this occurs, the psychiatrist must first deal with patients feeling angry or devalued before a full clinical appraisal of symptoms is commenced (Creed and Guthrie 1993; Guthrie and Creed 1996).

Recent epidemiological research in gastroenterology has included population-based samples. This is important because it may challenge ideas developed in the clinical setting. For example, *H. pylori* and nonsteroidal anti-inflammatory drug (NSAID) usage have been considered to be the underlying agents responsible for most cases of peptic ulcer. Certainly, eradication of *H. pylori* or NSAID discontinuation usually leads to ulcer healing, but population-based studies have shown that many people carry *H. pylori* without any evidence of peptic ulcer. Host factors are also important in the etiology of peptic ulcer (Levenstein 1999). We need to understand the nature of these host factors if patients with refractory ulcers, as well as ulcers with no obvious cause, are to be helped. Population-based studies have clarified the relationship between GI and psychiatric disorders; in particular, it is recognized that psychological variables are important determinants of treatment seeking.

The prevalence of psychiatric disorders in patients attending gastroenterology clinics has been studied repeatedly with reasonably consistent results. Approximately half of patients with functional disorders and 15%–30% of patients with structural gut disorders have mood, anxiety, or related disorders. The proportions are particularly high in certain groups, such as people with chronic hepatitis C virus (HCV) infection.

## Peptic Ulcer

It has been estimated that approximately 10% of individuals in Western countries will develop a peptic ulcer sometime during their lifetime (Rosenstock and Jorgensen 1995). The two major risk factors associated with

the development of both gastric and duodenal ulcers are the use of NSAIDs and the presence of infection with *H. pylori* (Kurata et al. 1997). Interestingly, since the late 1960s the overall incidence of peptic ulcer disease has begun to decline. This trend is believed to be a result of declining rates of infection with *H. pylori* (Parsonnet 1995). Although gastric ulcers and ulcers of the duodenum were seen as two different disorders in the past, more recently they are being conceptualized as part of the same disease spectrum attributed almost exclusively to NSAID use and/or infection with *H. pylori*. However, despite the revolution in our understanding of peptic ulcer, significant psychosocial dimensions remain to be considered with this disorder.

### *Prevalence of Psychiatric Disorders*

The number of sound studies concerning the prevalence of psychiatric disorders in peptic ulcer disease is relatively limited (see Table 21–1). A comprehensive review of the relevant literature in 1995 concluded that there was insufficient evidence to be certain that the prevalence of anxiety and mood disorders was greater in clinical populations of people with duodenal ulcers compared with the general population (Lewin and Lewis 1995). This lack of evidence reflects the methodological problems of most studies, which have used small, clinic-based samples in cross-sectional design. One of the most comprehensive studies included patients with peptic ulcer and inflammatory bowel diseases of recent onset (Craig 1989); 16% of patients had definite psychiatric disorders, and a further 32% had borderline (“subthreshold”) psychiatric disorders. These data illustrate an important point for psychosomatic medicine: subthreshold disorders may impair health-related quality of life and lead to a worse prognosis, so psychiatric or psychological treatments should not be confined to people who meet the DSM criteria for a psychiatric disorder. Many other studies have found somewhat higher prevalence figures for psychiatric disorders in peptic ulcer patients; this probably reflects the selection of people with chronic or relapsing disease seen in specialty clinics (Lewin and Lewis 1995; Tennant et al. 1986). There have been relatively few studies in recent years on this topic because the research literature has been focused heavily on *H. pylori* as well as NSAID use as the major causes of peptic ulcer disease.

One large-scale population-based study found a specific association between self-reported peptic ulcer disease and generalized anxiety disorder (but not with any other psychiatric disorder) (Goodwin and Stein 2002). Another has shown a specific association with neuroticism (Goodwin and Stein 2003), which held even after adjustment for cigarette smoking. Such studies concur with the

**TABLE 21-1. Prevalence of psychiatric disorder in peptic ulcer disease**

Study	Psychiatric disorder measure	Peptic ulcer disease, no.	Control subjects, no.	Statistical significance
Langeluddecke et al. 1987	STAI, ZDS	63	50 (medically ill patients)	No significant difference from MI patients
Langeluddecke et al. 1987	STAI, ZDS	83	59 (dyspepsia patients)	Less anxious than dyspepsia patients
Tennant et al. 1986	STAI, ZDS	87	Population normative data	Higher anxiety and depression scores than norms
Craig 1989	PSE	— <sup>a</sup>	— <sup>b</sup>	Prevalence of psychiatric disorder was less than in patients with functional GI disorder and more than in healthy control subjects
Magni et al. 1982	KSSRT	25 (duodenal ulcer) 36 (acute gastroduodenitis)	61 (matched control subjects)	Both groups more anxious than control subjects Only acute gastroduodenitis group had higher depression and somatization scores

Note. GI=gastrointestinal; KSSRT=Kellner-Sheffield Symptom Rating Test; MI=myocardial infarction; PSE=Present State Examination; STAI=State-Trait Anxiety Inventory; ZDS=Zung Depression Scale.

<sup>a</sup>16% had psychiatric disorders.

<sup>b</sup>34% of patients with functional GI disorder and 8% of control subjects had psychiatric disorders.

research and clinical observations that anxiety or depression appears to be associated with persistence of peptic ulcer (Levenstein et al. 1996).

The relationship between stress and peptic ulcer disease has been a topic of interest for many years. Early studies focused on personality profile as a predisposing factor for development of peptic ulcer, but there is no convincing evidence of a causal link between a particular personality type and duodenal ulcer (Lewin and Lewis 1995). In a classic study, Weiner et al. (1957) successfully predicted which men in a large cohort of U.S. Army draftees would have duodenal ulcers by combining psychological criteria with the biological criterion of high baseline pepsinogen secretion. Subsequent studies have found convincing evidence that the onset, perpetuation, and recurrence of peptic ulcers are associated with stressful life events. This has been demonstrated after earthquakes, where stress and the presence of *H. pylori* interacted (Matsushima et al. 1999). Other studies have demonstrated that with more chronic stressors that involve goal frustration—that is, in which the individual is repeatedly prevented from reaching a much sought-after goal—peptic ulcer disease was more persistent (Craig 1989; Ellard et al. 1990). The latter may reflect a personality type, associated with continuing at a task or toward a goal even when the odds are against success.

Some studies have focused on a group of patients who show the personality traits of social withdrawal, suspi-

ciousness, hostility, and dependency (Jess et al. 1989; Levenstein et al. 1992). Their ulcers appear to develop when stress leads to increased cigarette and alcohol consumption (Levenstein 2000). In clinical practice, it is worth assessing these personality attributes in persons who have recurrent or persistent ulcers, in whom discussion about possible preventive measures is important (Levenstein et al. 1996).

More recent studies have examined possible host factors that might interact with NSAID use and *H. pylori* to provide a more complete explanation of the relationship between *H. pylori* and ulcer development (Levenstein 2000). In addition to *H. pylori*, NSAIDs, smoking, and psychological stress (indirectly measured by anxiolytic use) appear to be independent risk factors for ulcer development (Anda et al. 1992; Levenstein et al. 1997; Rosenstock et al. 2003). Psychosomatic medicine specialists should be prepared to discuss these findings with patients as part of a strategy to prevent recurrent ulcers. Some patients understand the association between *H. pylori* and peptic ulcer as a one-to-one relationship, excluding the possibility that outcome might be influenced by their own behavior.

### *Health-Related Quality of Life*

Health-related quality of life is impaired in people with gastric or duodenal ulcers, which are exacerbated by anxiety or depression (Dimenas et al. 1995). Depression also

adversely affects the outcome of standard treatment for peptic ulcer (Xuan et al. 1999).

## Inflammatory Bowel Disease

Idiopathic inflammatory bowel disease (IBD) represents a spectrum of illnesses from ulcerative colitis and Crohn's disease to the less common but emerging disorders of microscopic colitis, collagenous colitis, and lymphocytic colitis. The latter three disorders tend to produce more subtle inflammation of the bowel, which usually can only be visualized on histological examination of colonic mucosa. Ulcerative colitis is a systemic disorder that can produce inflammation in the skin (pyoderma gangrenosum and erythema nodosum), eyes (conjunctivitis and uveitis), and joints (arthritis). In the bowel, ulcerative colitis involves only the colon. In the colon, its inflammatory effect tends to involve only the mucosa and is not transmural (i.e., not extending through all layers of the bowel). Crohn's disease, however, can involve any portion of the gut from the oropharynx to the perirectal area, and it tends to be transmural. Crohn's disease can frequently produce fistulae, fissures, and strictures of the bowel. It is difficult to judge the prevalence of IBD because many subtle cases go undiagnosed. Likewise, many episodes of diarrhea diagnosed as infectious colitis often actually represent minor flare-ups of IBD. Taking into account these limitations, the incidence of Crohn's disease in the United States is 3.6–8.8 per 100,000 (Mendeloff and Calkins 1995), and the incidence of ulcerative colitis is 3–15 cases per 100,000. The incidence of Crohn's disease has increased sixfold in the past 50 years (Nunes and Ahlquist 1983), whereas the incidence of ulcerative colitis has remained reasonably stable.

### *Prevalence of Psychiatric Disorders*

Patients with IBD show a higher prevalence of psychological disorder than the general population, but a lower prevalence of psychological disorder than patients with functional bowel disorder (Walker et al. 1995). The rate, mostly in the range of 21% to 35%, is similar to that found in other chronic physical illnesses (Creed et al. 2002). Mood disorder appears to be more common in older patients and in those with a previous history of psychiatric disorder (Acosta-Ramirez et al. 2001).

### *Stress, Psychiatric Disorder, and Gastrointestinal Function*

The relationship between psychiatric disorder and IBD is unclear (Table 21–2). Some investigators have suggested that certain patients with IBD may be particularly vulner-

able to developing psychiatric disorder because of experiences which are independent of the disease process (e.g., childhood victimization and abuse) (Walker et al. 1996). One study showed that relapses occur at times of stress (Duffy et al. 1991), but most other studies have failed to find an association with stress (North et al. 1991). Many authors report psychiatric disorder only in close relationship with increased disease activity, suggesting that the former is a consequence of an IBD flare (North et al. 1991); however, one study suggests that relapse is predicted by depression (Mittermaier et al. 2004).

Evidence from a population-based sample indicates an excess of anxiety and depression both immediately before and shortly after onset—findings that support both the etiological and psychological reaction theories relating psychological state to inflammatory bowel disease (Kurina et al. 2001). A recent cross-sectional study suggests that high levels of psychological distress are associated with recently diagnosed active disease, recent stressful life events, and, in those with many stressors, low social support (Sewitch et al. 2001).

Some patients with IBD may avidly attribute their symptoms to stress. This can be maladaptive if patients conclude the disease is somehow their (or someone else's) fault or if patients use it to rationalize avoidance of chronic drug therapy. It should be pointed out that general stress reduction measures may be helpful, but they are not an alternative to close adherence to the prescribed medications (Maunder and Esplen 2001; Maunder et al. 1997).

### *Health-Related Quality of Life*

There is clear evidence that anxiety and depression impair health-related quality of life in IBD (Guthrie et al. 2002; Nordin et al. 2002; Turnbull and Vallis 1995; Walker et al. 1996). This pattern is demonstrated in Figure 21–1, which shows the effect of anxiety and depressive disorders, including subthreshold disorders, on the four *physical* components of health-related quality of life. It can be seen that even after adjustment for severity of IBD, patients with possible anxiety or depressive disorders have significantly worse physical function, role limitation (physical), health perception, and pain than patients with very few or no psychiatric symptoms. Although some studies have reported a worse health-related quality of life in patients with Crohn's disease as compared with those with ulcerative colitis, this difference disappears after adjustment for gender and severity of IBD (Andrews et al. 1987; de Boer et al. 1998; Guthrie et al. 2002; Walker et al. 1995).

When IBD relapses, both physical and emotional symptoms are prominent. In remission, the former may

**TABLE 21-2. Prevalence of psychiatric disorder in patients with inflammatory bowel disease**

Study	Psychiatric disorder measure	Ulcerative colitis and Crohn's disease patients		Comment
		Total no.	% with psychiatric disorder	
Helzer et al. 1982	Standardized psychiatric interview/Feighner criteria	50	26	Prevalence similar to that in other medically ill patients (30%)
Andrews et al. 1987	DSM-III	162	33	No difference between Crohn's disease and ulcerative colitis groups
Tarter et al. 1987	DIS/DSM-III	53	26 (anxiety) 15 (panic) 10 (depression)	Greater prevalence than in control subjects
Magni et al. 1991		50	22 (lifetime) 62 (current)	More than in control subjects
Walker et al. 1996	DIS	40	35	No difference between IBD groups
De Boer et al. 1998	CES-D	224	32	No difference between IBD groups
Guthrie et al. 2002	HADS	112	26	No difference between IBD groups
Rose et al. 2002	CES-D	66	21	No control group

*Note.* CES-D=Center for Epidemiologic Studies Depression Scale; DIS=Diagnostic Interview Schedule; HADS=Hospital Anxiety and Depression Scale; IBD=inflammatory bowel disease.

remit, but impairment due to emotional distress may remain and require attention (Casellas et al. 2001). Failure to attend to this distress may leave the patient anxious and depressed and possibly at a higher risk of relapse (Andrews et al. 1987; Kurina et al. 2001). There is preliminary evidence that health-related quality of life improves if psychiatric morbidity is treated (Walker et al. 1996), and this should be the main aim of psychiatric treatment in people with concurrent psychiatric disorders and IBD.

The presence of psychiatric disorder in patients with IBD is also associated with many GI symptoms that are typical of irritable bowel syndrome—abdominal pain that is relieved by defecation; bloating; and altered bowel habits. People with IBD who also have these comorbid irritable bowel syndrome symptoms have the greatest impairment of health-related quality of life of all patients with IBD (Simren et al. 2002). Clinicians should therefore ask about irritable bowel syndrome-type symptoms even in patients with IBD and anticipate that these symptoms may improve with psychiatric treatment.

### ***Relationship Between Health Care Utilization and Psychological and Disease-Related Variables***

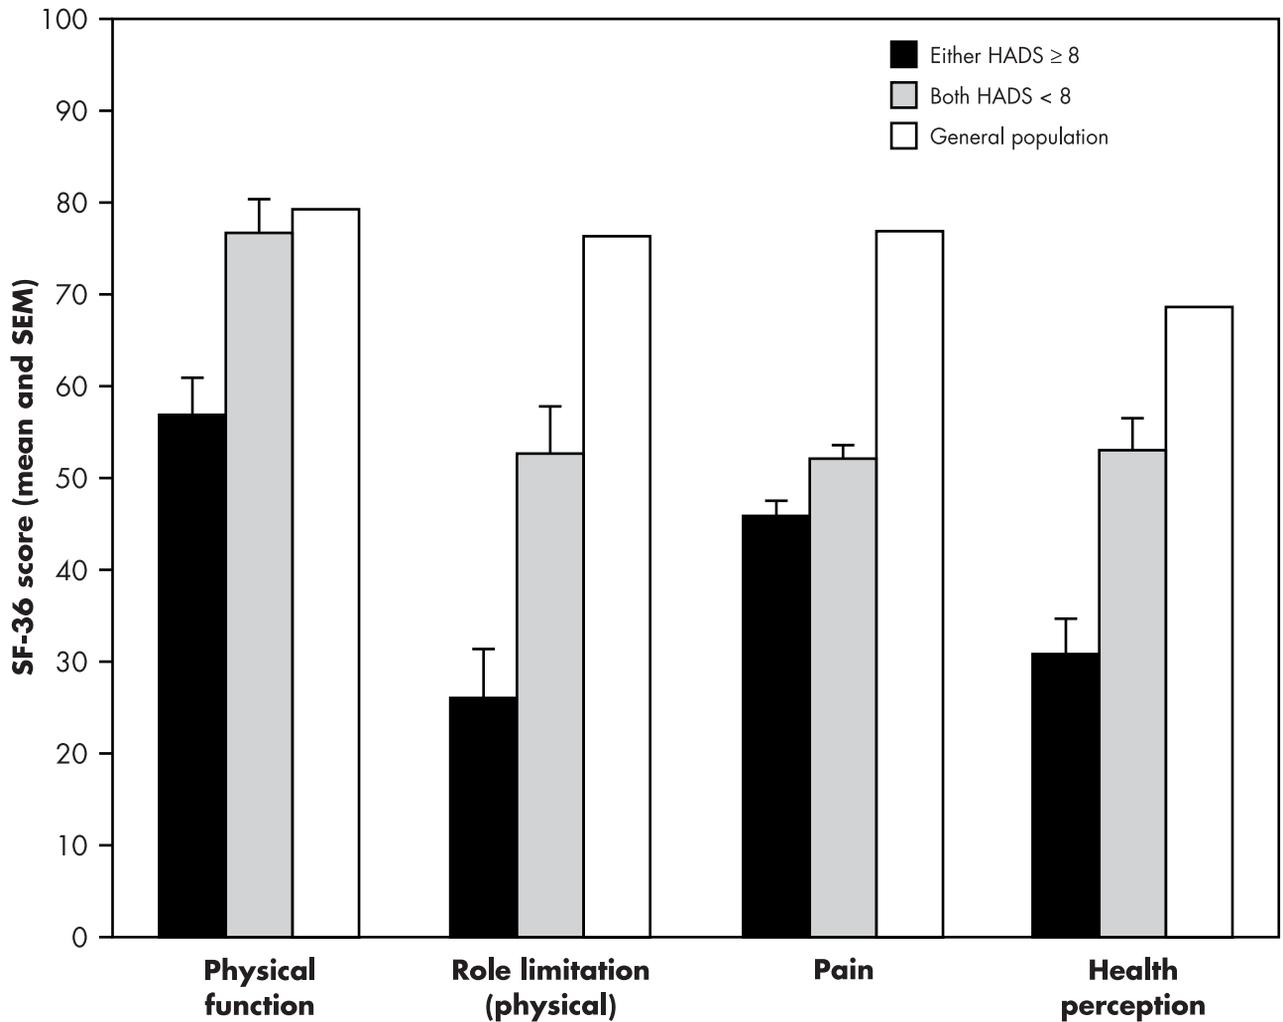

Although the severity of IBD is the main predictor of health service use, especially hospitalization, a number of psychological and social variables are also important independent predictors. These include depression (de Boer et al. 1998; Guthrie et al. 2002), emotional and social functioning, and patients' concerns (Drossman et al. 1989,

1991). Because many patients with IBD are young and striving to lead a normal life, any intervention that reduces the time spent visiting doctors is beneficial—another reason for energetically treating any concurrent psychiatric disorder.

### **Functional Gastrointestinal Disorders: Irritable Bowel Syndrome and Functional Dyspepsia**

Functional GI disorders represent a spectrum of disorders of function, which encompasses the functional esophageal disorders, such as noncardiac chest pain and functional dysphagia; functional dyspepsia (previously called nonulcer dyspepsia); irritable bowel syndrome; as well as functional constipation, functional diarrhea, and functional abdominal pain. The sine qua non of a functional GI disorder is the lack of structural or biochemical abnormalities that could explain the patient's symptoms, which requires that the diagnosis of functional GI disorders be symptom based.

In an attempt to improve the nomenclature, international working teams have been formed to address the issue of diagnostic criteria for the functional GI disorders. Based in Rome, these so-called Rome committees function in a manner similar to the DSM committees of the American Psychiatric Association. Diagnostic criteria for the various functional GI disorders have been created (Thompson et al. 2000).

**FIGURE 21-1.** SF-36 Health Survey physical subscale scores for patients with possible psychiatric disorder (HADS  $\geq 8$ ) versus patients without psychiatric disorder (HADS  $< 8$ ).

*Note.* Mean subscale scores for the general population are included for reference. HADS=Hospital Anxiety and Depression Scale.  
*Source.* Guthrie et al. 2002.

The most common functional GI disorder is irritable bowel syndrome (IBS), which comes in three general clinical forms: with constipation, with diarrhea, and with an alternating pattern of diarrhea and constipation. The diagnostic criteria for IBS are outlined in Table 21-3. The creation of standardized diagnostic criteria for the functional bowel disorders has led to significant improvements in research and clinical practice. Many patients with vague, unexplainable GI complaints were previously diagnosed as having IBS, when many of them in fact had other functional GI disorders. The various functional GI disorders have different natural histories, psychosocial correlates, and prognoses. Advances in nomenclature have greatly improved our ability to understand and study these disorders, which have significant psychosocial dimensions (Budavari and Olden 2003).

### *Prevalence of Psychiatric Disorders*

The prevalence of anxiety and mood disorders, particularly panic disorder, in patients attending gastroenterology clinics with functional bowel disorders (50%–60%) is approximately twice that of IBD (Drossman et al. 2000a, 2002). There appears to be little difference across diagnostic groups such as patients with IBS, functional dyspepsia, functional abdominal pain, and noncardiac chest pain (Biggs 2004; Dimenas et al. 1995). Anxiety is more prominent in first-time attenders, but depression seems more prominent in those who have chronic symptoms and who have been attending the clinic over a long period without remission (Guthrie et al. 1992). Panic disorder is frequent in some specialist settings (Lydiard et al. 1993). High levels of psychological distress are found in people who have numerous bodily symptoms outside of the GI

**TABLE 21-3. Rome II criteria for irritable bowel syndrome**

At least 12 weeks or more, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that has two out of the following three features:

- Relieved with defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool

Symptoms that cumulatively support the diagnosis of irritable bowel syndrome:

- Abnormal stool frequency (for research purposes, “abnormal” may be defined as more than three bowel movements per day and less than three bowel movements per week)
- Abnormal stool form (lumpy/hard or loose/watery stool)
- Abnormal stool passage (straining, urgency, or feeling of incomplete evacuation)
- Passage of mucus
- Bloating or feeling of abdominal distension

tract (so-called extraintestinal symptoms), including fibromyalgia (Sperber et al. 2000; Whitehead et al. 2002).

The onset of anxiety or mood disorder precedes or coincides with the onset of the bowel disorder in approximately two-thirds of IBS patients (Craig 1989; Ford et al. 1987). This suggests a close link between the psychiatric disorder and gut symptoms. The presence of (untreated) psychiatric disorder predicts a poor outcome, and conversely, reduction of psychiatric symptoms is associated with reduction of bowel symptoms (Creed 1999).

### ***Stress, Psychiatric Disorder, and Gastrointestinal Function***

A number of studies have shown that stress precedes the onset of functional bowel disorders, whether there is concurrent psychiatric disorder or not (Creed et al. 1988; Drossman 1998). The most common stresses relate to difficult personal relationships—marital separations, divorce, and other relationship breakups. Many patients tend to deny the importance of such events and claim that any psychological or social difficulties are the result of the bowel disorder rather than stress. Careful history taking with sufficient attention paid to time course of events will usually demonstrate the correct sequence.

Social stress is also the single most important predictor of outcome in patients with IBS who attend a gastroenterology clinic (Bennett et al. 1998). Failure to address the stressor(s) may therefore lead to persistent symptoms. Some patients are reluctant to discuss social stress, protesting that it is unrelated to the bowel disorder (Creed and Guthrie 1993). For most patients, however, a clear

explanation of the purpose of doing so leads to a fruitful discussion. For example, a series of patients with dyspepsia were asked to list their main complaints, and about two-thirds spontaneously mentioned “anxiety” before “dyspepsia”; therefore, an open question may enable the psychiatrist to rapidly elicit a person’s concerns (Haug et al. 1995).

### ***Health-Related Quality of Life***

Anxiety and mood disorders play a large part in the impairment of health-related quality of life observed in IBS (Creed et al. 2001; Walker et al. 1995; Whitehead et al. 1996). As in other medical conditions, the effects of physical and psychological symptoms are approximately additive in terms of their effect on quality of life (Creed et al. 2001, 2002; Wells et al. 1989). In dyspepsia, psychological distress is a better predictor of health-related quality of life than severity of the dyspepsia (Quartero et al. 1999), and the considerable impairment of health-related quality of life attributed to IBS may be the result of concurrent psychiatric disorders (Creed et al. 2001; Drossman et al. 2000b, 2000c; Talley et al. 1995a). In other words, there is a good prospect of improvement of health-related quality of life when the anxiety or mood disorder is satisfactorily treated, as has been demonstrated with both antidepressants and psychotherapy (Creed et al. 2003; Drossman et al. 2003; Guthrie et al. 1991; Hamilton et al. 2000). In severe functional GI disorders, a proportion of people are unemployed because of ill health; the disorder is closely associated with psychiatric status and may respond to appropriate psychological treatment (Creed et al. 2001, 2003).

### ***Relationship Between Health Care Utilization and Psychological and Disease-Related Variables***

Many people with functional dyspepsia or IBS do not consult a doctor (Drossman et al. 1988). Those who do so have more severe abdominal pain than nonconsulters, but they also have more anxiety and depression and, in particular, more worries about their health—especially fears of cancer (Creed 1999; Gomborone et al. 1995; Kettell et al. 1992; Koloski et al. 2003; Lydiard and Jones 1989). Adequately addressing these worries in the gastroenterology clinic may lead to fewer subsequent visits (van Dulmen et al. 1995). Psychiatrists should routinely ask about such fears and be prepared to deal with them directly, because they often persist even after diagnostic investigations have been normal. Some gastroenterologists seem puzzled when a patient has not been reassured adequately by the normal investigations; often insufficient time and effort has been spent explaining the significance of negative

results to patients and, when appropriate, to their partner or family members.

There are two reports of greatly increased health anxiety immediately prior to upper endoscopy (Lucock et al. 1997; Quadri and Vakil 2003). There is some reduction of health anxiety after endoscopy, which lasts for a year in the majority of patients. In one-third of people, after upper endoscopy, however, worries about serious illness have returned to their preendoscopy level 1 year later (Lucock et al. 1997). The sources of health anxiety in such people are not fully understood, but lack of social support and early life experience, including illness in the family, abuse, or neglect, both may play a part (Biggs et al. 2003; Whitehead et al. 1982). It is crucial for the psychiatrist to fully explore concerns about serious illness with the patient; such concerns are often related to illness in family members or remarks made to the individual by a physician that play on the patient's mind.

### ***Sexual Abuse and Functional Gastrointestinal Disorders***

There is an established literature that demonstrates an association between IBS and a history of childhood sexual abuse (Delvaux et al. 1997; Drossman et al. 1990, 1995; Leserman et al. 1996, 1998; Walker et al. 1995). However, these findings have not been replicated consistently in studies of consecutive clinic attenders, rather than selected clinic series (Biggs 2004; Talley et al. 1995a), or in population-based studies (Talley et al. 1998). It appears that a history of sexual abuse might be a predictor of chronicity and severity of a disorder (Longstreth et al. 1993) and may not be specific to IBS (Katon et al. 2001). A history of sexual abuse does appear to be more prevalent in people with chronic IBS than in those with IBD and is associated with adverse effects on adult sexual functioning and other aspects of health-related quality of life (Guthrie et al. 1987; Walker et al. 1995).

Reported childhood sexual abuse or related trauma is associated with increased health care utilization in functional bowel disorders (Biggs et al. 2003; Guthrie and Creed 2003; Leserman et al. 1998). The likely mechanisms appear to be general rather than specific to the pelvic or anal region, as has been suggested by some authors. Self-reported abuse is associated with complaints in adulthood of a greater number of bodily symptoms; this may be associated with a lower pain threshold and a tendency to be hypervigilant toward bodily symptoms (Salmon et al. 2003). Perhaps the mechanism most commonly involves mood, panic, and other anxiety disorders, which occur in those subjected to abuse during childhood (Blanchard et al. 2002). As we have seen, these psychiatric disorders are more common in functional bowel disorders than

organic GI diseases, and they are independently associated with higher health care utilization in IBS (Budaevri and Olden 2003).

In clinical practice, it is important for psychiatrists to assess possible childhood abuse as a routine in patients with functional GI disorders, especially those who have not responded to treatment. Whatever the type of disorder, patients will usually not have had the opportunity to speak to their gastroenterologist about such intimate aspects of their life (Drossman et al. 1990).

### ***Other Functional Gastrointestinal Disorders***

There is a wide array of other functional GI disorders other than IBS and functional dyspepsia—for example, gastroesophageal reflux, globus, functional abdominal pain, and cyclic vomiting. The characteristics of these disorders are described in the Rome book (Drossman et al. 2000a). They often coexist with other functional GI disorders, and their features are very similar to the two disorders described here; anxiety and depression are common. These functional GI disorders have been less well researched than IBS, and the abnormalities of GI physiology are not sufficiently consistent to be reliable. Clinical assessment and treatment follows the general pattern described in this chapter, with the exception that speech therapy may be helpful for globus (Khalil et al. 2003).

### **Liver Disease**

A variety of liver diseases are important in psychosomatic medicine. We focus here primarily on HCV infection. Viral hepatitis is also discussed in Chapter 27, "Infectious Diseases." In the developed nations, alcohol is the most common cause of liver disease (see Chapter 18, "Substance-Related Disorders"), and alcohol is a frequent aggravating factor in other causes of liver disease. Most forms of chronic liver disease can result in cirrhosis, leading to hepatic encephalopathy, which may manifest with symptoms of psychosis, mania, depression, apathy, or confusion before becoming a frank delirium (Dieperink et al. 2000) (see Chapter 6, "Delirium," and Chapter 31, "Organ Transplantation"). Wilson's disease (see Chapter 32, "Neurology and Neurosurgery") and the porphyrias (see Chapter 23, "Endocrine and Metabolic Disorders") are rare diseases affecting the liver whose first symptoms may be psychiatric. Fatigue is a common symptom in liver disease in general and may be caused by the disease, its treatment, or a comorbid depression. In one study of patients with primary biliary cirrhosis, fatigue was more closely associated with depression than with liver disease (Cauch-Dudek et al. 1998). Depression is also common in people undergoing liver transplantation, and there is some evi-

dence that the depression may improve following transplantation (see Chapter 31, "Organ Transplantation").

Chronic liver disease leads to significantly impaired health-related quality of life, and there is some evidence that successful treatment, either by transplant or by antiviral treatment, leads to improvement (De Bona et al. 2000; Dieperink et al. 2000). The severity of the hepatic disease is not necessarily the most important predictor of impaired health-related quality of life; one study suggests that comorbid conditions, including depression, are the major determinants of health-related quality of life (Fontana et al. 2001). Thus, treatment of depression in patients with chronic liver disease is important for three reasons: in its own right, to improve health-related quality of life, and to facilitate treatment of liver disease.

### *Chronic Hepatitis C Virus Infection*

Chronic HCV (previously known as non-A, non-B hepatitis) has become epidemic; it has become the major cause of chronic liver disease in the United States, with a prevalence of 1.8% of the population. It is estimated that 4 million Americans are infected with HCV (Alter 1997).

HCV infection is not infrequently acquired through intravenous drug abuse, which is also a strong risk factor for other psychiatric disorders (Dwight et al. 2000). In a recent case-control study, individuals with HCV infection were found to be significantly more likely to have major depressive, posttraumatic stress disorder (PTSD), and anxiety disorders as well as alcohol- and drug-use disorders (El-Serag et al. 2002). This strong propensity for psychiatric comorbidity in individuals infected with HCV is bidirectional. First, the HCV-infected population (exclusive of individuals who acquired the infection through blood transfusions) represent a population that clearly is at higher risk for psychiatric disorders. Similarly, individuals infected with HCV are more likely to be depressed than are people with other forms of end-stage liver disease, such as hepatitis B or alcohol-induced cirrhosis. In addition, depressive disorder is seen more frequently in individuals undergoing liver transplantation who are infected with HCV as compared with those who do not carry the virus (Singh et al. 1997). Some studies of war veterans with HCV have recorded a very high prevalence of alcohol and drug abuse (80%) combined with current depression and PTSD, which occurred in 60% of the sample (Nguyen et al. 2002).

In contrast to HCV, hepatitis B virus (HBV) is acquired mainly through sexual contact and through maternal-fetal transmission. It is not commonly transmitted via intravenous drug use, and it is much less likely to induce depression or other psychiatric symptoms as compared

with HCV. This makes it less of an issue for the consultation psychiatrist. Moreover, with the advent of HBV vaccination, the overall prevalence of this disease in Western society is dropping quite significantly.

A major concern now lies in the increased chance of developing significant depression with interferon (antiviral) treatment of hepatitis C. Interferon treatment has significant side effects, including almost universal fatigue, common neurological and cognitive symptoms, and depression (fulfilling the criteria for major depression in approximately one-third of people) (Bonaccorso et al. 2002; Finkleman 2003; Horikawa et al. 2003; Kraus et al. 2003). Suicidal ideation occurs frequently and often has led to cessation of treatment. In a prospective trial, individuals who received interferon were significantly more likely to develop depression and elevated levels of anger and hostility during interferon-alfa therapy compared with a control group, which did not receive the therapy (Kraus et al. 2003). Pretreatment levels of major depressive disorder (15.5%) and anxiety disorder (13.1%) rose in the interferon group to 35% and 26%, respectively. Overall, 58% of the individuals receiving interferon had a diagnosable psychiatric illness after initiation of therapy (Kraus et al. 2003). These findings have been replicated by others (Ho et al. 2001). Although high levels of depression have been reported in patients with HCV infection who had not received interferon treatment (Hilsabeck et al. 2002), well-documented increases in depression level were noted several weeks after initiation of the interferon (Finkelman 2003; Kraus et al. 2003).

In patients with chronic HCV infection, the severity of depressive symptoms is highly correlated with fatigue severity. By contrast, measures of hepatic disease severity, interferon dosage, and the severity of comorbid medical illnesses are not correlated with the patient's overall level of fatigue and functional disability (Dwight et al. 2000). The importance of recognizing psychiatric illness in the HCV-infected patient here is clear. Patients' symptoms of listlessness, anhedonia, fatigue, and physical pain may be mistaken as manifestations of their liver disease; however, it is much more likely that these symptoms are the result of a comorbid psychiatric disorder, most likely major depressive disorder (Porcelli et al. 1996; Wessely and Pariente 2002). The ability to modulate these symptoms has implications not only for improving the patient's overall well-being but also for helping the physician to correctly interpret the patient's clinical condition.

Antidepressants, most often selective serotonin reuptake inhibitors (SSRIs), are useful in the treatment of depressive disorder during interferon-alfa treatment. Paroxetine (Kraus et al. 2001, 2002), sertraline (Schramm et al. 2000), and citalopram (Gleason 2002) have all been ef-

fective in clinical trials for the treatment of interferon-induced depression in patients infected with HCV. Psychopharmacology in patients with liver disease is discussed in depth in Chapter 37, “Psychopharmacology.”

## Diagnostic Issues

---

The diagnosis of psychiatric disorders in gastroenterology patients does not usually present great difficulties. Some GI symptoms, such as pain, anorexia, or constipation, may be ambiguous (i.e., resulting from either psychiatric or GI disorders), but there are usually a host of other somatic and psychological symptoms that enable the psychiatrist to diagnose anxiety or depressive disorders. Somatization and somatoform pain disorders may be more difficult to distinguish from GI disorders, because both present with physical symptoms; but the diagnosis will usually become apparent after a careful history and physical and psychiatric examinations.

In practice, the more common problem lies in persuading gastroenterologists and primary care doctors to recognize anxiety or depressive disorders early in their management of GI diseases. If this does not occur, the search for possible organic causes of symptoms such as abdominal pain and diarrhea can become very extensive, leading the patient to become increasingly concerned that the illness must be serious as well as elusive. The doctor's attention can be drawn to the possibility of a psychiatric disorder by the use of a simple screening questionnaire such as the Beck Depression Inventory (BDI) (Beck et al. 1961) or the Hospital Anxiety and Depression Scale (HADS) (Drossman et al. 2000a; Zigmond and Snaith 1983).

Rarely, but especially in older people, an undiagnosed depressive illness can lead to marked diarrhea (as a manifestation of accompanying anxiety), abdominal pain, and weight loss. These symptoms may lead to the suspicion of an underlying GI malignancy and numerous investigations. Psychiatrists should be prepared to treat such a person energetically with antidepressants and monitor closely both the depressive and GI symptoms. Of course, it is possible for there to be two disorders—a malignancy and depression—in which case sleep, pain, mood, and hopelessness might improve, but weight and diarrhea might not.

Patients with carcinoma of the pancreas has a reputation for presenting first with depression (Passik and Breitbart 1996) (see Chapter 24, “Oncology”). Gastroenterologists may encounter patients with unsuspected anorexia nervosa with chronic diarrhea, generalized weakness, and hypokalemia from laxative abuse, or chronic vomiting induced by self or ipecac abuse (see Chapter 15, “Eating

Disorders”). Psychiatric symptoms in patients with ostomies are discussed in Chapter 30, “Surgery.”

## Treatment

---

### Clinical Assessment

The clinical psychiatric assessment of patients with GI disorders is similar to that in other medical disorders (see Chapter 1, “Psychiatric Assessment and Consultation”). In this section, we principally emphasize points that are relevant to patients seen by psychiatrists referred from gastroenterologists. Because the majority of relevant points concern functional GI disorders, these will be discussed first.

#### *Accurate Dating of Symptom Onset*

Because many patients may, rightly or wrongly, link their symptoms to stress, it is important to establish several dates: the date of onset and exacerbation of the GI symptoms and the date of onset of depressive or anxiety symptoms. These dates may be compared to the dates of any important life events to establish an accurate time course. Thus, for instance, the psychiatrist may be able to determine the sequence of a stressful life event, for example, discovery of spouse's extramarital affair, followed by the onset of anxiety symptoms, later marital separation, and subsequent simultaneous onset of depressive symptoms, abdominal pain, and diarrhea. This sequence suggests that the bowel symptoms are related to stress. It does *not*, however, prove that the symptoms are caused by a functional, as opposed to an organic, disorder, because symptoms of IBD may also get worse with stress and precipitate anxiety or depression. The time sequence allows the psychiatrist to evaluate any suggestion from the patient that the depression is unrelated or simply a reaction to the bowel disturbance. It also allows a full exploration of the patient's feelings about the life events.

#### *Systems Review*

It is also important to perform a thorough review of symptoms in other bodily systems, because many extraintestinal symptoms may accompany psychiatric disorders concurrent with a functional GI disorder. The patient may or may not have been asked about these symptoms as part of the gastroenterologist's assessment. By eliciting all of the patient's symptoms, the psychiatrist makes the patient *feel understood*, which is the first stage of management of patients with medically unexplained symptoms (Morriss et al. 1999). A thorough review of all systems may also aid in explaining the nature of functional

GI disorders and facilitate expanding beyond a limited discussion of bowel symptoms to a broad discussion of health and illness.

### ***Health Anxiety***

It is important to elicit fears of cancer or other serious illness. It is desirable for the gastroenterologist to take a psychosocial history and make a specific effort to address the patient's concerns about serious illness. If the consultation with a gastroenterologist is satisfactory, IBS patients will show reduction in overall anxiety, fear of cancer, and preoccupation and helplessness in relation to the pain; this result may lead to fewer subsequent visits to the clinic (van Dulmen et al. 1995). However, if these issues have not been addressed previously, the psychiatrist should address them. In addition, the psychiatrist should explore the reasons underlying fears of serious illness; one of the most common reasons is serious illness in the family. Depressive, panic, and other anxiety disorders and hypochondriacal personality traits may all be responsible for increased health anxiety (Colgan et al. 1988a).

### ***Early Environmental Experiences***

As noted earlier in this chapter, sexual abuse in childhood and related traumatic experiences may be common in some patients with functional GI disorders, especially those with high health care utilization.

### ***Abnormal Attitudes to Illness and Treatment***

In their extreme forms, the illness attitudes and behaviors in patients with functional GI disorders may amount to a psychiatric diagnosis of a somatoform disorder (see Chapter 12, "Anxiety Disorders") or a factitious disorder or malingering (see Chapter 14, "Deception Syndromes: Factitious Disorders and Malingering").

### ***Measurement and Monitoring***

Modern psychiatrists often use standardized instruments to measure the severity of depressive or anxiety disorders, particularly for screening and in research. Many common psychiatric instruments include GI symptoms, so it may be wise to consider the total score with and without these symptoms included, especially in borderline cases. For example, the BDI has items concerning aches and pains, upset stomach, constipation, and changes in appetite (Beck et al. 1961). The HADS (Zigmond and Snaith 1983) was designed for use in medical populations and may be particularly useful in GI patients because it specifically excludes items concerning bodily symptoms. The Rome committee has reviewed the instruments commonly used (Drossman et al. 1999, 2000a).

## Pharmacological Treatment

### ***Functional Gastrointestinal Syndromes***

Pharmacological treatment of IBS has been recently reviewed (Talley 2003). There is clear evidence of the effectiveness of tricyclic antidepressants in IBS (Clouse 2003; Jackson et al. 2000). Systematic reviews of the existing literature show an odds ratio of 4.2 (95% CI: 2.3 to 7.9) for the efficacy of TCAs over placebo, mostly measured in terms of pain relief (Jackson et al. 2000). The mechanism of the benefit derived from TCAs in functional bowel disorders is not entirely clear. They are effective in low doses with rapid onset, suggesting the benefits may be the result of analgesic and anticholinergic effects. Imipramine was helpful in chest pain in one study (Cannon et al. 1994), but the mechanism(s) of action are also not clear.

Too few studies have examined the effect of SSRI antidepressants to be clear about their efficacy, but they are active in doses that are effective in clinical depression, and the onset of action is slower, suggesting that they act through a different mechanism from tricyclic antidepressants (TCAs) (Creed et al. 2003; Kirsch and Louie 2000; Masand et al. 2002).

In larger studies, the effectiveness of TCAs and SSRIs in improving abdominal pain is related to medication adherence (Creed et al. 2003; Drossman et al. 2003). Some patients with constipation-predominant IBS cannot tolerate TCAs, and some with diarrhea may experience an increase in diarrhea with SSRIs. Dropout rates are high for either class of drug unless special effort is made to promote adherence (Clouse 2003; Creed et al. 2003). Newer drugs developed for IBS have been agonists and antagonists of enteric serotonin receptors (e.g., alosetron, tegaserod), but they do not seem to interact adversely with SSRIs.

In clinical practice, it is important to decide why antidepressants are being used—for their analgesic properties in people who have severe pain or to treat a concurrent depressive illness—and to carefully explain this to the patient. On many occasions, doctors have prescribed low-dose antidepressants for patients' pain, only to be told later that these patients did not take (or stopped taking) the medication because they learned that the drug is an antidepressant and they did not consider themselves depressed.

The Rome committee has reviewed in detail the use of psychotropic drugs in treating functional GI disorders (Drossman et al. 2000a). Antidepressants have also been used with some degree of success for functional dyspepsia. In a placebo-controlled trial, Mertz and colleagues demonstrated the effectiveness of amitriptyline at low doses in improving both well-being and dyspeptic symp-

toms in patients with functional dyspepsia (Mertz et al. 1998). A number of other agents may also provide symptom relief (see Stanghellini et al. 2003).

### ***Depression in People With Organic Gastrointestinal Disorders***

Antidepressant treatment for interferon-induced depression was discussed earlier in this chapter (see subsection “Chronic Hepatitis C Virus Infection”). Psychopharmacology in patients with GI diseases is reviewed in detail in Chapter 37, “Psychopharmacology.”

## **Psychological Treatment**

### ***Functional Gastrointestinal Disorders***

There have been many studies of psychological treatments of functional bowel disorders, but the sample sizes have been small in some studies, and different therapies and different measures have been used (Talley et al. 1996). The quality of some studies is not high, with follow-up rates sometimes less than 50% (Talley et al. 1996). However, the overall evidence suggests that these treatments are helpful. In one recent review, 10 of 13 studies showed superiority of psychological therapies over conventional medical treatment (Drossman et al. 2000a, p. 215). This result held for five out of six studies that controlled for expectancy of treatment. There was no difference according to specific treatment—dynamic interpersonal therapy, cognitive-behavioral therapy, hypnosis, and relaxation training all appeared to be successful. It is not clear whether these therapies have a specific effect on gut function or whether they act in a general way by reducing tension or improving interpersonal relationships and assertiveness. Because of their time-consuming nature and associated expense, psychological treatments tend to be reserved for the more severe cases.

In clinical practice, there is good reason to try a combination of psychological treatments and antidepressants, though there have not been adequate studies to demonstrate the efficacy of combined treatment (Olden and Drossman 2000). Because psychotherapy and pharmacotherapy probably have different modes of action, it is reasonable to assume that they may have synergistic effects. A detailed clinical assessment might reveal that a patient has a depressive disorder, excessive concern about serious illness that cannot be entirely attributed to the depressive disorder, and a clear marital problem. Such a patient might well benefit from antidepressant treatment combined with cognitive-behavioral therapy for the health anxiety and marital counseling. In their original description of the “irritable colon syndrome,” Chaudhury and Truelove

(1962) described a man whose symptoms completely resolved once his marital dispute was ended and he was happily settled in a new relationship.

### ***Peptic Ulcer and Inflammatory Bowel Disease***

There is nearly always a need to provide proper education and support to patients with organic GI diseases (peptic ulcer and IBD). The provision of information can lead to decreasing patient anxiety, empowering patients to participate more fully in their care and to obviate unnecessary worries such as an undue fear of cancer and the like.

Both dynamic interpersonal therapy and hypnosis have been studied in patients with peptic ulcer. These studies are interesting because they employed the same treatment method for patients with peptic ulcer as they did for patients with IBS. One used dynamic psychotherapy (Sjodin et al. 1985), and the other used hypnotherapy (Colgan et al. 1988b). Both found a more pronounced positive result in IBS, but the psychological treatments had a clear beneficial effect on ulcer symptoms compared to the control condition. This is a reminder that psychological factors may play a part in the etiology or perpetuation of the symptoms of peptic ulcer disease.

Psychotherapy trials, both controlled and uncontrolled, have not shown a benefit in improving outcome in IBD (Jantschek et al. 1998; Maunder and Esplen 2001).

## **Conclusion**

---

The detection and treatment of psychiatric disorders in patients presenting to gastroenterologists is an important aspect of clinical practice. Whereas anxiety and depression have a more prominent role in functional gastrointestinal disorders, they have important effects on treatment, outcome, and quality of life in patients with “organic” gastrointestinal disorders as well. Chronic hepatitis C infection is of particular concern, both because of its frequency in patients with serious mental illness and substance abuse and because of the psychiatric side effects associated with its treatment.

# 22 Renal Disease

---

Lewis M. Cohen, M.D.

Norman B. Levy, M.D.

Edward G. Tessier, Pharm.D., M.P.H.

Michael J. Germain, M.D.

**NEPHROLOGY HAS RECOGNIZED** the need for psychiatric consultation since the initial development of kidney dialysis in the late 1960s and early 1970s. Nearly universal access to treatment followed passage of the 1972 End-Stage Renal Disease amendment to the Social Security Act, which provided government subsidy for dialysis. Subsequently, the population has steadily grown, aged, and become more severely ill (McBride 1990). Psychiatry's potential role in the collaborative care of patients with renal disease is increasing.

Each year, approximately 80,000 Americans develop end-stage renal disease (ESRD). More than 340,000 individuals are treated for kidney failure (U.S. Renal Data System 2002); 240,000 people are receiving maintenance dialysis, and 100,000 have a functioning kidney transplant. In 2001, the prevalent dialysis population was 292,215 patients (U.S. Renal Data System 2003). The number of patients starting renal replacement therapy in the United States continues to increase each year by 5%–7%. An additional 8 million individuals are estimated to have chronic renal insufficiency (Robertson et al. 2002). The current annual cost for treating ESRD in the United States is approximately \$19 billion, and the average Medicare expenditure is \$54,000 per hemodialysis patient and \$17,000 per transplant patient. As of 2002, there were 3,600 dialysis facilities and 255 transplant programs in the United States (U.S. Renal Data System 2002).

Every year data have been collected, the average age of the ESRD incident population has increased. In 1986, the mean age was 56 years, and by 1995, it was 60 years (National Institutes of Health 2000). The fastest growth

has occurred among the oldest age groups. In 1996, 46% of the incident patients were age 65 years or older, and 20% were over 75 years of age. By 1999, 58% of the newly diagnosed chronic ESRD patients in New England were 65 years or older, and 17% were 80 years and older (Network of New England 1999).

It is not an exaggeration to claim that even young patients with ESRD have old bodies and that geriatric issues are commonplace in this population (Cohen et al. 2003a). The causes of renal failure include diabetes; hypertension; generalized arteriosclerosis; lupus; AIDS; and primary renal diseases, such as chronic glomerulonephritis, chronic interstitial nephritis, polycystic kidney disease, and other hereditary and congenital disorders. In 1999, only 9% of dialysis patients were free of significant comorbid conditions. Of particular importance, diabetes is now found in almost half of ESRD incident cases, and because of its plethora of microvascular and macrovascular complications, patients are especially likely to have increased morbidity (Lea and Nicholas 2002).

In some surveys, almost two-thirds of ESRD patients rate quality of life as being less than “good” (Levy and Wynbrandt 1975; Roberts and Kjellstrand 1988). In a recent survey at nine New England dialysis clinics involving 619 patients, 57% of the sample reported that physical health problems during the previous 4 weeks forced them to cut down on the amount of time spent on work or other activities, 69% accomplished less than they would prefer, and 71% were limited in the kind of work or activities that they could pursue (Poppel et al. 2003). A study of 14,815 dialysis patients demonstrated a significant cor-

relation between mortality and mental-health and physical-function scores on the SF-36 Health Survey (Knight 2003).

While the clinical challenges presented by the patient population steadily mount, there have been corresponding advances in the technology and treatments of renal transplantation and dialysis.

*Renal transplantation* (see also Chapter 31, "Organ Transplantation," and Chapter 34, "Pediatrics") is the treatment of choice for many patients, and if a transplant is successful, the patient's survival (U.S. Renal Data System 2002; Wolfe et al. 1999) and quality of life (Franke 2003; Laupacis 1996) are almost always better than they would be with dialysis. The major issue in transplantation is the shortage of donor organs. Transplanted kidneys may come from a living donor or through organ donation following death. During the past decade, the number of cadaveric transplants increased by only 16%, whereas living-related transplants have increased by 68% (U.S. Renal Data System 2003). Despite this, many more transplants are performed with cadaveric kidneys than with living-donor kidneys. More than 14,000 transplants were performed in 2000. Long-term kidney survival is greater with living donors. Most cadaveric kidneys are procured from brain-dead individuals following acute trauma, intracerebral bleeds, and cerebral vascular accidents. Commercially available organs from individuals who were willing to sell their kidneys are banned by federal statute in the United States and in many other countries. The critical shortage of cadaveric organs is leading many transplant programs to liberalize their requirements and to make use of kidneys from living, unrelated donors.

*Peritoneal dialysis* and *hemodialysis* are the two forms of dialysis. In peritoneal dialysis, dialysate fluid is introduced and then removed from the peritoneal space through an indwelling catheter. The peritoneum serves as a semipermeable membrane, and fluid and wastes are removed together with dialysate. Peritoneal dialysis may be performed by a machine in the home at night (continuous cycling peritoneal dialysis, or CCPD), or manually at home four to six times per day (continuous ambulatory peritoneal dialysis, or CAPD). Only 11% of ESRD patients use peritoneal dialysis as the initial mode of renal replacement therapy (U.S. Renal Data System 1997a). Hemodialysis may be conducted at the patient's home, but it usually takes place at dialysis units for 4-hour sessions held three times per week. Home dialysis requires the participation of another person, who must be available to assist with 12–15 hours of weekly treatment. There has been a great deal of recent interest in daily and nocturnal dialysis done at home or in a dialysis facility

(Lockridge et al. 2001). Data suggest that this new approach may result in improved quality of life and health. Although patients have not been randomized to dialysis modalities, most studies continue to show that patients receiving peritoneal dialysis rate their care higher than do those receiving hemodialysis (Rubin et al. 2004).

## Psychiatric Disorders in Renal Disease

---

In a review of psychiatric illness involving 200,000 U.S. dialysis patients, almost 10% had been hospitalized with a psychiatric diagnosis, and this was the primary reason for hospitalization of 25% of the subgroup (Kimmel et al. 1993). Depression and other affective disorders were the most common diagnoses, followed by delirium and dementia. Compared with other medical illnesses, the primary diagnosis of depression was higher in renal failure patients than in those with ischemic heart disease and cerebrovascular disease (Kimmel et al. 1993).

The diagnosis of major depressive disorder (MDD) was highlighted in the NIMH-NIDDK conference "Depression and Mental Disorders in Patients With Diabetes, Renal Disease, and Obesity/Eating Disorders" (Bethesda, MD; January 29–30, 2001). Although MDD is the second most common chronic disorder after hypertension encountered in general medical practice, surprisingly little is clear concerning something as basic as its prevalence among patients who receive hemodialysis. Studies of depression and ESRD have reported prevalence rates ranging from 0% to 100% (Cohen-Cole and Stoudemire 1987; Kimmel 2000; Kimmel 2002), reflecting widely variable definitions, criteria, and measurement methods.

Because depression frequently follows loss, its occurrence is understandable in the context of dialysis, where patients commonly lose strength, energy, sexual ability, employment, physical freedom, and independence. Another potential contributing factor to depression is survival guilt, when a fellow dialysis patient dies (Vamos 1997). A recent study highlighted the significance of comorbid disorders (e.g., diabetes) and job status in the etiology of clinical depression (Chen et al. 2003). Examination of the ESRD literature suggests that subsyndromal depressive syndromes are likely in about 25% of patients; and major depression is likely in 5%–22% of patients (O'Donnell and Chung 1997).

Our own diagnostic approach entails describing the criteria for major depression and eliciting the patient's opinion as to whether he or she believe himself or herself to be depressed, and then documenting the existence of associated factors, such as depressive episodes prior to the onset of renal failure, a family history of depression,

and previous suicide attempts (Cohen 1998; Cohen et al. 2000). The presence of depressive affect and cognition, such as poor self-esteem, worthlessness, hopelessness, and helplessness, is valuable in arriving at the correct diagnosis.

Major depression appears to be frequently unrecognized and untreated (Finkelstein and Finkelstein 2000). In a recent study of Connecticut dialysis patients ( $N = 123$ ) initiating dialysis treatment, almost half (44%) of the sample scored above the depressed range of the Beck Depression Inventory (score = 15), but only 16% of these patients were receiving antidepressant medications (Wattnick et al. 2003).

Suicide, the ultimate complication of depression, is reportedly more common among dialysis patients than in the general population (Abram et al. 1971; Haenel et al. 1980; Kimmel 2001). ESRD suicide rates were originally calculated by combining ordinary clinical suicides with deaths following dialysis discontinuation and deaths caused by noncompliance (Abram et al. 1971). Kishi and Kathol (2002) observed that suicide in the context of terminal illness is increasing, and although suicide usually is a consequence of comorbid major depression or alcohol abuse, it also may occur in the absence of demonstrable psychiatric illness. These "philosophical" or "preemptive" suicides are a focus of interest in the psychiatric and palliative-care communities (Cohen 1998). In an intriguing observation, Kjellstrand (1992) pointed out that Western Europe has one-third the dialysis-withdrawal rate of the United States and three times the number of deliberate suicides among dialysis patients.

Anxiety and depression are the most common psychological symptoms seen in the physically ill (Lefebvre et al. 1972); this is also true in ESRD. Anxiety may be present during dialysis treatments, particularly in hemodialysis. Hemodialysis involves the continuous removal of blood into a machine and its return to the patient's body. The fear of a medical emergency, such as significant blood loss or a cardiac event, may cause understandable anxiety. Phobias of needles and the sight of blood are common in the general population (see Chapter 12, "Anxiety Disorders"). Rapid removal of fluid and electrolytes may also produce hypotension, nausea, vomiting, and muscular cramps. Anxiety is evident in the uncertainty many patients have about the future, fears about sexual performance, and apprehension over their ability to cope with the ongoing demands of dialysis and expectations of staff and family (Levy 1990).

Substance use disorders, such as cocaine or heroin dependence, can directly lead to ESRD (Norris et al. 2001). They may also result in HIV infection and, later, AIDS, which can secondarily cause renal failure.

Cognitive disorders are common in the ESRD patient population and may be related to uremia, a variety of medical comorbidities (e.g., electrolyte disturbances, severe malnutrition, impaired metabolism, cerebrovascular disease), or adverse effects of treatment. *Uremia* refers to the clinical syndrome resulting from profound loss of renal function. Signs and symptoms vary considerably, with severity depending on both the magnitude and the rapidity with which renal function is lost. Central nervous system symptoms may begin with mild cognitive dysfunction, fatigue, and headache, progressing to a usually hypoactive delirium and, if untreated, coma. Restless legs syndrome, muscle cramps, and sleep disorders are also common. Other common symptoms include pruritus, anorexia, nausea, and vomiting. Metabolic abnormalities may include hyperkalemia, hyperphosphatemia, metabolic acidosis, and of course azotemia (elevated BUN and creatinine levels). The specific cause of uremic encephalopathy remains unknown. Many patients will tend to note progressive impairment as their day for dialysis approaches (Levy and Cohen 2000). After dialysis, they may experience a short period of delirium lasting from minutes to hours that is termed "dysequilibrium syndrome," likely caused by the rapid changes in fluid and electrolytes during the dialysis session. Acute changes in mental status are not commonly seen in CAPD, because this procedure is slow, continuous, and without sudden fluxes of fluid and electrolytes. The presence of a transient metabolic encephalopathy can be confirmed by an electroencephalogram, demonstrating diffuse slowing. Single photon emission tomography has been used to compare hemodialysis patients with matched controls (Fazekas et al. 1996). Patients with ESRD appear to have reduced cerebral blood flow in the frontal cortex and thalamus, and even well-dialyzed patients have subtle abnormalities of cognitive function (Levy and Cohen 2001). Finally, cognitive dysfunction in a uremic patient could be the result of the uremia and associated comorbidities, including, for example, electrolyte disturbances, severe malnutrition, impaired metabolism, and cerebrovascular disease.

The usual types of dementia, such as vascular and Alzheimer's, are increasingly encountered as the ESRD population continues to age. Vascular dementia is especially common because of the high prevalence of diabetes, hypertension, and atherosclerosis in ESRD patients.

The most serious cognitive disorder seen in dialysis patients in the 1970s and 1980s was "dialysis encephalopathy" or "dialysis dementia" (Levy and Cohen 2000). This usually fatal syndrome occurred in patients who had been on hemodialysis for at least 2 years, and the early signs were memory impairment, dysarthria, stuttering speech, depression, and psychosis (O'Hare et al. 1983). Patients

often displayed asterixis, bizarre limb movements, and generalized tremulousness. Magnetic resonance imaging of demented dialysis patients suggested that there was a toxic–metabolic etiology to their brain degeneration (Fazekas et al. 1995). The cause of this disorder is not fully understood, but aluminum was the most likely culprit, and it was found in phosphate-binding gels and in trace amounts in dialysate water (Alfrey 1986). There are conflicting data, however, concerning aluminum toxicity, because aluminum tends to be present in higher-than-normal quantities in the brain in other types of dementia, including Alzheimer's disease. Trace amounts of tin and zinc have also been blamed as a cause of this syndrome. In dialysis dementia, the EEG showed typical slow-wave bursts in the early stages (Alfrey 1986). This disorder markedly decreased in incidence following the general use of aluminum-free dialysates and the avoidance of aluminum phosphate binders.

## Effects of Psychological Factors on Choice of Modality and Compliance

---

Many factors are involved in the choice of the treatment modality for renal failure. A parallel situation occurs in the treatment of localized prostate cancer; the treating physician must choose between radical prostatectomy, conformal radiation, and radioactive seed implantation. In renal failure, the choice involves center hemodialysis versus various methods of self-care, such as home hemodialysis, CAPD, and CCPD. As in the example of prostate disease, the physician's orientation and preferences are often the main factors that influence treatment choice; ideally, patient preferences should be paramount. In contrast with European nephrologists, most American nephrologists treat patients with hemodialysis. Nephrologists who work in medical centers where renal transplantation is the centerpiece of treatment and hemodialysis space is limited will tend, when feasible, to favor transplantation. Economic factors may also influence the recommended treatment, and proprietary dialysis centers provide the majority of care in this country.

Psychosocial factors significantly impact the choice of treatment modality (Maher et al. 1983). A medical history marked by noncompliance argues against modalities of self-care. This is especially true for transplantation, where nonadherence to immunosuppressant treatment will generally result in organ rejection (Surman 1989). Modality decisions must take into account the social support system of the individual patient. In order for home dialysis to take place, it is essential not only that the patient have a home but also that another individual be available to pro-

vide care. This individual is usually the spouse or significant other. In some cases, insurance will permit hiring of a nursing assistant. The character structure of patients is also an influence on modality choice. The very independent patient will tend to favor modalities of self-care, whereas the dependent person will tend to prefer being cared for.

Compliance is a common problem and is often a central issue in the management of patients. Compliance is a complex, multidimensional array of behaviors, and its relationship with health outcomes in dialysis patients is difficult to study. However, the widespread belief among physicians and nurses that noncompliance results in worse outcomes, including higher mortality in ESRD, is supported by a large multicenter study (Leggat et al. 1997). ESRD occurs more frequently in people who have had previous difficulty adhering to the treatment requirements of those illnesses that lead to renal failure, such as diabetes and hypertension. Chronic overuse of nonsteroidal anti-inflammatory agents and analgesics is recognized to be a fairly common contributing cause of chronic renal insufficiency (Fored et al. 2001). Nephropathies caused by addictive substances, such as heroin, result in greater representation of nonadherent patients. It is difficult enough for the dialysis patient to engage in a lifelong procedure that occurs daily in the case of CAPD, and three times weekly in the case of hemodialysis, but the burdens of dietary restrictions and required medications add major compliance chores. Hemodialysis patients in particular, and peritoneal patients to a lesser degree, need to restrict their intake of protein, sodium, potassium (fruit), phosphates (dairy), and, most difficult of all, fluids. Required medications often include antihypertensive agents, phosphate binders, antacids, and drugs to treat comorbid conditions (e.g., insulin, nitrates, antidepressants, and lipid-lowering agents).

There is no validated method to measure compliance, but clinical indices include dialysis attendance, interdialytic weight gain, serum potassium, and medication adherence. Lack of adherence to treatment regimens is believed to be a common cause for inadequate dialysis and poor outcome (Kaveh and Kimmel 2001). Common non-compliant behaviors include skipping or missing dialysis sessions, and dietary and medication indiscretions. According to self-report, one peritoneal dialysis exchange per week is missed by 12% of patients, and two to three exchanges per week are skipped by 5% of patients (U.S. Renal Data System 1997b). Noncompliance is more common in younger patients, those without diabetes, and black and Hispanic patients, as compared with white and Asian patients (Blake et al. 2000). Among the factors associated with noncompliance are depression, hostility to-

ward authority, memory impairment, ethnic barriers, and financial problems (Anderson and Kirk 1982). The field of nephrology appreciates that appropriate patient and modality selection needs to be combined with a multidisciplinary approach to improve adherence (Raj 2002), with particular attention to patient education (Golper 2001).

## Diagnostic Issues

---

Does the psychiatric disorder come first or the medical illness and its treatment? It is probably most accurate to say that each influences the other. The order of events is largely irrelevant, because both need to be treated, and treatment does not require that this issue be resolved, if indeed it can ever be (Levenson and Glocheski 1991).

Progressive uremia and its treatment modalities are associated with both physical and psychological symptoms, and it is often difficult to delineate the etiology, particularly when patients have comorbid systemic disorders, such as diabetes. It is important to understand that dialysis only partially corrects the uremic state equivalent to less than 10 cc/min glomerular filtration rate, and in three-times-per-week hemodialysis, this clearance is provided only intermittently. This limited amount of clearance of uremic toxins is enough to prevent death; however, patients may remain symptomatic. There has been relatively little research focused on identifying common symptoms and examining different treatment approaches (Weisbord et al. 2004).

In the nephrology literature, there is a lack of clarity around the term *depression* and whether it refers to the affective symptom or the psychiatric disorder (Cohen 1996). Most ESRD research studies have relied on instruments that determine the severity of the symptom (Craven et al. 1988; Kimmel et al. 1998; Smith et al. 1985). In contrast, psychiatric studies in the medically ill now more often rely on the combination of such measures with a structured diagnostic interview based on DSM-IV criteria (American Psychiatric Association 2000) (e.g., Chochinov et al. 1994; Sullivan et al. 1999). In addition, the evaluation of depression is complicated by the fact that the somatic signs and symptoms of ESRD may fulfill the criteria for MDD. Many patients have diminished appetite, loss of energy, dryness of the mouth, constipation, and diminished sexual interest. However, during interviews some individuals will adamantly maintain that they are not depressed, and it is likely that the vegetative symptoms are being produced by the kidney failure and renal replacement therapy. For a full discussion of the diagnosis of depression in the medically ill, see Chapter 9, "Depression."

## Withholding or Withdrawing Dialysis: Renal Palliative Care

---

Psychiatrists have an opportunity to participate in the ongoing integration of palliative medicine and nephrology (Cohen and Germain 2003). Recent ESRD patient demographics reveal a robust increase in numbers, severity of comorbid illnesses, and age (Weisbord et al., in press). Consequently, it should be no surprise that despite continuing improvements in technology, more than 65,000 Americans with ESRD will die this year, and the annual mortality rate is around 23% (U.S. Renal Data System 2002). This mortality rate is comparable to that of non-Hodgkin's lymphoma and higher than that of prostate (0.2%), breast (2.4%), colorectal (17.4%), and ovarian (20.8%) cancer (Ries et al. 2002). The expected remaining lifetime of dialysis patients is one-quarter to one-fifth that of the age- and sex-matched general population (U.S. Renal Data System 2003). Although the figures are better for transplant patients, their expected remaining lifetime is still only 70%–80% that of the general population. To illustrate, a 60-year-old white, male dialysis patient would expect to have an average of around 3 remaining years of life, whereas his counterpart among the general population would have 19 more years. Despite the omnipresence of death, only a minority of ESRD patients complete formal advance directives or engage in ongoing discussions with staff about end-of-life treatment preferences (Cohen et al. 2001). Advance directives are more commonly used in dialysis patients in the United States compared with Germany and Japan (Sehgal et al. 1996). Multidisciplinary involvement is needed to lift the denial of death and improve the provision of end-of-life care and symptom management (Cohen et al. 1997).

Psychiatrists can play a crucial role in the complex determinations to withhold or withdraw renal replacement treatment. Treatment guidelines have been developed by a task force from the Renal Physician's Association, American Society of Nephrology, National Kidney Foundation, and other renal organizations (Moss et al. 2000). Guidelines also exist or are under development in other nations—for example, Japan (Sakaguchi and Akizawa 2002) and Italy (Buzzi 2001). The U.S. guidelines, which directed attention to the ethical and psychological issues in decisions to withhold or withdraw renal replacement treatment, were prompted by the finding that the percentage of patient deaths preceded by decisions to stop dialysis steadily increased during the 1990s. In the United States, between 1990 and 1995, more than 20,000 deaths were preceded by dialysis discontinuation (Leggat et al. 1997). During the same period of time, beginning in 1995, there

were 36,000 withdrawal deaths in the incident sample of patients (U.S. Renal Data System 2002). Furthermore, an unknown number of patients die after they or their families decide to withhold or not initiate dialysis. All of these decisions are emotionally complex and stressful for patients, caregivers, and staff. Psychiatrists can assist with determinations of patient capacity and also the potential influence of depression or other psychosocial factors.

In providing better end-of-life care for this very ill population, attention should focus on the following issues:

1. *Early frank discussions concerning prognosis and goals of care.* Ideally, these discussions, which include the family, should start when the patient is first diagnosed with progressive renal disease. Options of care to be discussed and offered ought to include the possibility of not starting dialysis (see below), especially if the burdens of dialysis outweigh the benefits. Patients should also know they have the option of stopping dialysis if suffering is unrelieved. Written advance directives such as the “Five Wishes” ([agingwithdignity.com](http://agingwithdignity.com)) can help focus the discussion and provide the family with guidance when the patient can no longer make decisions. Do-not-resuscitate orders should be strongly considered when cardiopulmonary resuscitation is likely to be futile (Moss et al. 2000).
2. *Attention to symptoms at all stages of the disease process.* Patients with ESRD have a high burden of symptoms, related to dialysis and their comorbid conditions (Cohen et al. 2001).
3. *Early hospice referrals.* Such referrals can take place in the hospital, home, nursing home, or inpatient hospice unit. Dialysis need not be stopped to receive hospice services, as long as the patient has a nonrenal terminal diagnosis. However, because of the financial burden, most hospice programs are reticent to become involved with patients who continue to receive dialysis. Unquestionably, all patients who terminate dialysis should be offered referral to hospice.
4. *Maximal palliative care at the end of life.* This care includes aggressive pain control, spiritual and emotional support, and attention to the patient’s terminal treatment preferences and goals.

The decision not to start dialysis is more common than withdrawal from dialysis. Patients who are already uremic at the time of decision to initiate dialysis may be encephalopathic and lack sufficient decision-making capacity. If dialysis is otherwise indicated, and the patient is refusing dialysis, it is appropriate to seek legal authorization to provide involuntary dialysis until the patient’s mental status has improved enough to enable an informed

decision (see Chapter 3, “Legal Issues,” and Chapter 4, “Ethical Issues”). Utmost sensitivity is needed in making withholding or discontinuation decisions, and one needs to be alert to cultural biases, countertransference, and other complicating factors. In a survey of American nephrologists, nearly 90% reported withholding dialysis at least once in the previous year, and over 30% reported withholding it at least six times (Singer 1992). In a prospective Canadian study, about 25% of patients with advanced chronic kidney disease referred for initiation of hemodialysis were not offered dialysis (Hirsch et al. 1994). There are significant differences between countries in how often dialysis is offered and the relative factors affecting the decision, even among the English-speaking nations. American nephrologists offer dialysis more often and give more weight to patient or family wishes and fear of lawsuit than do British or Canadian nephrologists. British nephrologists more often consider their perception of patients’ quality of life as a reason to provide or not provide dialysis than do their American counterparts (McKenzie et al. 1998). Primary care physicians can also withhold dialysis by not referring the patients to nephrologists for evaluation of their progressive renal failure. One study among physicians in West Virginia, for example, found that 20 of 76 primary care providers (26%) had effectively withheld dialysis for at least one patient through nonreferral to a nephrologist (Sekkarie and Moss 1998).

The conditions in the following patients are considered appropriate reasons to withhold dialysis based on recently published U.S. guidelines (Moss et al. 2000):

- Patients with severe and irreversible dementia
- Patients who are permanently unconscious (as in a persistent vegetative state)
- Patients with end-stage cancer or end-stage lung, liver, or heart disease who need considerable assistance with activities of daily living and may be confined to bed, chair, or involved in a hospice program
- Patients with severe mental disability who are uncooperative with the procedure of dialysis itself, are unable to interact with the environment or other people, or are persistently combative with family or staff
- Patients with severe, continued, and unrelenting pain, in whom dialysis may prolong life for a short period of time but will also prolong suffering
- Hospitalized patients (especially elderly) with multiple organ system failure that persists after 3 days of intensive therapy (The mortality rate in such patients is very high.)

Withdrawal from dialysis is often appropriate for the dying dialysis patient. It provides the patient and family with the blessing of a quick death (Cohen et al. 2003b).

The mean time to death after stopping dialysis is 8 days, and dialysis termination does not cause pain or discomfort (Cohen et al. 2001). It typically results in lethargy progressing to coma. Renal physicians' organizations, nephrology fellowship training directors, and dialysis corporations are all becoming more appreciative of the need to integrate palliative care in the treatment of this population. Psychiatrists have an important opportunity to assist in this effort.

## Treatment Issues

---

### Psychotherapy

There is a growing body of literature on this topic (Israel 1986; Sacks et al. 1990). In one of the earliest publications involving a 4-year intensive study of 25 patients on hemodialysis (Reichsman and Levy 1972), the sample was described as being among the biggest deniers of psychiatric illness in the experience of the authors. The subjects disowned personal factors as playing a role, and they invariably attributed problems to their physical illness. This observation is common among people with chronic medical disorders, and it complicates psychotherapeutic intervention. Nevertheless, there are data suggesting that a wide variety of forms of psychotherapy may be helpful. In a recent study of Japanese hemodialysis patients (Sagawa et al. 2003), cognitive-behavioral therapy (CBT) achieved a 65% reduction of fluid intake. In a study of five Boston patients (Surman and Tolkoff-Rubin 1984), hypnosis was successful in curtailing psychiatric symptoms. In a study of 116 patients, Cummings et al. (1981) demonstrated that behavioral contracting and weekly telephone contacts were effective in the short term in improving compliance with medical regimens. More recently, behavioral interventions were shown to improve compliance with fluid restriction in both a small quasi-experimental study (Sagawa et al. 2003) and a controlled trial (Christensen et al. 2002). A controlled trial of group therapy in Israeli dialysis patients showed a significant decrease in psychological distress and interdialytic weight gain in those who received group therapy (Auslander and Buchs 2002). A naturalistic nonrandomized study of group therapy in New York City found increased survival among participants in a patient support group compared with other patients, even after multiple psychosocial and psychological variables were controlled (Friend et al. 1986). In a novel study by Hener et al. (1996), patients were randomized with their spouses to a supportive couples group, a CBT couples group, or nonintervention controls. Both interventions improved patients' psychosocial adjustment.

Any form of psychotherapy stands the best chance of success if conducted during dialysis treatment sessions (Levy 1999). Patients with ESRD feel overdoctored and overburdened by the time requirements of treatment. Therefore, therapies should be piggybacked with medical treatment whenever feasible. Even group therapy can be performed while patients are being dialyzed. This necessitates an essential nonselection of participants, because an entire room or partially divided room of patients would be involved, some of whom may be resistant to anything called psychiatric. Groups that have been most successful are those that have a strong educational component. This component may comprise lectures from social workers, nutritionists, transplant surgeons, and nephrologists. Such sessions are especially valuable in the earliest phases of groups when patients may be most hesitant to talk about themselves. As time progresses, personal stories and problems usually emerge. Individual psychotherapy is mainly limited to those few patients who see themselves as having psychological problems and who are willing and able to engage in this form of treatment. The availability of psychoactive medications gives the psychiatrist an important "foot in the front door."

In respect to confidentiality, the psychiatrist must pay special attention to privacy issues in dialysis settings. Patients should always be offered the opportunity to meet in a private office. When patients are seen on dialysis units, curtains should be drawn, and the use of portable, white-noise machines may be helpful.

### Miscellaneous Treatment Issues

Aggression, irritability, drug abuse, persistent insomnia, and noncompliance are frequent reasons for referral. During the past several years, the authors have also received increasing requests from nephrologists to assist in determinations of capacity, as well as issues related to dialysis discontinuation decisions. The general topic of capacity and competency are discussed in Chapter 3, "Legal Issues," and Chapter 4, "Ethical Issues," but it is important to make explicit here that most nephrologists feel justified in pressuring patients who resist initiating dialysis to at least enter into a trial of several weeks or months of treatment. The rationale is that this is a life-and-death situation, and the patient's insight and judgment may be impaired by renal encephalopathy, interfering with their decision to initiate dialysis. This topic is addressed in the previously mentioned task force guidelines (Moss et al. 2000).

When it comes to delirium and dementia, the basic treatment involves recognition and correction of the underlying pathology. Intensified dialysis, parathyroidectomy,

tomy, and improved control of diabetes mellitus can each prove to be ameliorative. Neuroleptics or benzodiazepines may provide symptomatic treatment of agitation and delusions, and antidepressant medications can likewise be highly effective (Levy and Cohen 2001).

Sexual disorders and erectile dysfunction are common in the ESRD population, and these may sometimes result in consultations or requests for counseling. Many different behavioral and physical therapies offer the hope of some improvement. The latter include vacuum tumescence therapy, renal transplantation, use of recombinant human erythropoietin, and sildenafil (Rosas et al. 2001; see also Chapter 17, "Sexual Disorders").

## Psychopharmacology

Although antidepressants are frequently prescribed for patients with ESRD, there is only one very small controlled clinical trial (Blumenfeld 1997). There is interesting recent evidence that SSRIs may help control hypotension during dialysis (Yalcin 2002).

Most psychotropic medications are fat soluble with large volumes of distribution. With the exception of lithium, they are metabolized in the liver, and metabolites are eliminated in urine and bile. The majority of these drugs can be safely used in ESRD patients, but attention must be paid to medications with active metabolites, those that may be highly plasma-protein bound, and those with altered pharmacokinetics or pharmacodynamics.

When dose adjustments of psychiatric drugs in ESRD are required, it is usually because of comorbidities (e.g., diabetic autonomic neuropathy) and concurrent drug therapy (e.g., other agents metabolized by cytochrome P450 enzyme systems, and those with pharmacodynamic interactions), rather than the ESRD per se. Psychopharmacological management of transplant patients requires an appreciation of potential interactions with immunosuppressant medications (Robinson and Levenson 2001). Table 37–10 in Chapter 37, "Psychopharmacology," summarizes information about the use of individual psychotropic medications and the current knowledge of pharmacokinetic considerations. Given the size of the population, there has been a dearth of systematic investigations, and further psychopharmacological research is greatly needed.

## Conclusion

In this chapter we have summarized the existing literature on psychiatric care of patients with end stage renal disease. As the techniques of dialysis and transplantation have ad-

vanced, patients are living longer, including patients with more severe illness and more comorbidities. Because comorbid psychiatric disorders are widely prevalent among the dialysis and renal transplant populations, psychiatrists can play a vital role in management, including choice of treatment modality and promotion of compliance, as well as in palliative care for patients who wish to decline or discontinue dialysis. Finally, specific psychotherapeutic techniques and psychopharmacological interventions must be tailored to meet the special needs of patients with compromised renal function.

Alan M. Jacobson, M.D.

**THE ONSET, COURSE,** and outcomes of endocrine disorders have traditionally been linked to psychological and social factors. A growing body of neuroendocrine research has begun to illuminate important biological mechanisms underlying the interplay of psyche and soma, and there are important clinical ramifications of these connections. This chapter focuses primarily on these latter pragmatic issues. Diabetes mellitus is the most common endocrine condition and is now growing in epidemic proportions, so it has been given major emphasis. Other topics covered include disturbances in thyroid, parathyroid, adrenal, growth, prolactin, and gonadal hormones; pheochromocytomas; and metabolic disorders including electrolyte and acid-base disturbances, vitamin deficiencies, and the porphyrias.

### Diabetes

---

#### Type 1 Diabetes

Type 1 diabetes is a chronic, autoimmune disease that affects an estimated 500,000 to 1 million people in the United States. It is most commonly diagnosed in children and young adults, with peak onset occurring during pu-

berty (i.e., ages 10–12 in girls and 12–14 in boys). (See also Chapter 34, “Pediatrics,” for discussion of diabetes in pediatric populations.) The exact cause of type 1 diabetes is not known; however, it appears that genetic and environmental factors trigger an autoimmune response, which attacks the insulin-producing beta cells of the pancreas. Prolonged hyperglycemia can lead to the severe macro- and microvascular complications of diabetes, such as cardiovascular disease, retinopathy, nephropathy, and peripheral and autonomic neuropathy (Kahn and Weir 1994).

The Diabetes Control and Complications Trial (DCCT), a 9-year, multicenter intervention study in the United States, established that improvement in glycemic control delays the onset and slows the progression of diabetic complications (Diabetes Control and Complications Trial Research Group 1993). The DCCT’s findings have informed and increased the complexity of what is now the standard treatment for type 1 diabetes. As such, treatment is aimed at lowering and stabilizing blood glucose to near normal levels through dietary control, exercise, blood glucose monitoring, and multiple daily insulin injections. Intensive blood glucose management for type 1 diabetes usually entails three or more insulin injections per day (or the use of a continuous insulin infusion pump)—with the

goal of mirroring as closely as possible the physiological patterns of insulin release and near-normal blood glucose levels. Hemoglobin A<sub>1c</sub> is a laboratory value reflective of average blood glucose concentrations over a 2- to 3-month period. It is used as the standard measure of diabetes self-care success and treatment effectiveness, with a typical target of as close to 7% as possible (normal range in people without diabetes is 4%–6%).

## Type 2 Diabetes

Approximately 90%–95% (16 million in the United States) of all people with diabetes have type 2 diabetes, which encompasses a variety of abnormalities involving blood glucose metabolism. The hallmark of the disease is insulin resistance, in which the body requires progressively increased pancreatic insulin production to achieve normal glycemia. In patients with type 2 diabetes, the pancreas can no longer meet the need, and chronic hyperglycemia results. Risk factors for type 2 diabetes include obesity and sedentary lifestyle, because both lead to insulin resistance. Onset of type 2 diabetes is typically during middle age, but with growing rates of obesity at younger ages, children and adolescents are starting to develop the disease at higher rates. Because they decrease insulin resistance, prescribed weight loss and regular exercise are first-line treatments for type 2 diabetes (Beaser 2001).

The United Kingdom Prospective Diabetes Study (UKPDS), the largest and longest prospective study of type 2 diabetes to date, found that for every 1-point reduction in hemoglobin A<sub>1c</sub>, there was a corresponding 35% reduction in risk of diabetes complications. Successfully treating hypertension led to similar or greater reduction in cardiovascular complications (Krentz 1999; Matthews 1999). Treatment for type 2 diabetes is aimed at lowering and stabilizing blood glucose levels through weight loss (when applicable), dietary control, exercise, blood glucose monitoring, oral hypoglycemic medication, and treatment with insulin injections if insulin resistance and hyperglycemia persist.

## Stress and Diabetes

There is conflicting evidence whether stress directly affects the onset of diabetes or its course (Helz and Templeton 1990; Mooy et al. 2000; Wales 1995). Stress hormones are involved in the body's counterregulatory response to insulin, so it is likely that stress plays a role in increasing blood glucose. A number of studies have shown that glycemic control is poorer in people with diabetes who report more stress (Garay-Sevilla et al. 2000; Lloyd et al. 1999). However, it is not clear whether stress

directly influences metabolic regulation or whether people under stress change their self-care behaviors. In an effort to evaluate the effects of stress under controlled conditions, a few laboratory studies have been undertaken. Although some laboratory studies have suggested that psychological stress can impair glucose control in both type 1 (Moberg et al. 1994) and type 2 diabetes (Goetsch et al. 1993), other studies have not demonstrated this effect (Kemmer et al. 1986). Thus, it is not yet clear to what extent stressful events directly affect the physiology of glucose regulation.

## Psychiatric Disorders and Diabetes Management

The publication of the DCCT and UKPDS studies demonstrated that intensive management of type 1 and type 2 diabetes improves long-term health outcomes in diabetes (Diabetes Control and Complications Trial Research Group 1993; Krentz 1999; Matthews 1999; UK Prospective Diabetes Study Group 1998a, 1998b). However, the goal of achieving near-normal blood glucose values requires a complex set of daily behaviors and problem solving. Many patients have difficulty sustaining the burden of self-care over time—the stress of coping with a chronic disease is a major risk factor for psychopathology and nonadherence to complex treatment recommendations. There is a growing literature examining the relationship of type 1 and type 2 diabetes and psychiatric disorders, especially depression, anxiety, and eating disorders. In both types of diabetes, psychiatric disorders have been linked to treatment nonadherence, worse blood glucose control, and ultimately greater prevalence of micro- and macrovascular complications. Because disease outcomes in diabetes are so dependent on patient behaviors, attitudes, and cognitions, optimal treatment is multidisciplinary, including psychiatrists and other mental health professionals, and takes into account the psychology of individual patients, their support systems, and doctor–patient relationships.

### *Depression and Diabetes*

The prevalence of depression in diabetes is two to three times higher than that found in the general population (Anderson et al. 2001; Gavard et al. 1993). Several studies suggest that patients with depressive disorders appear to develop worse glycemic control and have a heightened risk of diabetes complications such as retinopathy, nephropathy, hypertension, cardiac disease, and sexual dysfunction (Ciechanowski et al. 2000; M. de Groot et al. 2001). However, it remains unclear if depression is a cause

or an effect of poorer outcomes in diabetes. In a recent meta-analysis of 24 studies of depression, hyperglycemia, and diabetes, Lustman et al. (2000a) reported a consistently strong association between elevated hemoglobin A<sub>1c</sub> values (indicating chronic hyperglycemia) and depression. However, they were unable to determine the direction of the association through their analyses, so it remains unclear if hyperglycemia causes depressed mood or if hyperglycemia is a consequence of depression. Further, Lustman et al. (2000a) noted that the relationship may be a reciprocal one, in which hyperglycemia is provoked by depression as well as independently contributes to the exacerbation of depression.

Until recently it was assumed that depression develops as a consequence of diabetes with both psychosocial and biological mechanisms suggested to account for this excess prevalence. Although depression may be a result of complications and disease duration, it has been found to occur relatively early in the course of illness before the onset of complications (Jacobson et al. 2002; Kovacs et al. 1997; Mayou et al. 1991). Therefore, it does not appear that the increased rate of depression in diabetes can be explained solely by emotional reactions to a chronic disease with complications. Another meta-analysis, by M. de Groot et al. (2001), of studies of depression and diabetes indicated that an increase in depressed symptoms was consistently associated with an increase in severity and number of diabetes complications. Depression may cause poorer outcomes in diabetes through biological and behavioral mechanisms because symptoms of depression such as decreased motivation, poor energy, and hopelessness likely interfere with adherence to diabetes treatment and lead to worse glycemic control (M. de Groot et al. 2001).

Studies of type 2 diabetes are less clear with regard to the development of psychiatric disorders (Talbot and Nouwen 2000). The increased rates of depression seen in patients with type 2 diabetes appear in some instances to precede the onset of illness, thereby raising an entirely different hypothesis about the etiological relationship—that is, that depressive disorders themselves may place patients at risk for developing type 2 diabetes. Support for this hypothesis derives in part from the fact that patients with depression can have alterations in the hypothalamic-pituitary axis, which lead to increased rates of cortisol production and other counterregulatory hormones leading to insulin resistance (Musselman et al. 2003). Other biological mechanisms include alterations in central glucose transporter function and increased inflammatory activation (Cameron et al. 1984; Geringer 1990; Hudson et al. 1984). Depressed patients also decrease physical activity and increase cardiovascular risk factors by smoking

and eating high-caloric and fatty foods, which place them at higher risk for developing type 2 diabetes (Marcus et al. 1992).

Some investigators have suggested that the metabolic problems of diabetes (increased rates of hypoglycemia and hyperglycemia) could themselves play a causal role in the development of depression. There is increasing evidence that diabetes leads to changes in white matter in the brain (Dejgaard et al. 1991), and that these white matter abnormalities, if present in regions of the brain involved in affect regulation (e.g., the limbic system), may play a causal role in the development of depression (Jacobson et al. 2000). At this point, such white matter changes are of unknown etiology; however, they may be associated with accelerated vascular disease in diabetes.

Screening measures such as the Beck Depression Inventory (BDI) (Lustman et al. 1992, 2000b; Musselman et al. 2003) may be useful in identifying patients with diabetes and depression. In fact, the BDI has been found to accurately distinguish between depressed and nondepressed patients with diabetes even after elimination of neurovegetative symptoms that could otherwise be attributed to diabetes (Lustman et al. 1992). Diabetes-specific measures of quality of life, such as the Problem Areas in Diabetes Scale (PAID) (Polonsky et al. 1995; Welch et al. 1997, 2003) and the Diabetes Quality of Life Measure (DQOL) (Jacobson 1996; Jacobson et al. 1994), may also be useful in screening patients who are overburdened by the demands of self-care and risk of complications and may be at increased risk for depression.

There is now evidence that specific treatment of depression can lead to improvements in diabetes treatment adherence and improved glycemic control. No large-scale, randomized, controlled trials exist in the area of psychopharmacological treatment of depression in diabetes. However, two small controlled studies have demonstrated that nortriptyline and fluoxetine are effective treatments for depression in diabetes. However, nortriptyline improved mood but did not improve glucose regulation, whereas fluoxetine was associated with improvements in both (Lustman et al. 1997, 2000b). Compared with patients receiving diabetes education only, patients treated with cognitive-behavioral therapy (CBT) to address their depression symptoms showed significant improvements in hemoglobin A<sub>1c</sub> levels (Lustman et al. 1998). It appears that standard treatments for depression not only lead to improvement in depressive symptoms but also can lead to better glycemic control. Thus, whatever the causal links between depression and diabetes, psychiatric treatment can improve psychological and biomedical outcomes (Jacobson and Weinger 1998; Lustman et al. 1998, 2000a).

In summary, the high prevalence of depression and its adverse effects in diabetes, combined with clinically proven treatments, argues for aggressive identification and treatment of depression as early as possible in diabetes. Depression should always be suspected in patients who are having difficulty adapting to diabetes and show poor or worsening glycemic control.

### ***Bipolar Disorder and Diabetes***

A number of studies have demonstrated a significantly increased prevalence of diabetes (mainly type 2) in patients with bipolar disorder: 10%–12% of bipolar outpatients (Cassidy et al. 1999; Ruzickova et al. 2003) and 26% of bipolar inpatients (Regenold et al. 2002) have diabetes. Much of the association appears to be related to more obesity in bipolar patients, which is associated with but not fully accounted for by weight gain–associated psychotropic drugs (McElroy et al. 2002). Several other explanations for the increased prevalence of diabetes in bipolar disorder have been considered, including lifestyle, psychiatric and medical comorbidities, shared genetic risk, and physiological ways either disorder might aggravate the other.

### ***Schizophrenia and Diabetes***

There is a growing literature suggesting that patients with schizophrenia have a risk two to four times greater than that in the general population of developing type 2 diabetes (Dixon et al. 2000). The reasons for this added risk are unclear. It may reflect the generally poor lifestyle choices of individuals with schizophrenia—that is, they are quite sedentary, frequently smoke, and tend to overeat high-carbohydrate and high-fat foods. However, attention has recently been focused on the role played by antipsychotic medications, most of which can cause weight gain, glucose intolerance, and hyperlipidemia (Buse 2002; Dixon et al. 2000; Geller and MacFadden 2003; Henderson 2002; Henderson and Ettinger 2002; Koro et al. 2002; Lindenmayer et al. 2003; Newcomer et al. 2002; Ryan and Thakore 2002; Sernyak et al. 2002) (see Chapter 37, “Psychopharmacology,” for a full discussion). With several of the atypical antipsychotics, the onset of diabetes may occur suddenly and dramatically, with emergent ketoacidosis or hyperosmolar coma, in schizophrenic patients (Buse 2002; Dixon et al. 2000; Geller and MacFadden 2003; Henderson 2002; Henderson and Ettinger 2002; Koro et al. 2002; Lindenmayer et al. 2003; Newcomer et al. 2002; Ryan and Thakore 2002; Sernyak et al. 2002). It is believed that antagonism of serotonin 5-HT<sub>1A</sub> receptors may play a role in decreasing levels of insulin and increasing hyperglycemia (Wirshing et al. 2003). The diabetes typically recedes once the antipsychotic medication is stopped, but it is likely that

sudden emergence of symptoms occurs in patients who already had glucose intolerance, for the increased risk of diabetes among individuals with schizophrenia precedes the use of the atypical agents (Dixon et al. 2000).

Therefore, glucose intolerance should be assessed when treatment with antipsychotics is initiated and should be monitored regularly. Unfortunately, fasting blood glucose is a relatively insensitive method, so that when there is a high index of suspicion (e.g., history of gestational diabetes, family history of diabetes, presence of obesity), postprandial blood glucose testing may be warranted. In patients with known diabetes, antipsychotics least likely to cause weight gain and glucose intolerance should be favored (e.g., aripiprazole and ziprasidone) (see Chapter 37, “Psychopharmacology”).

### ***Eating Disorders and Diabetes***

Despite its promise of reducing long-term complications of type 1 diabetes, a negative side of intensive diabetes management is weight gain (see also Chapter 15, “Eating Disorders”). For example, during the first 6 years of follow-up in the DCCT, patients in the intensively treated group gained an average of 10.45 pounds more than the patients in the standard treatment cohort (Diabetes Control and Complications Trial Research Group 1988). The most recent follow-up data, 9 years after completion of the DCCT, indicated that once patients on intensive treatment gained weight, this weight was difficult to lose (Diabetes Control and Complications Trial Research Group 2001). A survey of patients’ responses to the recommendations of the DCCT study documented that women with type 1 diabetes were especially concerned about tight glucose control causing weight gain (Thompson et al. 1996). It has been argued that the heightened attention to food portions, blood sugars, and risk of weight gain in intensive diabetes management parallels the obsessional thinking about food and body image characteristic of women with eating disorders, and this might place women with diabetes at heightened risk for developing eating disorders. Women with type 1 diabetes may use insulin manipulation (i.e., administering reduced insulin doses or omitting necessary doses altogether) as a means of caloric purging. Intentionally induced glycosuria is a powerful weight loss behavior and a symptom of eating disorders unique to type 1 diabetes.

The most recent controlled studies suggest an increased risk of eating disorders among female patients with type 1 diabetes. For example, Jones et al. (2000) report that young women with type 1 diabetes had 2.4 times the risk of developing an eating disorder and 1.9 times the risk for subclinical eating disorders than age-matched

women without diabetes. Intermittent insulin omission or dose reduction for weight loss purposes has been found to be a common practice among women with type 1 diabetes. For example, in a group of 341 women with type 1 diabetes between ages 13 and 60 years, Polonsky et al. (1994) found that 31% reported intentional insulin omission. Rates of omission peaked in late adolescence and early adulthood, with 40% of women between ages 15 and 30 years reporting intentional omission. This behavior, even at a subclinical level of severity, places women at heightened risk for medical complications of diabetes. Women reporting intentional insulin misuse had higher hemoglobin A<sub>1c</sub> values, higher rates of hospital and emergency room visits, and higher rates of neuropathy and retinopathy than women who did not report insulin omission (Polonsky et al. 1994). In a longitudinal study, Rydall et al. (1997) reported that after 4 years, 86% of patients classified as having high levels of eating disorders had retinopathy, as compared with 43% and 24% of women with moderate or no reported eating disturbance, respectively. Women with diabetes and eating disorders are in poorer glycemic control, with hemoglobin A<sub>1c</sub> values approximately 2 or more percentage points higher than those in similarly aged women without eating disorders (Rydall et al. 1997). The chronic hyperglycemia found in women with diabetes who intentionally omit or reduce their insulin doses places these women at much greater risk for frequent episodes of diabetic ketoacidosis and the long-term onset of macro- and microvascular complications of diabetes.

Because such patients may not use other means of purging (such as self-induced vomiting or laxative abuse), their eating disorders may go undiagnosed. Once established as a long-standing behavior pattern, the problem of frequent insulin omission can be particularly difficult to treat, pointing to the importance of early detection and intervention. Questions like “Do you ever change your insulin dose or skip insulin doses to influence your weight?” can be helpful in screening for insulin omission especially when patients present with persistently elevated hemoglobin A<sub>1c</sub> levels or unexplained diabetic ketoacidosis.

Because obesity is a significant risk factor in type 2 diabetes, recurrent binge eating may increase the chances of developing it in part because of significantly higher body mass index (BMI) (Striegel-Moore et al. 2000). The literature on binge eating in type 2 diabetes is still in its infancy, with initial studies relying on small, nonrepresentative samples. Kenardy et al. (1994) found that 14% of the patients with newly diagnosed type 2 diabetes experienced problems with binge eating compared with 4% of the age-, sex-, and weight-matched control group. Recurrent binge eating can be expected to make it very difficult to control diabetes.

A multidisciplinary team approach, including an endocrinologist or diabetologist, nurse educator, nutritionist with eating disorder and diabetes training, and mental health practitioner, is ideal for the treatment of comorbid eating disorders and diabetes (Kahn and Weir 1994; Mitchell et al. 1997). Depending on the severity of the eating disorder and other comorbid psychopathology, a psychiatrist may also be needed for psychopharmacological evaluation and treatment. At this time, little research has examined treatment efficacy for eating disorders in the context of diabetes; however, a large research literature on treatment outcomes in bulimia nervosa supports the use of CBT in combination with antidepressant medications as the most effective treatment (Peterson and Mitchell 1999; B. T. Walsh and Devlin 1995). These approaches would need to be adapted slightly to directly address the role of insulin omission as the means of caloric purging.

Early on in treatment, intensive glycemic management of diabetes is not an appropriate target for a person with diabetes and an eating disorder. As noted earlier, overly intensive diabetes management may actually aggravate obsessional thinking about food and weight in patients with eating disorders. The first goal should focus on medical stabilization. Gradually, the team can build toward increasing doses of insulin, increases in food intake, greater flexibility of meal plan, regularity of eating routine, and more frequent blood glucose monitoring.

### *Diabetes and Sexual Function*

For information on diabetes and sexual function, see Chapter 17, “Sexual Disorders.”

### *Diabetes and Cognitive Functioning*

Several researchers have studied the impact of diabetes on cognitive functioning. It has been shown that adolescents and children with onset of diabetes before age 6 experience some cognitive difficulties (Bjorgaas et al. 1997; Kaufman et al. 1999; Rovet and Ehrlich 1999; Rovet et al. 1987; Ryan et al. 1985). In a series of longitudinal studies, Northam and colleagues tested children with diabetes 2 and 6 years after diagnosis. They found that speed of processing, vocabulary, learning, and block design performance was worse in these patients as compared with a control group (Northam et al. 1998). In addition, they found that recurrent hypoglycemia predicted worse performance on measures of learning, attention, and short-term memory (Northam et al. 2001). Finally, Northam et al. (1999) found that chronic hyperglycemia led to problems with visual organization as measured by the Rey Complex Figure Test.

Equivocal results have been obtained as to the role of repeated hypoglycemic events on cognition in adults. Deary and colleagues observed mild IQ deficits and slowing of psychomotor speed using a cross-sectional design, whereas the longitudinal analyses from the DCCT suggested no deficits in cognition (Bale 1973; Deary et al. 1993; Langan et al. 1991). Long-term exposure to hyperglycemia and related micro- and macrovascular damage have also been posited to heighten risk of cognitive decline and dementia in diabetes. In fact, two studies report a 60%–100% increased risk for cognitive decline among patients with diabetes as compared with those without diabetes (Gregg and Brown 2003). This increased risk appears to be mediated primarily by an increase in vascular dementia rather than a heightened risk for Alzheimer's disease in diabetes (Gregg and Brown 2003).

### *Hypoglycemia in Diabetic and Nondiabetic Individuals*

Hypoglycemia has been a popular explanation for anxiety symptoms, especially panic attacks, with past widespread use of 5-hour glucose tolerance tests for diagnosis and recommendations for dietary management with multiple small meals. This practice is no longer commonly recommended by physicians, but hypoglycemia is still a popular diagnosis among alternative medicine practitioners and many patients. Symptomatic hypoglycemia rarely occurs except in diabetic (mainly insulin-dependent) patients and patients with insulinomas. Although marked hypoglycemia does cause symptoms of adrenergic hyperactivity, they can be reliably distinguished by patients from panic attacks (Schweizer et al. 1986; Uhde et al. 1984).

However, insulin-induced hypoglycemia is an aversive experience, which has been reported to cause phobic anxiety—that is, a fear of hypoglycemia—in diabetic patients, leading to poorer diabetic control (Green et al. 2000).

## **Thyroid Disorders**

---

Hyperthyroidism and hypothyroidism are accompanied by a variety of physiological, psychiatric, and cognitive symptoms. In this section, we focus on cognitive and psychiatric symptoms associated with thyroid problems.

### **Hyperthyroidism**

Hyperthyroidism is accompanied by a host of physiological symptoms, including nervousness, sweating, fatigue, heat intolerance, weight loss, and muscle weakness (Kornstein et al. 2000). The most common cause of hyper-

thyroidism (or thyrotoxicosis) is Graves' disease. Graves' disease is an autoimmune disorder that results in hyperthyroidism when thyroid-stimulating immunoglobulins (TSIs) bind to thyroid-stimulating hormone (TSH) receptors and mimic TSH. TSIs thereby stimulate the synthesis of hormones ( $T_4$  and  $T_3$ ), while serum TSH levels are very low or undetectable (Porterfield 1997). The factors that trigger this immune response are unknown. Patients with type 1 diabetes are at increased risk for Graves' disease. There is some evidence that stress can precipitate Graves' disease (Santos et al. 2002; Yoshiuchi et al. 1998) and aggravate treated disease (Fukao et al. 2003).

Patients with Graves' disease often present with anxiety, hypomania, depression, and/or cognitive difficulties. Both physiological and psychiatric symptoms correlate poorly with thyroid hormone levels (Trzepacz et al. 1989). These symptoms typically resolve with antithyroid therapy (Alvarez et al. 1983; Kathmann et al. 1994) or with use of beta-blockers such as propranolol (Trzepacz et al. 1988b). Treatment options for Graves' disease include antithyroid medications, thyroidectomy, and radioactive iodine. Graves' disease patients have been reported to have difficulties with sustained attention and visuomotor speed tasks (Alvarez et al. 1983) and with memory and concentration (MacCrimmon et al. 1979). It is possible that the memory and concentration difficulties appear only after long-term thyroid dysregulation. We do know that without treatment for Graves' disease, psychiatric symptoms such as major depressive disorder, generalized anxiety disorder, and hypomania will persist (Trzepacz et al. 1988a). Affective psychosis (e.g., depression and mania) can also result from thyrotoxicosis (Brownlie et al. 2000).

Although thyroid disorders are known to affect behavior, the relationship between thyroid hormones per se and brain functions has not been well studied. To investigate the effect of  $T_3$  (the biologically active thyroid hormone), Kathmann et al. (1994) conducted a study using only healthy subjects. They varied  $T_3$  levels to note the effect on brain performance. They found that subjects made subjective overestimates of time intervals and were able to increase their word fluency, in the absence of more global cognitive problems (Kathmann et al. 1994).

Anxiety and irritability are common in Graves' disease prior to treatment. Only a few studies (Trzepacz et al. 1988b) have investigated the prevalence of psychiatric complaints in hyperthyroid patients and whether these complaints persist after treatment. R.A. Stern et al. (1996) conducted a survey of members of the National Graves' Disease Foundation to investigate patient self-report of psychiatric and cognitive symptoms. The most common symptoms reported were irritability (78%), shakiness

(77%), and anxiety (72%). Slowed thinking was reported by 40%.

In addition to anxiety and cognitive difficulties, some patients with hyperthyroidism experience depression secondary to their medical condition. When patients are given antithyroid therapy, depressive symptoms often disappear. Thus, antithyroid therapy should be the first course of action in treating depression in these patients (Kathol et al. 1986). However, treatment for depression may be indicated if the symptoms are sufficiently problematic or persistent. Hyperthyroidism may present differently depending on the age of the patient. In younger patients, hyperthyroidism typically presents as hyperactivity or anxious dysphoria (Bhatara and Sankar 1999), whereas in the elderly, it can present as apathy or depression (Bailes 1999).

## Hypothyroidism

Hypothyroid patients often experience weakness, fatigue, somnolence, cold intolerance, weight gain, constipation, hair loss, hoarseness, stiffness, and muscle aches (Kornstein et al. 2000). The most common cause of hypothyroidism is autoimmune thyroiditis (Hashimoto's thyroiditis). Hypothyroidism can also be a side effect of lithium. Radioactive iodine, the most commonly used modality for treating hyperthyroidism (such as in Graves' disease), may cause hypothyroidism, which may go undiagnosed for several years after treatment for hyperthyroidism (New York Thyroid Center 2003).

The symptoms of hypothyroidism overlap with retarded depression and the diagnosis is easy to miss in patients already diagnosed as depressed. Physical signs of hypothyroidism include weakness, bradycardia, facial puffiness, weight gain, hair loss, hoarseness, and slowed speech (Kornstein et al. 2000). The best screening test for hypothyroidism is measurement of serum TSH concentration, but an elevated TSH should be followed by a free T<sub>4</sub> determination to confirm the diagnosis. A serum TSH determination will be misleading in the patient with secondary hypothyroidism caused by pituitary or hypothalamic disease. In such a patient, a free T<sub>4</sub> measurement will usually allow the clinician to make the appropriate diagnosis.

Severe hypothyroidism is relatively rare, although milder hypothyroidism is fairly common (Joffe and Levitt 1992). Hypothyroidism can be divided into three grades (Haggerty and Prange 1995). Grade 1 refers to patients with *overt* hypothyroidism who are usually symptomatic and have elevated serum TSH and low serum free T<sub>4</sub> concentrations. Patients with *subclinical* hypothyroidism are classified as having grade 2 or 3; these patients typically

have either mild or no symptoms of thyroid hormone deficiency. The laboratory features of grade 2 hypothyroidism are an elevated serum TSH level and a serum free T<sub>4</sub> level within the normal range. Patients with grade 3 hypothyroidism have normal TSH and free T<sub>4</sub> levels, and the diagnosis can only be confirmed by an exaggerated serum TSH response to thyrotropin-releasing hormone (TRH). Subclinical hypothyroidism is fairly common, affecting 5%–10% of the population, mainly women, and occurs in 15%–20% of women over the age of 45. Subclinical hypothyroidism is particularly common in elderly women.

## Cognitive Function

Hypothyroidism can impair memory function. It is not well understood whether this impairment is limited to memory or whether it extends to other cognitive skills such as attention, inhibition of irrelevant information, and task switching. One possibility is that cognitive inefficiency in hypothyroidism is a result of secondary depression. However, in some cases, cognitive problems are independent of depression. For example, Burmeister et al. (2001) found no relationship between cognitive ability and level of depression in a group of hypothyroid patients (although patients in this study scored within normal limits on most aspects of cognition). This study suggests that patient perceptions of cognitive difficulty (rather than actual cognitive dysfunction) may be a result of depression, fatigue, or response bias.

Patients with subclinical hypothyroidism often show subtle signs of cognitive dysfunction on tests of memory that may improve after treatment (Baldini et al. 1997; Capet et al. 2000; Jensovsky et al. 2002). Further, although most hypothyroid patients who receive treatment are prescribed thyroxine, administration of both thyroxine and triiodothyronine may improve cognitive performance more than thyroxine alone (Bunevicius et al. 1999). More recent studies, however, do not support this observation (Sawka et al. 2003; J.P. Walsh et al. 2003). Mennemeier et al. (1993) demonstrated that after thyroid treatment, some forms of cognition returned to normal levels (e.g., performance on the Object Assembly subtest of the Wechsler Adult Intelligence Scale and on the Peterson-Peterson task that assesses short-term memory), whereas other functions remained impaired (e.g., logical memory or paired-associate learning). Whether to treat subclinical hypothyroidism, however, remains controversial.

## Depression

Hypothyroidism is a known cause of secondary depression. Almost all patients with hypothyroidism have some

concurrent symptoms of depression (Haggerty and Prange 1995). In the early stages of hypothyroidism, circulating  $T_4$  levels drop, while  $T_3$  levels often remain in the normal range. The brain preferentially uses  $T_4$ , as compared with other body tissues, and is thus more sensitive than other areas of the body to lower levels of  $T_4$  (J.J. Haggerty et al. 1990). This imbalance in thyroid hormones may contribute to mood disorder, and subclinical hypothyroidism is now recognized as a potential risk factor for depression (Haggerty and Prange 1995).

Patients with bipolar disorder with either rapid cycling or mixed episodes have particularly high rates of subclinical hypothyroidism. In one study, almost 40% of rapid or mixed episode bipolar patients were found to have subclinical hypothyroidism (although lithium-induced thyroid dysfunction could have contributed) (Joffe et al. 1988). Every patient with rapid-cycling bipolar disorder should be evaluated for (subclinical) hypothyroidism and receive thyroxine if TSH levels are elevated. Some patients may benefit even if they are euthyroid (Haggerty and Prange 1995).

### ***Psychosis***

Untreated hypothyroidism can result in psychosis, so-called myxedema madness. This condition was fairly common—reported in up to 5% of all hypothyroid patients (Kudrjavcev 1978)—before the widespread use of modern thyroid function tests, but it is now rare. Psychotic symptoms typically remit when TSH levels return to normal, although cognitive dysfunction may continue (J. J. Haggerty Jr. et al. 1986). The syndrome can be difficult to diagnose because of confusion between hypothyroidism and primary Axis I psychopathology (Darko et al. 1988). An other rare possibility in hypothyroid patients is Hashimoto's encephalopathy, a delirium with psychosis, seizures, and focal neurological signs, associated with high serum antithyroid antibody concentrations, responsive to corticosteroids, and thought to be an autoimmune disorder (Chong et al. 2003).

### ***Congenital Hypothyroidism***

Congenital hypothyroidism usually occurs as a result of thyroid agenesis or dysgenesis, although inherited defects in thyroid hormone synthesis may also play a role. From a global perspective, iodine deficiency is the most common cause of congenital hypothyroidism. Newborns with untreated hypothyroidism develop the syndrome of cretinism, characterized by mental retardation, short stature, poor motor development, and a characteristic puffiness of the face and hands. Because early treatment is essential to prevent permanent mental retardation, all infants born in

the United States are screened for hypothyroidism at birth (Kooistra et al. 1996). Treatment with thyroid hormones before age 3 months can result in normal intellectual development in the majority of infants.

## **Parathyroidism**

### ***Hyperparathyroidism***

Hyperparathyroidism can cause bone disease, kidney stones, and hypercalcemia via oversecretion of parathyroid hormone (PTH). Symptoms of hypercalcemia include anorexia, thirst, frequent urination, lethargy, fatigue, muscle weakness, joint pain, constipation, and, when severe, depression and eventually coma.

The prevalence of hyperparathyroidism is 0.1%. It is three times more common in women than in men, and its prevalence increases with age. Hyperparathyroidism may occur as a consequence of radiation therapy to head and neck or lithium therapy (Bendz et al. 1996). Prior to 1970, more than 90% of patients with hyperparathyroidism presented with renal disease or bone disease. However, after the introduction of routine calcium screening, fewer than 20% of patients present with renal or bone disease, and more than 50% of patients present with no symptoms at all.

With mild hypercalcemia, patients may show personality changes, lack of spontaneity, and lack of initiative. Moderate hypercalcemia (serum calcium concentration 10–14 mg/dL) may cause dysphoria, anhedonia, apathy, anxiety, irritability, and impairment of concentration and recent memory. In severe hypercalcemia (serum calcium concentration >14 mg/dL), confusion, disorientation, catatonia, agitation, paranoid ideation, delusions, auditory and visual hallucinations, and lethargy progressing to coma may occur (Kornstein et al. 2000). Verbal memory and logical abilities are also impaired (Reus 1986). After treatment of hypercalcemia, psychotic and cognitive symptoms disappear in most patients. However, psychosis has also been reported postparathyroidectomy, possibly because of the rapid decrease in serum calcium concentrations (Reus 1986).

### ***Hypoparathyroidism***

Patients with hypoparathyroidism present with hypocalcemia causing increased neuromuscular irritability. Typical symptoms include paresthesias, muscle cramps, carpopedal spasm, and rarely facial grimacing. Psychiatric symptoms may include anxiety and emotional irritability and lability (Kornstein et al. 2000). Severe hypocalcemia causes tetany and seizures. Hypoparathyroidism is caused by inadequate parathyroid hormone secretion, usually as a result of parathyroid or thyroid surgery.

Kowdley et al. showed that cognitive and neurological deficits are often present in patients with long-standing hypoparathyroidism ( $\geq 9$  years). These deficits are thought to be related to the presence of intracranial calcification and thus irreversible (Kowdley et al. 1999).

## Adrenal Gland Disorders

---

### Cushing's Syndrome

Cushing's syndrome (CS) results from abnormally high levels of cortisol and other glucocorticoids. The most common cause is the pharmacological use of corticosteroids, followed by excessive adrenocorticotrophic hormone (ACTH) secretion (most commonly by a pituitary tumor, referred to as Cushing's disease) and adrenal tumors (Porterfield 1997). Symptoms and signs of CS include truncal obesity and striae, diabetes, hypertension, hyperglycemia, muscle weakness, osteopenia, skin atrophy and bruising, increased susceptibility to infections, and gonadal dysfunction.

CS patients commonly experience a range of psychiatric symptoms (Kornstein et al. 2000), with rates varying widely across studies. Depression is the most prevalent psychiatric disturbance associated with CS. A full depressive syndrome has been reported in up to 50%–70% of cases (Sonino et al. 1998), accompanied by irritability, insomnia, crying, decreased energy and libido, poor concentration and memory, and suicidal ideation (Kornstein et al. 2000). The high prevalence suggests that there is a specific mechanism linking CS and depression. In the past, the depression was attributed to a psychological reaction to the physical symptoms; however, this hypothesis is unlikely because mental symptoms often precede physical changes (Fava 1994; Sonino and Fava 1998, 2001). There is support in the literature for two possible mechanisms linking CS and depression: 1) depression in patients with Cushing's disease may be caused by hypothalamic dysfunction (Sonino et al. 1998), and 2) elevated cortisol levels may directly cause depression in CS (Sonino et al. 1998).

Anxiety has been reported in 12%–79% of cases (Loosen et al. 1992; Starkman and Scheingart 1981; Starkman et al. 1981). Kelly et al. (1996) reported that 3% of CS patients experienced hypomania. Periods of hyperactivity subside as the disease progresses (Starkman and Scheingart 1981; Starkman et al. 1981). There are also case reports of CS patients presenting with a variety of psychotic symptoms, for example, mania (Kathol et al. 1985), schizophreniform psychosis (Hirsh et al. 2000), hallucinations, paranoia, and erotomania (Tadami et al. 1994). A misdi-

agnosis of bipolar disorder has particularly occurred in cyclical CS (Kathol et al. 1985).

Cognition may be impaired in patients with CS. For example, Starkman et al. (2001) found that, compared with a healthy control group, Cushing's disease patients scored poorly on Verbal and Performance IQ measures and had lower memory quotients, with verbal skills the most affected. The deficits in cognitive function were not explained by depression (Starkman et al. 2001). The neocortex and the hippocampus are rich in glucocorticoid receptors (Sapolsky 2000; Starkman et al. 2001), so it is not surprising that learning and memory are affected in CS. In fact, Cushing's disease causes reduction in hippocampal volume, reversible after cortisol levels return to normal. This effect is age-dependent, such that the older the individual, the less plastic is the hippocampus and the less susceptible the patient is to recovery (Starkman et al. 1999).

Cushing himself acknowledged that psychological "traumas" might play a role in the pathogenesis of adrenal disorders (Sonino 1997). Indeed, there is a small body of research suggesting that patients with Cushing's disease experience more stressful events in the year before diagnosis compared to patients with pituitary tumors secreting growth hormone and prolactin (Kelly et al. 1996; Sonino and Fava 2001). Furthermore, there is evidence that stressful events play a causal role in the development of Cushing's disease but not in other forms of CS (Mazet et al. 2003; Sonino and Fava 1998). Therefore, the relationship of stressful life events to the onset of Cushing's disease is comparable to the relationship of such events to the onset of depression in general (Fava et al. 1981).

### Adrenal Insufficiency: Addison's Disease and ACTH Deficiency

Insufficient production of adrenal corticosteroids can be caused by a number of mechanisms. Primary adrenal insufficiency, or Addison's disease, results in deficient secretion of mineralocorticoids and glucocorticoids. The major causes of Addison's disease are autoimmune destruction of the adrenal cortex, tuberculosis, and HIV (Kornstein et al. 2000). The most common cause of secondary adrenal insufficiency is suppression of ACTH secretion by chronic glucocorticoid administration. Less common secondary causes include diseases that result in pituitary destruction. In secondary adrenal insufficiency, ACTH levels are low, whereas in Addison's disease, the deficiency in cortisol results in an increase in ACTH production. This increase in ACTH can cause hyperpigmentation, particularly in sun-exposed skin, scars, and mucous membranes.

The decrease in mineralocorticoid levels results in contraction of the extracellular volume, leading to postural hypotension. In addition to hypotension, individuals with adrenal insufficiency are prone to hypoglycemia when stressed or fasting. Although electrolytes can be normal in mild Addison's disease, hyponatremia and hyperkalemia are typical (Kornstein et al. 2000). Water intoxication with hyponatremia can occur if a water load is given, because cortisol deficiency impairs the ability to increase free water clearance. Other manifestations of adrenal insufficiency include anemia, anorexia, nausea, vomiting, diarrhea, abdominal pain, weight loss, and muscle weakness.

Although there has been no formal study, psychiatric symptoms such as apathy, social withdrawal, fatigue, anhedonia, poverty of thought, and negativism have been reported in up to 60%–90% of patients with Addison's disease (Popkin and Mackenzie 1980). Some form of depression has been observed in 30%–50% of patients (Kornstein et al. 2000). Nonspecific symptoms such as weakness, fatigue, and anorexia often appear before more specific findings, making it difficult to attribute the cause to adrenal insufficiency. Cognitive impairment, especially memory loss, is often present but ephemeral and varying in severity. During Addisonian crisis, patients may experience delirium, disorientation, confusion, and even psychosis (Kornstein et al. 2000). Adrenal insufficiency is particularly likely to be misdiagnosed as primary major depression in patients with chronic medical illness previously treated with high doses of corticosteroids, resulting in unrecognized secondary adrenal insufficiency.

Although the diagnosis of adrenal insufficiency may be suspected on the basis of a low serum cortisol in the morning, definitive diagnosis requires an ACTH stimulation test. This is typically performed using cosyntropin, a synthetic ACTH analogue. An increase in the serum cortisol concentration to greater than 20 ng/dL following cosyntropin injection excludes the diagnosis of adrenal insufficiency.

The cause of depression in patients with Addison's disease is not clear. Regardless of the etiology of adrenal insufficiency, urgent treatment is indicated. Both glucocorticoid and mineralocorticoid replacement are usually necessary in the treatment of Addison's disease, whereas glucocorticoid replacement alone is sufficient in secondary adrenal insufficiency.

Adrenal insufficiency is also a feature in adrenoleukodystrophy, a rare, X-linked inherited metabolic disease, which also leads to leukoencephalic myeloneuropathy. Adult onset is rare but commonly presents with psychiatric symptoms, including mania, psychosis, and cognitive dysfunction (Garside et al. 1999).

## Acromegaly

---

Acromegaly is a disease of excess growth hormone (GH) secretion. Deficiency of growth hormone in children results in short stature, as discussed in Chapter 34, "Pediatrics." The most common cause of acromegaly is a GH-secreting adenoma of the anterior pituitary. These benign tumors account for 30% of all hormone secreting pituitary adenomas (L.J. DeGroot et al. 2001). Clinical manifestations of acromegaly include headache, cranial nerve palsies, acral enlargement (frontal bossing), increased hand and foot size, prognathism, soft tissue overgrowth (macroglossia), glucose intolerance, and hypertension (Melmed 2001). Suprasellar extension of the tumor may cause visual field defects.

Psychiatric disturbances associated with acromegaly, described in 1951 in a study of 28 patients, include mood lability and personality changes (Bleuler 1951). Cases of patients with acromegaly and depression (Avery 1973; Margo 1981), and less commonly psychosis (Schulte 1976), have been reported. Psychiatric symptoms in acromegaly have been attributed to the endocrine disorder itself and the psychosocial stress of disfigurement (Abed et al. 1987). Personality change, including loss of initiative and spontaneity with marked lability in mood, has been described in acromegalic patients (Pantanetti et al. 2002). However, one study of 60 acromegalic patients concluded that although psychiatric morbidity was higher in the women versus the men, there was no increase in psychiatric morbidity in general, nor was there an increased incidence of depression in comparison with the general population (Abed et al. 1987). Additionally, the authors found no relationship between GH levels and scores on the Present State Examination, a standard psychiatric interview. Thus, the literature to date does not conclusively support any particular increase in psychopathology in acromegaly.

Treatment of acromegaly may include surgery, medication, and radiation. Surgery is the primary treatment for GH-secreting pituitary adenomas and may enhance the effectiveness of subsequent medical therapy (L.J. DeGroot et al. 2001). Medical management includes somatostatin analogues (e.g., octreotide), dopamine agonists (e.g., bromocriptine), and radiation. High doses of bromocriptine are often necessary to reduce levels of GH, which increases the incidence of adverse effects. The treatment of acromegaly with bromocriptine has been associated with psychotic reactions (Boyd 1995; Le Feuvre et al. 1982; Turner et al. 1984). In a study of 600 patients with pituitary tumors treated with dopamine agonists, 1.3% experienced auditory hallucinations, delusions, and mood

changes (Turner et al. 1984). A GH receptor antagonist, pegvisomant, has recently become available as another option for patients for whom surgery fails, and it has few adverse effects (Clemmons et al. 2003).

## Pheochromocytoma

---

Pheochromocytomas are rare catecholamine-secreting tumors derived from the adrenal medulla and sympathetic ganglia. The clinical signs and symptoms result from the release of catecholamines, leading to increased heart rate, blood pressure, myocardial contractility, and vasoconstriction (Keiser 1991). Symptoms of pheochromocytoma can include headache, profuse sweating, palpitations, apprehension, and a sense of impending doom (Melmed 2001). Because these are nonspecific symptoms, pheochromocytomas may mimic anxiety disorders (especially panic), migraine or cluster headaches, amphetamine or cocaine abuse, alcohol withdrawal, brain tumors, subarachnoid hemorrhage, neuroblastoma in children, or temporal lobe seizures (L.J. DeGroot et al. 2001).

Cases of classic panic attacks in patients with pheochromocytoma have been reported in both adults and children (Carre 1996; Gokce et al. 1991; Prokhorova and Fritz 2002). Less commonly, depression has been observed (Gokce et al. 1991). Lambert (1992) described a patient with undiagnosed pheochromocytoma presenting as an exacerbation of PTSD and proposed that release of catecholamines from the tumor may have triggered dissociation.

Both tricyclic antidepressants (TCAs) and serotonin reuptake inhibitors have unmasked silent pheochromocytomas (Korzets et al. 1997; Lefebvre et al. 1995). The mechanism of action of TCAs is via inhibition of neuronal uptake of the high circulating levels of catecholamines (Korzets et al. 1997), and monoamine oxidase inhibitors (MAOIs) would be expected to be even more hazardous. The mechanism with selective serotonin reuptake inhibitors (SSRIs) is less clear (Seelen et al. 1997).

The diagnosis of pheochromocytoma is made by measurement of 24-hour urine to document increased excretion of catecholamines or catecholamine metabolites, including vanillylmandelic acid (VMA) and metanephrines. The availability of plasma metanephrine assays has greatly simplified the evaluation of the patient with a suspected pheochromocytoma. Plasma metanephrine determinations have an extremely high sensitivity, approaching 99%, and overall specificity in the 85%–90% range (Lenders et al. 2002). The finding of elevated urinary catecholamine levels is not specific for pheochromocytoma and can lead to misdiagnosis. A variety of psychological and

physiological stressors can elevate levels of urinary catecholamines (Dimsdale and Ziegler 1991; Fukuda et al. 1996). Urinary VMA levels can be elevated with ingestion of foods high in vanillin, including vanilla extract, bananas, coffee, nuts, and citrus fruits (Sheps et al. 1990). Elevated urinary VMA levels are the least specific indicator of pheochromocytoma, whereas elevated metanephrines are the most sensitive (T.A. Stern and Cremens 1998). Misdiagnosis of pheochromocytoma has been reported in patients with hypertension and raised urinary catecholamines who were taking clozapine (Krentz et al. 2001; Li et al. 1997) or selegiline (Cook and Katritsis 1990; Lefebvre et al. 1995).

Multiple cases of factitious pheochromocytoma have been reported (Hyams et al. 1985; Kailasam et al. 1995; Keiser 1991; Spitzer et al. 1998; T.A. Stern and Cremens 1998). Case reports include intentional vanilla extract ingestion (T.A. Stern and Cremens 1998), phenylpropanolamine abuse (Hyams et al. 1985), surreptitious injection of catecholamines intravaginally (Spitzer et al. 1998), epinephrine injection (Keiser 1991), and conscious altering of autonomic function with Valsalva maneuvers (Kailasam et al. 1995).

The rare possibility of a pheochromocytoma should be considered in patients with panic attacks, headaches, and labile hypertension, particularly those who do not respond to treatment. It is not necessary to screen for pheochromocytoma in patients who only have psychiatric symptoms; elevated catecholamines are common and likely to be false positives. Some psychotropic drugs may cause hypertensive reactions that mimic pheochromocytoma, and in other cases, the drugs may be unmasking an unsuspected pheochromocytoma.

## Hyperprolactinemia

---

Hyperprolactinemia is the most common pituitary hormone hypersecretion syndrome (Melmed 2001). The differential diagnosis of hyperprolactinemia includes pituitary adenomas, physiological causes (pregnancy and lactation), medication effects, chronic renal failure (via decreased peripheral PRL clearance), primary hypothyroidism, and lesions of the pituitary stalk and the hypothalamus (e.g., hypothalamic tumors). Clinical signs in women include galactorrhea, menstrual irregularities, infertility, and decreased libido. Men present with diminished libido and rarely with galactorrhea. The relationship between elevated prolactin and affective disorder was first described by Sachar et al. (1973).

Numerous studies and case reports demonstrate an association between hyperprolactinemia and depression

and anxiety, as well as resolution of symptoms with treatment of hyperprolactinemia (Cohen 1995; Fava et al. 1983; Holroyd and Cohen 1990; Reavley et al. 1997; Thienhaus and Hartford 1986). Fava et al. (1982) found that hyperprolactinemic patients reported a significant increase in symptoms of depression, anxiety, and hostility compared with amenorrheic and healthy control subjects. However, the link between hyperprolactinemia and depression has been disputed because of small sample sizes and different inclusion criteria across studies (Merritt 1991). In a sample of 65 women with hyperprolactinemia, a surprisingly high prevalence of anxiety and a small increase in measures of hostility were found, yet no significant difference was seen in the prevalence or severity of depression (Reavley et al. 1997). The authors of this study subdivided subjects with hyperprolactinemia into those with pituitary adenomas on computed tomography (CT) versus those with normal CT scans. The subgroup of patients with normal CT scans had an increased prevalence of anxiety, which was thought to be secondary to “functional hyperprolactinemia.” The authors proposed that this subgroup had a primary psychiatric disturbance with secondary increased prolactin.

Medication-induced hyperprolactinemia has been associated with antipsychotics and, to a lesser extent, antidepressants. Conventional antipsychotic drugs block dopamine D<sub>2</sub> receptors on lactotroph cells and thus remove the main inhibitory influence on prolactin secretion (Wieck and Haddad 2003). Prolactin levels between 10 and 100 ng/L are typical in drug-induced hyperprolactinemia (Melmed 2001). Serum prolactin levels in patients taking therapeutic doses of typical neuroleptics are increased six- to tenfold from mean baseline prolactin levels (Arvanitis and Miller 1997; Gruen et al. 1978; Kuruvilla et al. 1992; Meltzer and Fang 1976; Oseko et al. 1988).

Atypical antipsychotics vary with respect to their effects on prolactin. Clozapine, quetiapine, and olanzapine either cause no increase in prolactin secretion or increase prolactin transiently (Meltzer et al. 1979; AstraZeneca 1998; Small et al. 1997; Tollefson and Kuntz 1999), but sustained hyperprolactinemia can occur in patients taking risperidone (Becker et al. 2003). Haloperidol raises the serum prolactin concentration by an average of 17 ng/mL, whereas risperidone may raise it by 45–80 ng/mL, with larger increases in women than in men (David et al. 2000).

Antidepressants with serotonergic activity, including SSRIs, MAOIs, and some TCAs, can cause modest elevations of prolactin (Checkley 1991; Haddad et al. 2001) and may further elevate prolactin levels in patients also taking prolactin-elevating antipsychotics (Wieck and Haddad 2003).

Women taking psychiatric medications that chronically elevate prolactin levels are at risk for premature bone loss secondary to hypoestrogenism. Patients taking prolactin-elevating antipsychotics should be educated about—and regularly monitored for—signs and symptoms of hyperprolactinemia (David et al. 2000; Haddad et al. 2001).

In patients with affective disorders who are both unresponsive to treatment and have galactorrhea and/or amenorrhea, hyperprolactinemia should be considered as a causal factor (Holroyd and Cohen 1990).

## Gonadal Disorders

---

### Perimenstrual Disorders and Menopause

For information on perimenstrual disorders and menopause, refer to Chapter 33, “Obstetrics and Gynecology.”

### Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a common disorder, affecting 5%–10% of women of childbearing age. Clinical manifestations include amenorrhea or oligomenorrhea, infrequent or absent ovulation, increased levels of testosterone, infertility, truncal obesity or weight gain, alopecia, hirsutism, acanthosis nigricans, hypertension, and insulin resistance. The cause of the disorder is unknown. There is some evidence that valproate is associated with PCOS (McIntyre et al. 2003; O'Donovan et al. 2002).

There are adverse psychosocial consequences of PCOS. Women with PCOS may complain they feel “abnormal or freakish” (Kitzinger and Willmott 2002), related to hirsutism, obesity, and altered reproductive function (Eggers and Kirchengast 2001; Kitzinger and Willmott 2002). A study using standardized self-report measures found that social phobia, anxiety, and depression may occur in one-third to two-thirds of women with PCOS (Barth et al. 1993). Psychological problems have been commonly reported in women with hirsutism of any cause (Sonino et al. 1993). Although these physical abnormalities may affect feelings of self-worth and femininity, some research suggests that psychological morbidity, such as depression, may be caused by hormonal shifts in PCOS, not psychosocial factors (Derogatis et al. 1993). Rasgon et al. (2002) reported a patient with treatment-resistant depression and untreated PCOS whose depressive symptoms resolved when she was treated with metformin and spironolactone. In a sample of 32 women with PCOS, 16 had CES-D scores indicative of depression (Rasgon et al. 2003). Although the causal linkage between

psychological symptoms and PCOS is not resolved, their frequency points to the importance of screening all PCOS patients for psychiatric syndromes, especially depression.

## Testosterone Deficiency

Testosterone deficiency in men can result from diseases affecting the testes, pituitary gland, or hypothalamus. Consequences of testosterone deficiency vary depending on the stage of sexual development. Testosterone production declines naturally with age, so that a relative testosterone deficiency occurs in older males. Hypogonadal disorders of the testes (primary hypogonadism) are most commonly caused by Klinefelter's syndrome, mumps orchitis, trauma, tumor, cancer chemotherapy, or immune testicular failure (see Chapter 28, "HIV/AIDS," for a discussion of hypotestosteronism in HIV infection). Pituitary lesions caused by tumors, hemochromatosis, sarcoidism, or cranial irradiation can lead to secondary hypogonadism. The classic cause of hypothalamic hypogonadism is Kallmann's syndrome (hypogonadotropic hypogonadism with hyposmia, sensorineural hearing loss, oral clefts, micropenis, and cryptorchidism). Hypogonadism in childhood is characterized by failure of normal secondary sexual characteristics to develop and diminished muscle mass. In adult men, typical complaints are sexual dysfunction, diminished energy, decreased beard and body hair, muscle loss, and breast enlargement.

Although it has been suggested that decreasing testosterone levels as men age may be associated with changes in mood and cognition, there is no clear relationship between psychiatric syndromes and testosterone level (Sternbach 1998). However, a recent study found an adjusted hazard ratio for depression in hypogonadal men of 4.2 (95% CI=1.5–12.0,  $P=0.008$ ) (Shores et al. 2004). The concept of a male climacteric and related mood, anxiety, and cognitive disorders is controversial (Sternbach 1998).

Patients with Klinefelter's syndrome (XYY) are reported to have higher rates of mental retardation and a wide variety of psychiatric and behavioral symptoms, but these are a consequence primarily of the chromosomal abnormality rather than hypogonadism (Swanson and Stipes 1969).

Questions remain about the value of testosterone replacement in age-related testosterone decline as well as in the treatment of depressive disorder in hypogonadal men. Testosterone appears to improve mood, as well as sexual dysfunction and muscle strength, in hypogonadal men (Wang et al. 2000). However, a placebo-controlled trial of intramuscular testosterone in hypogonadal men with major depressive disorder whose depression did not respond

to SSRIs demonstrated no antidepressant benefits (Seidman and Rabkin 1998). The potential serious side effects of testosterone should be carefully considered before initiating replacement therapy in men with age-related low testosterone levels (Nolten 2000).

Testosterone deficiency in women can cause impaired sexual function, low energy, and depression, but what level represents deficiency and the indications, risks, and benefits of replacement are even less well defined than in men (Padero et al. 2002).

## Other Metabolic Disorders

---

### Electrolyte and Acid–Base Disturbances

#### *Hyponatremia*

Hyponatremia's principal manifestations are neuropsychiatric, and their severity is related both to the degree and rapidity with which it develops. Patients may have lethargy, stupor, confusion, psychosis, irritability, and seizures. There are many different causes, but those of particular psychiatric relevance include the syndrome of inappropriate antidiuretic hormone secretion (SIADH), which can be caused by many psychotropic drugs (especially carbamazepine), and psychogenic polydipsia. The signs of hypernatremia are also predominantly neuropsychiatric and include cognitive dysfunction, delirium, seizures, and lethargy progressing to stupor and coma. Similar symptoms are seen with any hyperosmolar state, for example, extreme hyperglycemia. Hypernatremia is usually caused by dehydration with significant total body water deficits.

#### *Hypokalemia*

Hypokalemia produces muscular weakness and fatigue and, if severe, may cause severe paralysis (hypokalemic periodic paralysis), but central nervous system functions are not typically affected. Nevertheless, patients with symptomatic hypokalemia are sometimes misdiagnosed as depressed. Hypokalemia is very common in eating disorders. (See Chapter 15, "Eating Disorders," for full discussion of the metabolic complications of eating disorders.) The adverse effects of hyperkalemia are mainly cardiac, but severe muscle weakness may also occur.

#### *Hypocalcemia, Hypercalcemia, Hypomagnesemia, and Hypermagnesemia*

Hypocalcemia and hypercalcemia were described earlier in this chapter under parathyroid disorders. Magnesium levels usually rise and fall in concert with calcium levels.

Hypomagnesemia can cause anxiety, irritability, tetany, and seizures. Low magnesium levels are very common in alcoholic patients and in refeeding starving patients (including those with anorexia nervosa and catatonia). Cyclosporine causes hypomagnesemia, which can contribute to its neuropsychiatric side effects (Craven 1991). Hypomagnesemia is much less common, but it causes central nervous system depression.

### *Hypophosphatemia*

Hypophosphatemia causes anxiety, hyperventilation, irritability, weakness, delirium, and, if severe, seizures, coma, and death, in addition to symptoms in many other organ systems. Hypophosphatemia occurs in the same settings as hypomagnesemia.

### *Acidosis and Alkalosis*

Metabolic acidosis results in compensatory hyperventilation. When the acidosis is severe and acute, as in diabetic ketoacidosis, fatigue and delirium are present and may progress to stupor and coma. Patients with chronic metabolic acidosis appear depressed, with prominent anorexia and fatigue. Patients with severe metabolic alkalosis present with apathy, confusion, and stupor. Respiratory acidosis results from ventilatory insufficiency; and respiratory alkalosis, from hyperventilation (see Chapter 20, "Lung Disease").

## Vitamin Deficiencies

The clinical signs of vitamin B<sub>12</sub> deficiency can include megaloblastic anemia, myelopathy (subacute combined degeneration), dementia, delirium, peripheral neuropathy, and a variety of psychiatric symptoms including psychosis, anxiety, mood disorder, catatonia, and personality change. Psychiatric symptoms may be the sole presenting complaint and can occur even in the absence of hematological changes. Vitamin B<sub>12</sub> deficiency occurs most often in pernicious anemia, but it also should be suspected in chronic peptic ulcer disease, after gastrectomy or gastric bypass, in alcohol dependence, in inflammatory bowel disease, and in eating disorders, as well as in vegetarians and malnourished individuals. Vitamin B<sub>12</sub> deficiency can be masked by folate supplementation or iron deficiency (Kunkel et al. 2000).

Folate deficiency causes cognitive dysfunction and depression. The hematological abnormalities are similar to those in B<sub>12</sub> deficiency. Folate deficiency was common in pregnancy until supplementation became part of routine prenatal care. Folate deficiency occurs frequently in patients taking certain anticonvulsants, in the elderly, in al-

coholic persons, in patients with eating disorders, and in other malnourished populations.

Pellagra, originally thought to be a deficiency of niacin, is now recognized to be a complex deficiency of multiple vitamins and amino acids. The classic triad of symptoms is dermatitis, dementia, and diarrhea, but psychosis, apathy, insomnia, and delirium have all been reported. Pellagra is now rare in the developed nations, but cases are still reported in anorexia nervosa, inflammatory bowel disease, and alcoholism.

Thiamine deficiency (beriberi) causes cardiac and neuropsychiatric syndromes, including peripheral neuropathy and Wernicke-Korsakoff encephalopathy. Wernicke's consists of vomiting, nystagmus, ophthalmoplegia, fever, ataxia, and confusion that can progress to coma and death. Korsakoff's is a dementia with amnesia, impaired ability to learn, confabulation, and often psychosis. Improvement usually occurs with thiamine replacement but may be slow. Giving intravenous glucose to a thiamine-deficient patient without coadministering thiamine may precipitate acute beriberi. Thiamine deficiency is well known and most frequent in alcoholic patients, but it also occurs in patients undergoing chronic dialysis, patients refeeding after starvation (including patients with anorexia nervosa), and individuals on fad diets.

Pyridoxine (vitamin B<sub>6</sub>) deficiency causes peripheral neuropathy and neuropsychiatric disorders, including reports of seizures, migraine, chronic pain, depression, and psychosis. Homocysteine is elevated in B<sub>6</sub> deficiency and may play a role in accelerating vascular disease and dementia. Pyridoxine deficiency is common because many drugs act as its antagonists. Clinical trials of B<sub>6</sub> supplementation in healthy elderly subjects to date have not shown improvements in mood or cognition, but there have been no controlled trials in the cognitively impaired (Malouf and Grimley 2003).

Vitamin E deficiency can cause areflexia, ataxia, and decreased vibratory and proprioceptive sensation. Although an association between low vitamin E levels and depressive symptoms has been reported, the data to date do not support this (Tiemeier et al. 2002).

## Porphyrias

The porphyrias are a group of rare disorders of heme biosynthesis that can be inherited or acquired. Neuropsychiatric manifestations occur in the two neuroporphyrins (acute intermittent porphyria and plumboporphyria) and two neurocutaneous porphyrias (hereditary coproporphyrin and variegate porphyria) (Gonzalez-Arriaza and Bostwick 2003). Acute intermittent porphyria is the most common. Recurrent acute attacks are typical in all four,

with variable manifestations. In acute porphyria, the cardinal signs are abdominal pain, peripheral neuropathy, and mental disturbances (Regan et al. 1999). Psychiatric symptoms, including anxiety, depression, psychosis, and delirium, have been reported in 20%–58% of cases (Ibrahim and Carney 1995). Seizures, autonomic instability, dehydration, electrolyte imbalance, and dermatological changes may also occur. Symptoms may vary considerably among patients and in the same patient over a period of time, and they can mimic symptoms of other psychiatric and medical disorders, making diagnosis a challenge. The diagnosis is made by measuring porphyrins and their metabolites in stool and urine during an acute episode. Between episodes, porphyrin levels return to normal. Diagnosis is more likely to be made when there is a high index of suspicion. The diagnosis may be especially difficult because neuropsychiatric symptoms may continue well after the end of an acute episode. Therapy is primarily supportive and includes identifying precipitants. Although barbiturates clearly can trigger attacks, there is inadequate evidence regarding the role of other psychotropic drugs. Whether stress is a precipitant remains controversial (Gonzalez-Arriaza and Bostwick 2003; Holroyd and Seward 1999; Ibrahim and Carney 1995).

## Conclusion

Endocrine and metabolic disorders frequently occur in conjunction with common psychiatric conditions. The causal linkages and mechanisms vary widely. In some situations, the endocrine state manifests in part as a psychiatric condition. In other instances, the psychiatric condition may be a complex biopsychosocial and/or biological response to the endocrine disorder. Psychiatric conditions and their treatment may also increase risk of endocrine disorders. Moreover, treatment with psychotropic drugs can induce endocrinopathies. Consequently, understanding the ways in which these disorders intersect represents an important facet of knowledge for the practitioners treating patients with psychiatric and/or endocrine disorders.

---

Mary Jane Massie, M.D.

Donna B. Greenberg, M.D.

**CANCER IS A** major public health problem in the United States and other developed nations. In 2004, more than 1.4 million new cases of cancer will be diagnosed and more than one-half million people will die of cancer in the United States (Jemal et al. 2004). Although one in four deaths is now caused by cancer, there has been a decline in death rates from many cancers, including those of the prostate, breast, colon, and rectum. However, as the death rate decreases and the population ages, there will be more people living with cancer, with an anticipated doubling from 1.3 million to 2.6 million between the years 2000 and 2050. Although only modest cancer-specific survival differences are evident for blacks and whites receiving comparable treatment for similar-stage cancer, African Americans still carry a higher burden because they are often diagnosed at a later stage and have poorer survival within each stage. Differences in access to treatment, stage at presentation, and mortality from other diseases represent the primary targets of research and interventions designed to reduce disparities in cancer outcomes (Bach et al. 2002).

In this chapter, we review psychological factors in cancer risk and progression, the most frequently encountered psychiatric disorders (depression, anxiety, and delirium) in adult cancer patients, psychiatric issues in specific cancers, psychiatric aspects of cancer treatments, psychiatric interventions in cancer patients, survivor issues, and cancer patients' use of complementary and alternative medicine treatments. See Chapter 34, "Pediatrics," for additional coverage of cancer in children.

---

## Psychological Factors Affecting Cancer Risk and Progression

---

Although many people believe that psychological factors play a major role in cancer onset and progression, scientific evidence has not yet clarified these relationships, and the role of psychological factors remains controversial (Levenson and McDonald 2002).

The most active area has been the effort to link depression with the onset and course of cancer. Depressive symptoms were associated with a higher-than-normal frequency of cancer and twice as high a risk for death from cancer in an early large epidemiological study (Persky et al. 1987; Shekelle et al. 1981). Later epidemiological studies and a meta-analysis did not find statistically or clinically significant associations (Gallo et al. 2000; McGee et al. 1994; Vogt et al. 1994).

Others have wondered whether emotional states affect outcome in cancer patients. Emotional distress may predict lower survival with lung cancer (Faller et al. 1999), as may anger in metastatic melanoma patients (Butow et al. 1999). Other studies have found positive, negative, or mixed associations between depression and mortality in cancer patients (Garssen and Goodkin 1999; Watson et al. 1999). Depression may directly affect the course of illness in patients with cancer because it results in poorer pain control (Glover et al. 1995), poorer compliance (Ayres et al. 1994), and less desire for life-sustaining therapy (Lee and Ganzini 1992).

---

Dr. Massie gratefully acknowledges Theresa Carpenter's and Alex Pisani's assistance in the preparation of this chapter and the continued generous support of her work by William E. Pelton and Sylvia Rosenberg.

The finding that bereavement is associated with a decrement in immune function rekindled an interest in whether bereavement affects cancer risk (Schleifer et al. 1983), but neither cancer onset nor progression has been clearly shown to be influenced by bereavement (Helsing and Szklo 1981; Levav et al. 2000; McKenna et al. 1999).

Cancer patients' degree of emotional expressiveness and its possible effect on prognosis have been the subject of a large body of literature. Early descriptive case reports noted shorter survival in patients with a depressed, resigning attitude compared with patients who were able to express more negative emotions, such as anger. Using a variety of conceptualizations of the "expressive" versus "repressive" dichotomy in various cancer types, several investigators found reduced cancer risks in more expressive subjects (G.A. Kune et al. 1991; Temoshok et al. 1985). Other clinical and epidemiological studies have not supported such an influence in cancer risk or in cancer mortality (Buddeberg et al. 1991; Cassileth et al. 1985; Ragland et al. 1987; Shekelle et al. 1981). In separate studies, investigators found that patients with breast cancer (Greer et al. 1979) and those with leukemia (Tschushke et al. 2001) who had a "fighting spirit" had longer survival than those with stoic acceptance or those who were hopeless or helpless, but other outcome studies in cancer patients found no such association (Watson et al. 1999).

Social relations and social support are complex phenomena. How they affect cancer patients may vary with cancer site and extent of disease (Helgeson and Cohen 1996). Some research has tentatively linked life stressors with cancer recurrence or progression, although not unequivocally (Ramirez et al. 1989). More frequent stressful life events preceding the onset of cervical, pancreatic, gastric, lung, colorectal, and breast cancer have been shown in a number of human studies (Geyer 1991; S. Kune et al. 1991). Many other studies have failed to find any association between preceding stressful life events and cancer onset, relapse, or progression (Giraldi et al. 1997; Maunsell et al. 2001). Occupational stress might increase the risk of lung cancer (Jahn et al. 1995; Lynge and Anderson 1997) and colorectal cancer (Courtney et al. 1993).

## Psychiatric Disorders in Cancer Patients

---

A person's ability to manage a cancer diagnosis and treatment commonly changes over the course of the illness and depends on medical, psychological, and social factors: the disease itself (i.e., site, symptoms, clinical course, prognosis, type of treatments required); prior level of

adjustment; the threat that cancer poses to attaining age-appropriate developmental tasks and goals (i.e., adolescence, career, family, retirement); cultural, spiritual, and religious attitudes; the presence of emotionally supportive persons; the potential for physical and psychological rehabilitation; the patient's own personality and coping style; and prior experience with loss.

## Depression

Depression has received the most attention in cancer patients and has been challenging to study because symptoms span the spectrum from sadness to major affective disorder, and mood change is difficult to evaluate when a patient experiences repeated threats to life, cancer treatments, fatigue, and pain. In other words, depressive symptoms may represent a normal reaction, a psychiatric disorder, or a somatic consequence of cancer or its treatment. Many depressed patients adhere poorly to treatment schedules and other recommendations; some may have reduced chance of survival (Faller and Bülzebruck 2002; Watson et al. 1999).

Cancer, exclusive of site, is associated with a rate of depression that is higher than that in the general population and at least as high as the rate associated with other serious medical illnesses (Massie 2004). Depression has been studied in patients with cancer using a range of assessment methods (Trask 2004), including self-report, brief screening instruments, and structured clinical interviews. In general, the more narrowly the term is defined, the lower the prevalence of depression that is reported. The clinical rule of thumb is that 25% of cancer patients are likely depressed enough at some point in the course of disease to warrant evaluation and treatment. Many research groups have assessed depression in cancer patients, with widely variable reported prevalence (major depression, 0%–38%; depression spectrum syndromes, 0%–58%) in more than 150 studies (Massie 2004). Cancer types highly associated with depression include oropharyngeal (22%–57%), pancreatic (33%–50%), breast (1.5%–46%), and lung (11%–44%). The prevalence of depression is reported to be less in patients with other cancers, such as colon cancer (13%–25%), gynecological cancer (12%–23%), and lymphoma (8%–19%) (Massie 2004). It is difficult to compare the prevalences reported in different studies because each study uses different definitions of depression, and because the time since diagnosis and the cancer type, stage, and treatments often vary. Whether high rates of depression associated with some cancers result from the pathophysiological effect of the tumor (e.g., pancreatic cancer) or from treatment effects (e.g., steroids) is not clear.

Depression in cancer patients results from 1) stress related to the cancer diagnosis and treatment; 2) medications; 3) underlying neurological or medical problems, such as nutritional deficiencies (e.g., folate, B<sub>12</sub>), endocrine disturbances (e.g., thyroid abnormalities, adrenal insufficiency), brain metastases, and leptomeningeal disease; or 4) recurrence of a preexisting affective disorder. Whereas the diagnosis of depression in physically healthy patients depends heavily on the somatic symptoms of anorexia, fatigue, and weight loss, these indicators are of less value in the assessment of a cancer patient, because they are common to both cancer and depression. Clinical diagnosis rests on psychological symptoms: social withdrawal; anhedonia; dysphoric mood; feelings of hopelessness, helplessness, worthlessness, or guilt; poor self-esteem; or suicidality. Cancer patients likely at higher risk for depression are those in poor physical condition and in the advanced stages of illness who have inadequately controlled pain, a history of depression, or other significant life stresses or losses (Massie and Popkin 1998; Newport and Nemeroff 1998). An increased risk has also been associated with pancreatic, head and neck, and lung cancers (Ginsberg et al. 1995; Holland et al. 1986).

During acute anticancer treatment, the diagnosis of depression is often missed. Oncologists often underestimate the level of depressive symptoms and do not prescribe adequate treatment or assess the response (Passik et al. 1998). They tend to recognize low mood, pain, and anxiety, but they do not ask about suicidal ideation. When physicians are uncertain of the correct psychiatric treatment or its benefit, they are less apt to ask, and patients, not wanting to appear weak or to risk abandonment, are less apt to reveal their discouragement to oncologists (Greenberg 2004). Not infrequently, the psychiatric consultant is asked to evaluate a “depressed” cancer patient who really has a hypoactive delirium, poorly controlled pain, fatigue, or anorexia-cachexia syndrome.

## Cancer-Related Suicide

Although few cancer patients commit suicide, they may be at a somewhat greater risk than the general population (Fox et al. 1982; Louhivuori and Hakama 1979; Massie and Popkin 1998). Passive suicidal thoughts are relatively common as patients battle a life-threatening illness, and these thoughts provide a sense of control in those overwhelmed by suffering, uncertainty, and helplessness. Both patients and doctors struggle to understand the degree to which noncompliance with or refusal of treatment represents a deliberate decision to end life (Nuland 1994).

An increased risk of suicide in cancer patients is associated with male gender, advanced stage of disease, poor

prognosis, delirium with poor impulse control, inadequately controlled pain, depression, history of psychiatric illness, current or previous alcohol or substance abuse, previous suicide attempts, physical and emotional exhaustion, social isolation, and extreme need for control. Recognition of suicidal thoughts should lead to emergent psychiatric evaluation with frank discussion (see also Chapter 9, “Depression”).

## Anxiety

Anxiety is a normal response to threat, uncertainty, and loss of control. It is common as patients face the existential plight of cancer and the specific threats of deformity, abandonment, pain, or death. The diagnosis and treatment of cancer is stressful and often traumatic. After the initial shock and disbelief of diagnosis, patients typically feel anxious and irritable. They may experience anorexia, insomnia, and difficulty with concentration because they are distracted by intrusive thoughts about their prognosis. Often this acute anxiety dissipates as a treatment plan is established and prognosis clarified. Anxiety is common at crisis points such as the start of a new treatment or the diagnosis of recurrence or illness progression, but it also occurs before routine follow-up visits without evidence of disease. Cancer often changes body functions and appearance and disrupts personal relationships and social roles (Noyes et al. 1998). In a recent cross-sectional observational study of 178 patients with cancer, almost half had significant anxiety, but the rate of anxiety disorder and its subtypes was 18%, comparable to that in the normal population. Two cases were attributed to drugs like interferon, but none of the others were attributed to medical variables (Stark et al. 2002).

Specific syndromes of anxiety can prevent the patient from accepting appropriate medical treatment. Patients with claustrophobia have difficulty tolerating magnetic resonance imaging (MRI) scans, radiation therapy, or placement in isolation because of neutropenia. Needle phobia and other health-related phobias (see Chapter 12, “Anxiety Disorders”) may interfere with chemotherapy and surgery. Radiation phobia makes some patients reluctant to accept radiation treatment. Anticipatory anxiety may prevent patients from following up with diagnostic or treatment visits.

In recent years, improved antiemetic treatments have reduced the number of patients who vomit with chemotherapy, but nausea is still common (Hickok et al. 2003). The nausea and vomiting with treatment are aversive stimuli that may condition anxious responses to reminders of treatment. Younger patients, patients with more emetic treatments, and those with trait anxiety are more prone to conditioning (Andrykowski 1990). Survivors of

leukemia who had anticipatory nausea and vomiting during treatment are more apt to have a visceral reaction to reminders of treatment (Greenberg et al. 1997).

Evaluation of acute anxiety in cancer patients includes consideration of conditions that mimic anxiety disorders. Antiemetic phenothiazines (prochlorperazine, perphenazine, promethazine) or metoclopramide, especially when given intravenously, may cause restlessness or severe akathisia. The inner feeling of restlessness is frequently misdiagnosed as anxiety. The abrupt onset of anxiety and dyspnea may signal pulmonary emboli, which are common among cancer patients. The experience of severe, intermittent, or uncontrolled pain is associated with acute and chronic anxiety, and the patient's confidence that he or she has the analgesics to control pain alleviates anxiety. Furthermore, anxiety amplifies pain, and the momentum behind additional requests for analgesia may be anxiety rather than somatic pain (see also Chapter 12, "Anxiety Disorders").

Reminders of the traumas of cancer can provoke anxiety and physiological arousal. A sample of women 2 years after diagnosis of stages I to III breast cancer had heightened arousal (as measured by skin conductance, heart rate, and facial muscle electrical activity) during mental imagery of the traumatic event as they listened to their own narrative of their two most stressful experiences associated with breast cancer. Breast-specific posttraumatic stress symptoms were noted in 24%, but only 9% reported full posttraumatic stress disorder (PTSD). Those with the strongest responses had current PTSD, and the majority had comorbid major depressive disorder (Pitman et al. 2001).

The prevalence of cancer-related posttraumatic stress disorder (PTSD) in women treated for breast cancer varies from 3% to 10% (Green et al. 1998). Younger age, less education, and lower income are associated with more PTSD symptoms (Cordova et al. 1995) as well as more advanced disease and lengthier hospitalizations (Jacobsen et al. 1998). Medical sequelae of cancer treatment (e.g., paresthesias because of nerve injury) may act as a trigger for memories of treatment (Kornblith et al. 2004).

### ***Treatment of Anxiety Disorders***

The management of anxiety symptoms begins with the provision of emotional support and information for the patient and family. Patients are relieved to have their anxiety recognized, to understand the interplay of psychological and somatic symptoms, and to find that that severe distress is treatable.

Many patients are helped through behavioral techniques such as relaxation, distraction, and cognitive reframing (Fawzy et al. 1995). In addition to behavioral

interventions, individual psychotherapy and group interventions can reduce anxiety in cancer patients. A group intervention that included education, emotional support, and behavioral training reduced tension and phobias in cancer patients (Spiegel et al. 1989).

Phobias related to medical procedures are common in children with cancer (and also some adults). Although careful preparation of children in advance of painful procedures (e.g., role-playing) may reduce anxiety, specific behavioral interventions, including relaxation training and distraction, may be indicated for some symptoms (Redd 1989). Self-hypnosis is a highly effective treatment for both generalized anxiety and specific phobias in children and adolescents.

### **Mania**

In cancer patients, corticosteroid medications are the most common reason for hypomania or mania. Steroids are commonly given as a component of chemotherapy for lymphoma, as an antiemetic or to prevent hypersensitivity reactions with chemotherapy, or to prevent edema in the CNS during radiation therapy. Psychotic mania secondary to steroids may be misdiagnosed as delirium. Interferon has also been associated with mania and mixed affective syndromes (Greenberg et al. 2000). Diencephalic tumors are a rare cause of secondary mania (see also Chapter 11, "Mania, Catatonia, and Psychosis").

### **Delirium**

Delirium is common in cancer as a result of metabolic sequelae of the disease and treatment, medications, metastatic tumors in the brain, and, more rarely, paraneoplastic syndromes. The prevalence of delirium in cancer patients has been reported as 5%–30% and is substantially higher (40%–85%) in terminal stages of illness (Fleishman et al. 1993). Delirium is associated with greater morbidity and mortality in patients and greater distress in patients, their families, and caregivers.

Early symptoms of delirium are often unrecognized or misdiagnosed by medical or nursing staff as depression or anxiety. Early recognition of delirium is essential because the etiology may be a treatable complication of cancer. In addition to the general causes of delirium (see Chapter 6, "Delirium"), there are particular considerations in cancer patients. Primary brain tumor and brain metastases (especially common with lung and breast cancer) can cause delirium. Immunosuppressed cancer patients, especially those with hematological malignancies, are at high risk for opportunistic infection. Head and neck cancer patients undergoing surgery are at high risk for

delirium because of their older age and high prevalence of alcohol abuse and withdrawal. Several antineoplastic agents (e.g., cytarabine, methotrexate, ifosfamide, asparaginase, procarbazine, and fluorouracil) and immunotherapeutic agents (e.g., interferon and interleukins) can cause delirium and other changes in mental status (Table 24–1) (Brown and Stoudemire 1998). Some antibiotics (e.g., quinolones) and antifungals (e.g., amphotericin B), as well as opioids, anticholinergics, and nutritional deficiencies, can cause delirium. Hypercalcemia causes delirium in patients with bone metastases or ectopic hormone production. Hyperviscosity syndrome with lymphoma, Waldenström's macroglobulinemia, and myeloma are unusual causes of delirium. There are also rare autoimmune encephalopathies resulting from paraneoplastic syndromes (Lieberman and Schold 2002) that manifest with cognitive impairment and delirium. Limbic encephalopathy is a specific type of autoimmune encephalopathy (see Chapter 32, "Neurology and Neurosurgery") that presents with impaired memory, fluctuating mood, and seizures (Kung et al. 2002). (See Chapter 6, "Delirium," for the general management of delirium and Chapter 40, "Palliative Care," for terminal delirium.)

## Pain and Psychiatric Symptoms in Cancer Patients

Depression and anxiety are very common in cancer patients suffering from severe pain. In one early study, 39% of patients with a psychiatric diagnosis (often depression) experienced significant pain, whereas only 19% of patients with no psychiatric diagnosis had significant pain (Derogatis et al. 1983). The psychiatric symptoms of patients who are in significant pain should initially be considered a consequence of uncontrolled pain. Acute anxiety, depression with despair (especially when the patient believes the pain means disease progression), agitation, irritability, lack of cooperation, anger, and insomnia all may accompany pain. Such symptoms should not be diagnosed as a psychiatric disorder unless they persist after pain is adequately controlled. Undertreatment of pain is a major problem in both adult and pediatric cancer patients. Long-term psychiatric sequelae of cancer are less frequent in children whose pain is well treated. There is no evidence of increased risk of abuse or addiction in cancer patients receiving opioids. In fact, many patients associate the narcotics with the unpleasant aspects of the illness and avoid them after their recovery. (The issues in pain management are discussed in full in Chapter 36, "Pain.")

**TABLE 24–1. Neuropsychiatric side effects of common chemotherapeutic agents**

<b>Hormones</b>
<b>Corticosteroids</b>
Mild to severe insomnia, hyperactivity, anxiety, depression, psychosis with prominent affective and manic-like features
<b>Tamoxifen</b>
Sleep disorder, irritability
<b>Biologicals</b>
<b>Cytokines</b>
Encephalopathy
<b>Interferon</b>
Depression, mania, psychosis
Delirium, akathisia
<b>Interleukin-2</b>
Dysphoria, delirium, psychosis
<b>Chemotherapy agents</b>
<b>L-Asparaginase</b>
Somnolence, lethargy, delirium
<b>Cisplatin</b>
Encephalopathy (rare), sensory neuropathy
<b>Cytarabine</b>
Delirium
Leukoencephalopathy: syndrome of personality change, drowsiness, dementia, psychomotor retardation, ataxia
<b>5-Fluorouracil</b>
Fatigue, rare seizure or confusion, cerebellar syndrome
<b>Gemcitabine</b>
Fatigue
<b>Ifosfamide</b>
Lethargy, seizures, drunkenness, cerebellar signs, delirium, hallucinations
<b>Methotrexate</b>
Intrathecal regimens can cause leukoencephalopathy (acute and delayed forms)
High dose can cause transient delirium
<b>Procarbazine</b>
Somnolence, depression, delirium, psychosis
<b>Taxanes</b>
Sensory neuropathy, fatigue
<b>Thalidomide</b>
Fatigue
<b>Vincristine, vinblastine, vinorelbine</b>
Depression, fatigue, encephalopathy

## Cancer-Related Fatigue

Fatigue is a sign of illness in patients who have certain tumors (e.g., lymphoma) or extensive liver metastases. Both chemotherapy and radiation treatment are associated with predictable periods of fatigue following treatment. Causes of cancer-related fatigue are listed in Table 24–2. Psychia-

trists play an important role in the treatment of depression and sleep disorders, and these common conditions may be more important as a cause of fatigue than the cancer or its treatment. Hypnotics and other psychotropic drugs may also contribute to fatigue. Patients who have persistent fatigue with progressive disease or cancer treatment may respond well to low-dose psychostimulants and do not increase the dose over time.

## Anorexia–Cachexia Syndrome

Cachexia in cancer patients is debilitating and life-threatening. It is associated with anorexia, fat and muscle wasting, decreased quality of life, and psychological distress. The causes of cachexia are gastrointestinal dysfunction, altered metabolism and host response to cancer (cytokine production), hormone production by tumors, and anticancer treatments (Inui 2002) (see Table 24-3).

Anorexia may be the result of depression or anxiety. Preexisting eating disorders complicate nutritional management in cancer patients. Treatments of anorexia and cachexia in cancer patients are shown in Table 24-4.

## Psychiatric Issues in Specific Cancers

diagnosed in 2004. Men over 65 account for 80% of these cancers (Jemal et al. 2004). In general, although the reaction of men with prostate cancer depends on age, marital status, recent losses, and social support, older men are less likely to seek or accept intervention for emotional distress.

The recent increased incidence of prostate cancer directly relates to improved detection with the serum prostate specific antigen test (PSA). The PSA has limitations as a broad screening tool (Garnick 1993) because of its lack of sensitivity and specificity. False-positive results can be seen with prostatitis and benign prostatic hypertrophy, as well as with manipulation of the prostate. Distress surrounding each PSA test has been dubbed “PSA anxiety” (Roth and Passik 1996) and may be even greater in spouses than in patients (Kornblith et al. 1994).

It is difficult to distinguish indolent forms of prostate cancer that will not impact the quality or quantity of a patient’s survival from more lethal varieties. It is also difficult to assess the relative risk of treatment complications that may significantly impair quality of life. Controversy among clinicians about primary treatment (surgery vs. radiation) or “watchful waiting” creates uncertainty and makes treatment decisions difficult. Counseling assists patients with these choices, based on the extent of disease, age of patient, life expectancy, expense, and geography (Harlan et al. 1995), and the choices are often based on the potential side effects (e.g., impotence, urinary incon-

**TABLE 24-4. Treatment of cancer anorexia-cachexia syndrome**

**Hypercaloric feeding (enteral and parenteral nutrition)**

- Does not increase skeletal muscle mass
- Useful for nutritional support for patients with potentially therapy responsive cancer

**Drugs**

Amino acids; ATP

Corticosteroids

- Increase sense of well-being
- Useful adjunct for pain control
- Decrease nausea
- May cause osteoporosis, muscle weakness, immunosuppression, delirium
- No demonstrated effects on body weight

Progestational

Megestrol acetate

- Increases body weight (fat) gain
- Increases appetite and sense of well-being
- Can cause thromboembolic phenomena, edema, hyperglycemia, hypertension, adrenal insufficiency (abrupt discontinuation)

Medroxyprogesterone acetate

- Increases appetite and body weight
- Available in depot and oral suspension

Antiserotonergic

Cyproheptadine

- Increases appetite; does not prevent weight loss

Ondansetron

- Does not prevent weight loss

Prokinetic

Metoclopramide

- Treatment for chemotherapy-induced emesis
- May relieve anorexia

Cannabinoids

- Dronabinol (Marinol)
- May improve mood and appetite
- Minimally effective in increasing body weight in cancer
- Can cause euphoria, dizziness

Emerging drugs

Melatonin, thalidomide

Nonsteroidal anti-inflammatory drugs (prostaglandin inhibitors)

Testosterone

**Educational and behavioral approaches**

tinence, and bowel problems). In general, men undergoing surgery, older men, and men with less serious disease have less mental distress (Litwin et al. 2002).

A model of an effective psychiatric liaison to a genitourinary clinic at a cancer center, which includes a brief meeting of the patient with a psychiatrist at the initial

clinic visit, has been described (Roth et al. 2000). Patients are screened for coping mechanisms; depressed mood; anxiety; and disturbances in concentration, sleep, daily functioning, and family life. They are introduced to the concept of a multidisciplinary team approach including the psychiatrist. Roth et al. (1998) found that a third of men screened on initial visit had high levels of anxiety, but a large proportion did not want further psychiatric evaluation or treatment. Men who are reluctant to participate in individual therapy may agree to participate in psycho-educational or support groups and use other sources of information about the illness and treatment options (e.g., interactive video program).

In prostate cancer patients, the most important risk factor for depression is a past history of depression (Ingram et al. 2003; Pirl et al. 2002). Androgen deprivation therapy (ADT) by orchiectomy or chronic administration of gonadotropin-releasing hormone agonists may cause hot flashes, loss of sexual interest, fatigue, anemia, decreased muscle mass, and osteoporosis. Men with prostate cancer who received ADT reported poorer quality of life compared with men who underwent any prostate cancer treatment without hormonal treatment (Wei et al. 2002).

## Breast Cancer

Breast cancer is the most common cancer in women, second only to lung cancer in cancer deaths in women. More than 215,000 women in the United States will be diagnosed with breast cancer in 2004, and more than 40,000 women will die (Jemal et al. 2004). The number of women diagnosed with breast cancer has increased as a result of mammography screening, and the modest improvement in the death rate is probably attributable to successful treatment of cancers diagnosed at an early stage. More than 85% of women diagnosed with stage I (small cancers confined to the breast) cancers will be alive 5 years later. Survival drops dramatically when cancers are diagnosed at later stages.

Although only 5% of breast cancer occurs in women younger than 40 years, a disproportionately large number of younger women seek psychiatric consultation to consider treatment options; sexual side effects of treatments; fertility; self- and body image; prophylactic contralateral mastectomy; genetic testing; and the effects of cancer on relationships, children, and career.

The treatments of breast cancer are surgery, irradiation, chemotherapy, and antiestrogen therapy (tamoxifen, raloxifene, anastrozole, and exemestane). Local control is still critical; the size, location, and aggressiveness of the tumor usually dictate the initial surgery (mastectomy vs. limited resection). Use of sentinel-node mapping reduces,

but does not eliminate, the risk of developing unsightly and disabling lymphedema. Although many women now have a choice between mastectomy and limited resection, mastectomy is preferred by some instead of daily irradiation treatment for 5–6 weeks. Natural tissue or silicone or saline implant breast-reconstruction techniques provide satisfactory to excellent results for women eligible for reconstruction. Involvement of the patient's husband or partner in preoperative medical appointments, in viewing the scar, and in discussions about resuming sexual activity is helpful for optimal recovery.

Chemotherapy with alkylating agents can cause alopecia, ovarian failure, premature menopause, and weight gain. Taxanes can cause painful and disabling peripheral neuropathy. Antiestrogen therapy is prescribed over a period of years and may cause insomnia, hot flashes, irritability, and depression in some women (Duffy et al. 1999). Many women undergoing chemotherapy report difficulty with concentration and memory, but these reports do not correlate consistently with persistent deficits on neuropsychological testing, and the difficulty may primarily be caused by the malaise of chemotherapy and concomitant symptoms.

Psychological distress is common at the conclusion of cancer treatment. Women feel vulnerable and less protected when not being seen regularly by their oncologist (Rowland and Massie 2004). Increased doctor visits and emotional support at this time are often beneficial. Ganz et al. (1996) found that survivors appear to attain maximum recovery from the physical and emotional trauma at 1 year after breast surgery. Sexual problems are important to address after acute treatment (see Chapter 17, "Sexual Disorders").

The emotional burden of breast cancer treatment is high, particularly for young women who hope to become pregnant. Although there is no evidence that pregnancy affects the outcome of breast cancer, continuation versus elective termination of pregnancy is a consideration for some who are diagnosed very early in a pregnancy and are unwilling to postpone treatment with teratogenic alkylating agents. Most young women, even women who are considered to have a good prognosis and are likely cured by initial treatments, ponder the ramifications of adoption or future child bearing, taking into account the unpredictability of disease recurrence or progression.

### *Genetics*

The two most significant risk factors for breast cancer are increasing age and family history. The hereditary breast or ovarian cancer syndrome accounts for 5%–7% of all breast cancer cases and 10% of all ovarian cancer cases,

and is attributed to germ-line mutations in *BRCA1* and *BRCA2* genes (Robson et al. 2001). In the pre-gene-testing era, bilateral prophylactic mastectomy was a treatment option for women with strong family histories of breast cancer and extreme anxiety about their risk, and psychiatrists often were involved in preoperative assessment. Now that gene testing is available, women who likely have a hereditary predisposition are first referred for consultation with a clinical geneticist, which includes preparing a pedigree, documenting cancer diagnoses, estimating cancer risks, and discussing options for genetic testing and cancer screening and prevention (Robson and Offit 2002). The woman who tests positive for a gene mutation is advised to enroll in a high-risk surveillance clinic where she will receive information about chemoprevention and the potential effectiveness of risk-reducing surgery. Bilateral prophylactic mastectomy (PM) is associated with a greater than 90% reduction in the incidence of breast cancer in women with a family history of breast cancer (Hartmann et al. 1999). Prophylactic oophorectomy (PO), usually performed laparoscopically as an ambulatory procedure, reduces breast cancer risk by 50% in *BRCA1* mutation carriers and prevents most ovarian cancer in women with *BRCA1/BRCA2* mutations (Weber et al. 2000).

In some cancer centers, psychiatric consultation is an essential part of the evaluation process. The psychiatric evaluation of a woman who is considering prophylactic surgery includes a review of the woman's family and personal psychiatric history (e.g., body dysmorphic disorder, depressive disorder, personality disorder); family history of all cancers; perception of cancer risk and anxiety associated with perceptions; understanding of actual risk; satisfaction with previous plastic surgery(ies); litigation history; history of abuse, rape or assault; sexual, pregnancy, and breast-feeding history; desire to have (more) children and planned timing of PM and PO in relationship to future pregnancies; and the feasibility of child rearing with uncertainty about the future. A partner's role in considering the decision to have PM or PO is explored. Patients have an opportunity to clarify information, discuss decisions and the decision-making process, and obtain psychological understanding and support. Regardless of whether PM and PO will be selected as an option, strategies to reduce anxiety are discussed. Some women at high risk choose to have PM or PO in the absence of genetic testing. In this case, psychiatric evaluation should be a standard component of the surgical evaluation. The women who later express regret about having had prophylactic mastectomy are those who feel that the decision to have surgery was driven by their surgeon (Payne et al. 2000).

## Colorectal Cancer

Although screening can detect precancerous polyps, more than 140,000 people in the United States will be newly diagnosed with colorectal cancer in 2004, and more than 56,000 will die (Jemal et al. 2004). Only 36% of colorectal cancers are diagnosed at an early stage, and surgical resection is the only curative therapy. A patient's adjustment is closely related to the type and extent of surgery, the presence or absence of a stoma and ostomy, and the partner's adjustment. Psychosocial adjustment to colon cancer can be complicated by anorexia, nausea and vomiting, weight loss, abdominal discomfort, diarrhea, and constipation. Concerns about body image, sexual functioning, fatigue, pain, and odor can lead to social withdrawal (Bernhard et al. 1999; Sahay et al. 2000). In patients with liver metastases, serum interleukin-2r, a cytokine, may be an independent predictor of depression (Allen-Mersh et al. 1998). Confusion occurs in 1% colon cancer patients in the last 6 months of life but in 28% in the last 3 days. Significant financial burden occurs in the 3–6 months before death (McCarthy et al. 2000).

A recent survey of colorectal cancer survivors demonstrated that they had a relatively uniform and high quality of life, irrespective of stage at and time from diagnosis. Noncancer comorbid disorders and low-income status had more influence on quality of life than stage or time since diagnosis. Compared with an age-matched population, long-term survivors reported higher quality-of-life scores, but they had higher rates of depression. Frequent bowel movements and chronic recurrent diarrhea were a problem for many (Ramsey et al. 2002) (see Chapter 30, "Surgery," for a discussion of ostomies). There are many self-help groups that provide vital education and coping skills for these patients and their families.

## Lung Cancer

There will be an estimated 173,000 new cases of lung cancer diagnosed and 160,000 deaths in 2004 in the United States (Jemal et al. 2004). Lung cancer accounts for 25% of all cancer deaths. Although it is the most preventable of all cancers, with 87% of cases linked to cigarette smoking, lung cancer is difficult to diagnose early. About one-fifth of patients with non-small-cell lung cancer (NSCLC) have depressed mood at the time of diagnosis, and their depression tends to persist. In one study, depression following the diagnosis or resection of operable NSCLC predicted depression 1 year later (Uchitomi et al. 2003). At the time of diagnosis, many tumors are inoperable. In unresectable NSCLC, self-reported anxiety and depression at baseline was found to predict subse-

quent psychological distress (Akechi et al. 2001).

Depressive symptoms and difficulty concentrating are more common at diagnosis of small-cell lung cancer than NSCLC. Small-cell lung cancer, more than any other tumor, is associated with paraneoplastic syndromes such as Cushing's syndrome, hyponatremia, and autoimmune encephalopathy. Because pulmonary emboli are common during treatment, dyspnea and anxiety should be evaluated carefully. Hypoxia due to preexisting chronic obstructive pulmonary disease and postradiation hypothyroidism may contribute to cognitive dysfunction. Postthoracotomy neuralgic pain is common.

In lung cancer, there is a substantial risk of brain metastases. Isolated lesions may be removed surgically, but cranial radiation is common once the metastasis is noted. Patients with small-cell lung cancer often receive prophylactic cranial radiation because the risk of brain metastases is 50% over 2 years. Some cognitive deficits have been noted in long-term survivors of small-cell cancer whether or not they received cranial radiation. Leukoencephalopathy has occurred after treatment for small-cell cancer as a result of the combination of chemotherapy and radiation, but changes in chemotherapy have decreased this risk.

In one recent study of 145 survivors of NSCLC who were 5 or more years disease-free, most were hopeful. Half viewed the cancer experience as contributing to positive life changes (Sarna et al. 2002).

Many smokers with cancer experience guilt, but many continue to smoke. Continued smoking is associated with decreased survival, development of a secondary primary cancer, and increased risk of developing or exacerbating other medical conditions. Chemotherapy and radiation are likely to produce more complications and greater morbidity among smokers than among non-smokers (Sanderson et al. 2002). Although some health care providers are hesitant to raise the issue of smoking cessation during the stress of initial diagnosis, the literature supports early antismoking intervention with patients and their family members (Sanderson et al. 2002). But in terminal lung cancer, if the patient derives pleasure from smoking, cessation interventions are not indicated. For further review of lung cancer, see Chapter 20, "Lung Disease."

## Ovarian Cancer

The second most frequent gynecological cancer among women in the United States, ovarian cancer, is the fourth most frequent cause of cancer death and has the highest mortality rate of all gynecological cancers (Jemal et al. 2004). Annually, more than 25,000 new cases of ovarian

cancer are diagnosed, and 16,000 deaths result. Ovarian cancer usually has an insidious onset and progression; 70% of cases are stages II to IV at time of diagnosis. The 5-year survival rate is only 37%, and of those who respond to treatment, nearly 90% will have a recurrence with a fatal outcome.

Because CA 125 levels often rise before symptoms appear, patients' emotions often rise and fall with the report of the CA 125 level (Fertig 1998). Kornblith and colleagues found that more than 60% of ovarian cancer patients were worried, tired, feeling sad, and in pain (Kornblith et al. 1995).

Patients report difficulties with sexual desire, response, and communication after gynecological cancer treatment (Schover 1997) (see Chapter 17, "Sexual Disorders"). Infertility concerns are vital for younger women, who require information about fertility and emotional support to make treatment decisions and to cope with those choices.

## Melanoma

More than 55,000 Americans will be diagnosed with melanoma in 2004 (Jemal et al. 2004). Melanoma is a very variable tumor. Fawzy and associates reported that a short-term focused psychological treatment could diminish distress and prolong survival (Fawzy et al. 2003). The intervention was associated with survival benefit after 6 years, but the benefit weakened after 10 years.

Patients with advanced disease are currently treated with a 12-month protocol of interferon- $\alpha$ , the side effects of which include fatigue, anxiety, insomnia, depression, and rarely mania (Kirkwood et al. 2002). Paroxetine started at the time interferon- $\alpha$  is started has been shown to reduce the incidence of depression (Musselman et al. 2001). Brain metastases are always a consideration in advanced disease.

## Head and Neck Cancers

Head and neck cancers carry the risks of facial deformity and loss of speech. These tumors are most frequent in patients with a history of alcohol abuse and smoking. Treatment is daunting and leads to mucositis, pain, dysphagia, and dry mouth or sticky saliva, all of which make eating difficult. Feeding tubes and tracheotomies are often necessary (List et al. 1997). Hypothyroidism is common following radiation treatment to the neck (Mercado et al. 2001). Because these tumors are more common among isolated men with a history of substance abuse, the risk of suicide has been thought to be high, but one study suggested that the rate of suicide remains low (Henderson and Ord 1997).

## Pancreatic Cancer

Depression, anxiety, restlessness, and insomnia have been thought to be common first signs of pancreatic cancer, before physical signs appear, and physicians have wondered whether pancreatic hormones or neuropeptides might be responsible (Alter 1996; Frascarelli et al. 1967; Green and Austin 1993; Joffe et al. 1986; Krech et al. 1991). One clinical study reported that depressive thoughts were more common in people with pancreatic cancer than in those with gastric cancer (Holland et al. 1986), and a recent epidemiological study found that depression preceded pancreatic cancer more often than other GI malignancies (odds ratio 4.6) (Carney et al. 2003). In a depressed patient, clues to the diagnosis of pancreatic cancer include abdominal symptoms and weight loss out of proportion to the degree of psychological symptoms. However, the symptoms of pancreatic cancer are typically vague and nonspecific. Symptoms of upper abdominal disease occur in 25% of patients 6 months before diagnosis. Anorexia, early satiety, and back pain are features of progressive disease. Diabetes may also be present (DiMaggio 1999). One study of 130 patients presenting with pancreatic cancer found 38% had scores above 15 on the Beck Depression Inventory. Depression was more common in those who had pain (Kelsen et al. 1995).

Following diagnosis, patients come to surgical evaluation, but few have surgically treatable disease. Finding that the tumor is not resectable is an additional psychological blow. Management of pain and discomfort includes pancreatic enzymes to relieve the cramps of fat malabsorption, octreotide for diarrhea, prevention of constipation, narcotics, and sometimes celiac block, as well as antidepressants for depression.

## Psychiatric Aspects of Cancer Treatments

---

### Chemotherapy

The neuropsychiatric side effects of common chemotherapeutic agents are listed in Table 24-1. The effects of chemotherapy on cognition are under investigation, but there are no definitive findings thus far (Phillips and Bernhard 2003). For the most part, there are no significant clinical interactions between cancer drugs and antidepressant medications, antipsychotic medications, and benzodiazepines. Procarbazine, a weak monoamine oxidase (MAO) inhibitor, is an exception. Alcohol may lead to an Antabuse-like reaction, and antidepressant medications should be prescribed only with consideration of possible MAO inhibition in mind.

## Radiation

Radiation treatment usually requires a patient to remain absolutely still on a flat table for 5–10 minutes daily, 5 days a week, so that a prescribed dose can be applied to a specific site over 2–9 weeks. Patients worry that they cannot remain still either because of claustrophobia or because of inadequate pain control. Fatigue continues to increase during the month following radiation treatment but then begins to diminish. Nausea and vomiting from radiation treatment, more severe when viscera are irradiated, is reduced by serotonin 5-HT<sub>3</sub> antagonists like ondansetron. Brain irradiation causes more profound fatigue than treatment of other sites. Concomitant dexamethasone reduces cerebral edema, but late sequelae of brain radiation may occur, including radiation necrosis in focal areas or leukoencephalopathy. Newer methods to reduce the volume of brain that requires radiation may reduce these risks.

## Bone Marrow Transplantation

Bone marrow transplantation (BMT) is used to treat acute and chronic leukemia, aplastic anemia, lymphomas, some solid tumors, and immunological deficiency states. There is no correlation between type of transplant and psychological morbidity (Leigh et al. 1995). Wettergren and colleagues found that patients undergoing autologous BMT who had more functional limitations coped worse than did patients who were less functionally impaired (Wettergren et al. 1997).

The psychological stress of BMT begins when transplant is first considered. It offers a chance of cure but carries significant risk of morbidity and mortality. In one study of BMT candidates, one-third reported depression (Baker et al. 1997); in another study, two-thirds reported a high level of anxiety (Keogh et al. 1998).

An important part of the pretransplant planning is to evaluate and shore up the patient's social support. Parents making this decision for a child may show depressive symptoms pretransplant and develop mental and physical exhaustion as the process continues (Pot-Mees and Zeitlin 1987). Some family members have alterations in immune status at various phases of the transplant (Futterman et al. 1996) and overall report distress similar to that of patients (Siston et al. 2001).

During high-dose chemotherapy and irradiation, visitors are limited to avoid infection. Patients often experience nausea, vomiting, and fatigue. During this time, psychiatric disorders are extremely common, especially adjustment disorder with anxiety and depression. Graft-versus-host disease is not generally associated with occurrence of mental disorders (Sasaki et al. 2000), although when severe, it may result in delirium.

The transplant itself (a brief intravenous infusion of several packets of concentrated bone marrow) is anticlimactic compared to the pretransplant regimen and the anxious recovery period waiting for platelet and red and white blood cell counts to “come back,” the evidence of hematological recovery. Hypervigilant patients keep charts of their cell counts, anticipating the day of “probable” recovery; others request medications to “sleep through the experience,” a passive attitude antithetical to caregivers who want the patient to participate in self-care.

After a prolonged period of dependence, patients are often very fearful as they anticipate hospital discharge and must assume greater roles in self-care. Persistent fatigue is a major problem when patients resume normal activities at home and work (Hann et al. 1997). Chronic anxiety and depression are the most common psychiatric sequelae, and psychological adjustment is particularly difficult for those patients who have delayed or disrupted important developmental life tasks.

In general, successful adaptation to BMT is associated with the ability to use information about illness and treatment, coupled with the ability to delegate control and authority temporarily and to trust the staff (Lesko and Holland 1998). A study of adults undergoing allogeneic BMT for acute leukemia found three variables affected outcome: illness status, presence of depressed mood, and the extent of perceived social support (Colon et al. 1991). Depressed mood pretransplant is associated with poorer survival (Colon et al. 1991; Loberiza et al. 2002), perhaps suggesting the potential benefit of early psychiatric intervention.

Long-term survivors of BMT for acute leukemia show no difference in psychological and social functioning than those who received standard chemotherapy (Wellisch et al. 1996). A decrease in sexual frequency and satisfaction is seen in women (Mumma et al. 1992).

Bone marrow transplant recipients are at increased risk for developing central nervous system (CNS) toxicity such as neuropsychological impairment, including compromised motor and cognitive test performance (Tschuschke et al. 2001).

## Surgery

See Chapter 30, “Surgery,” for a full discussion of the emotional aspects of surgery.

## Psychiatric Interventions in Cancer

---

### Psychotherapy

Psychotherapy can often help patients to accept the diagnosis of cancer; sort out treatment options; overcome

fear; depression, or denial; and enhance patients' ability to cope with cancer treatment (Weisman 1979). Suffering is intensified by lack of meaning, and some interventions for cancer patients have focused on the maintenance of morale and the search for meaning (Frankl 1946; Greenstein and Breitbart 2000; Weisman 1993). Chochinov (2002) has developed methods to support patients' desire for dignity at the end of life.

Psychosocial interventions can reduce distress, facilitate problem-solving strategies, and augment a sense of control. Cognitive and behavioral models can be tailored to the specific tumor type. Educational and behavioral training, either in group or individual psychotherapy, are the best-documented approaches to reducing distress in cancer patients (Fawzy et al. 1995; Newell et al. 2002).

Although some enthusiasts have advocated counseling for all cancer patients on the assumption that they can benefit from help and will take advantage of it, in one study, only two-thirds of the patients identified as high risk accepted counseling (Worden and Weisman 1984). Refusers had a positive outlook, minimized the implications of their diagnosis, and viewed the offer of therapy as a threat to their emotional equilibrium. Those who accepted counseling were less able to deny the diagnosis and its implications; they were less hopeful and were more apt to experience their situation in religious or existential terms. Thus, pushing too hard for group or individual psychotherapy is countertherapeutic for some patients. Because of the bond between families and the psychiatrist who took care of their relative over the course of a long illness, families often enter into bereavement counseling with this same psychiatrist after the patient's death to provide a healing conclusion to a long illness.

Group therapy and self-help groups allow cancer patients to receive support from others who are coping with similar problems. In a group setting, patients can glean practical tips and see the range of normal reactions to illness, as well as adaptive coping styles and strategies that make adjustment to illness easier. Group therapy helps to decrease the sense of isolation and alienation as the patient and family see that they are not alone adjusting to illness. Groups are often disease specific or targeted for patients at the same stage of illness. Past concerns about having dying patients in a group with those recently diagnosed or whose prognosis was good have been dispelled.

Spiegel et al. (1989) developed supportive expressive group psychotherapy led by trained professionals for women with breast cancer. The goal of supportive-expressive psychotherapy is to help patients with existential concerns and disease-related emotions as well as to deepen social support and physician relationships and provide symptom control. The therapist challenges pa-

tients' tendency to withdraw from the implications of having metastatic breast cancer. Such groups relieve distress while reducing avoidance of the implications of the diagnosis. This strategy improves mood and pain perception, especially in the most distressed (Goodwin et al. 2001).

Studies of psychosocial interventions in hopes of prolonging survival have had a mixed outcome. Spiegel and colleagues' report of greater longevity in a small number of women with advanced breast cancer undergoing group supportive-expressive psychotherapy was not replicated in larger studies (Goodwin et al. 2001; Spiegel et al. 1989). Fawzy and colleagues' study of a structured psychoeducational intervention for patients with early-stage melanoma showed a modest survival benefit at 6 years that weakened at 10-year follow-up (Fawzy et al. 1993, 2003). Patients can be told that group support contributes to living better, not necessarily longer.

## Psychopharmacology

Patients commonly ask whether psychiatric drugs increase cancer risk or render antineoplastics ineffective. There is no evidence for either belief (Steingart and Cotterchio 1995; Theoharides and Konstantinidou 2003).

### *Depression*

The selective serotonin reuptake inhibitors (SSRIs) are the first-line antidepressants prescribed in cancer settings because they are effective, have few sedative and autonomic side effects, and have few drug interactions. A small minority of cancer patients experience transient weight loss when starting an SSRI; however, weight usually returns to baseline level, and the anorectic properties of these drugs are usually not a limiting factor in those with cancer anorexia-cachexia. Ondansetron can be used to block initial serotonin-mediated nausea. Antidepressants like mirtazapine that can cause weight gain may be advantageous in anorexic-cachectic cancer patients but are not a good choice in those who are gaining weight from steroids or from chemotherapy (Theobald et al. 2002). If recurrent periods of inability to eat and drink tend to interrupt the antidepressant regimen, then fluoxetine, with its longer half-life, has an advantage. The SSRIs and venlafaxine reduce both the number and the intensity of hot flashes and night sweats in nondepressed women who become menopausal after chemotherapy for breast cancer or who have a recurrence of vasomotor symptoms when they discontinue hormone replacement therapy (Duffy et al. 1999; Loberiza et al. 2002; Stearns et al. 2000; Weitzner et al. 2002). Hot flashes are also an issue for men on androgen deprivation treatment regimens.

Bupropion's stimulating properties make it useful in lethargic patients, but because of its association with increased seizure risk, it should be used with caution in patients who are malnourished or who have a history of seizures or brain tumor. Bupropion may assist in smoking cessation, especially in patients with lung or head and neck cancers.

The tricyclic antidepressants (TCAs) are used to treat both depression and the neuropathic pain syndromes caused by chemotherapy and surgery. Nortriptyline and desipramine have more favorable side-effect profiles compared with amitriptyline, with fewer anticholinergic symptoms.

Psychostimulants (i.e., dextroamphetamine and pemoline), can promote a sense of well-being, treat depression, decrease fatigue, stimulate appetite, and improve cognitive function. Psychostimulants are used as an adjuvant to potentiate the analgesic effects of opioid analgesics and are commonly used to counteract opioid-induced sedation (Rozans et al. 2002). Psychostimulants offer clear benefits, especially in terminally ill patients, because there may be an improvement in symptoms within hours to days. See also Chapter 9, "Depression," for a full discussion of the pharmacological treatment of depression.

In patients with primary bipolar disorder, mood stabilizers and neuroleptics can be continued. Lithium tends to increase the patient's white blood count and usually can be continued during cancer treatment. However, complications of chemotherapy, including vomiting, diarrhea, dehydration, and renal insufficiency, may raise lithium levels, and symptoms of toxicity, nausea, diarrhea, and confusion may be misattributed to chemotherapy. See Chapter 11, "Mania, Catatonia, and Psychosis," for a full discussion of the pharmacological treatment of mania and psychosis.

### *Anxiety*

Prior to treatment with a benzodiazepine, all patients should be screened for depressive symptoms as well as for specific anxiety disorders such as PTSD and obsessive-compulsive disorder. When anxiety is a manifestation of a primary depressive disorder, treatment should be an antidepressant with, or instead of, a benzodiazepine. The experience of cancer treatment may reawaken problems in patients who were the victims of earlier traumas, increasing their risk of anxiety and depressive symptoms (Baidar et al. 2000).

Benzodiazepines are frequently given to patients for acute anxiety and are often prescribed to augment antiemetics during chemotherapy. Dosing depends on the patient's tolerance and the drug's duration of action. Lo-

razepam and alprazolam are favored in the acute setting because of their rapid onset of action and benefit on an "as-needed" basis. Buspirone and antidepressants are alternatives for longer treatment of anxiety. Low doses of neuroleptics are useful in patients who are unresponsive to or intolerant of benzodiazepines or in patients with severe anxiety and agitation. If patients have been taking a benzodiazepine chronically, they may suffer withdrawal if the dose is not tapered. See Chapter 12, "Anxiety Disorders," for a full discussion of the psychopharmacological treatment of anxiety.

### *Delirium*

See Chapter 6, "Delirium," for a full discussion of the psychopharmacological treatment of delirium.

### *Electroconvulsive Therapy*

Although the use of electroconvulsive therapy (ECT) in patients with brain tumor was once believed to be contraindicated because of the risk of brain herniation, there are numerous case reports describing safe and effective use of ECT in such patients (Patkar et al. 2000). See Chapter 39, "Electroconvulsive Therapy," for a full discussion of ECT.

## **Survivor Issues**

---

Advances in cancer treatment over the past 30 years have led to a rapidly growing population of more than 9 million long-term survivors in the United States, many of them children and young adults. The long-term adjustment of many appears to be largely unimpaired (Kornblith et al. 2004). Some cured cancer patients have delayed medical complications (i.e., organ failure, CNS dysfunction, sterility, secondary malignancies, and decreased physical stamina) and psychiatric concerns, including fears of termination of treatment; preoccupation with the threat of disease recurrence (the Damocles syndrome) and a sense of greater vulnerability to illness; pervasive awareness of mortality and difficulty with reentry into normal life (the Lazarus syndrome); persistent guilt (the survivor syndrome); difficult adjustment to physical losses and handicaps that lead to problems with peer acceptance and social integration; diminished self-esteem or confidence; perceived loss of job mobility; and fear of job and insurance discrimination. Concerns about infertility, often understandably submerged at the time of diagnosis and treatment, reappear when treatment concludes. The survivor's intellectual functioning is also a major concern. Children and adults with brain tumors or

CNS involvement, and those undergoing bone marrow transplant, are at risk from both the disease and the treatment. Most have residual deficits, with neuropsychological impairment including compromised motor and cognitive test performance (Anderson et al. 2001; Bhatia 2003; Phipps et al. 2000).

Potential resources include the National Coalition of Cancer Survivorship, the Office of Cancer Survivorship of the National Cancer Institute, and the organizations whose Web sites are shown in Table 24–5.

## Complementary and Alternative Medicine

Some 80% of cancer patients use complementary and alternative medicine (CAM) treatments. Some alternative treatments (acupuncture; relaxation; yoga; meditation; massage; tai chi; biofeedback; music, art, movement, and aroma therapies) are offered as adjuncts to traditional cancer care aimed at increasing quality of life and decreasing symptoms with no promise of cure. Other therapies such as shark cartilage, colonics, herbal remedies, and high-dose vitamin therapies do not improve quality of life and may be harmful. Some remedies are highly toxic (Markman 2002). Laetrile, now banned in the United States, contains cyanide; chaparral tea causes liver damage; and Ma huang contains ephedrine, a CNS stimulant. No CAM technique or preparation has been demonstrated to cause tumor regression. Memorial Sloan-Kettering Cancer Center has a Web site (<http://www.mskcc.org/aboutherbs>) on which it provides unbiased scientific reviews about potential drug interactions and adverse effects of some 135 herbal and botanical agents relevant to cancer patients (Mitka 2003).

In the United States, 83 million people use alternative therapies for malignant and nonmalignant disorders, and 70%–90% do not describe these treatments to their doctors (Gertz and Bauer 2001), in part because doctors often do not ask or provide negative remarks about CAM. A study of women with newly diagnosed early-stage breast cancer found that 28% used alternative medicine (Burstein et al. 1999). Interestingly, the use of alternative medicine was independently associated with depression, fear of recurrence of cancer, lower scores for mental health and sexual satisfaction, and more physical symptoms, suggesting that those who seek alternative medicine therapies may be experiencing more anxiety, depression, or physical symptoms. Those taking alternative medications may be more in need of but less open to psychiatric consultation.

Most patients who elect to use untried or unproven therapies do so in a desperate search for a cure or for a

# 25 Rheumatology

---

Chris Dickens, M.B.B.S., Ph.D.

James L. Levenson, M.D.

Wendy Cohen, M.D.

**RHEUMATOLOGICAL DISORDERS** are an overlapping group of conditions that are characterized by chronic inflammation involving connective tissues and organs. The disorders arise as the result of autoimmune processes, and the various diseases are differentiated on the basis of the clinical presentation and the patterns of immune disturbance.

In the following chapter, we describe aspects of the rheumatological disorders that are likely to be relevant to a clinician working in the field of psychosomatic medicine. Most of the chapter is devoted to rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE), because these disorders are likely to be encountered most commonly; other disorders, including osteoarthritis, Sjögren's syndrome, systemic sclerosis, temporal arteritis, polymyositis, polyarteritis nodosa, Behçet's disease, and Wegener's granulomatosis, are also discussed. Issues relating to the psychiatric problems resulting from treatments are dealt with at the end of the chapter because of the considerable degree of overlap between the different disease states. Fibromyalgia is covered in Chapter 26, "Chronic Fatigue and Fibromyalgia Syndromes."

## General Principles of Diagnosis and Assessment

---

### Detecting Central Nervous System Involvement in Rheumatological Disorders

Although many clinical signs and symptoms, as well as laboratory test results, are suggestive of neuropsychiatric involvement, none is diagnostic. Diagnosis is primarily based on a constellation of clinical findings, lab test re-

sults, and neuroimaging that are corroboratory and that exclude comorbid conditions and secondary causes of neuropsychiatric symptoms (Sibbitt et al. 1999).

### *Mental Status Examination and Neuropsychological Testing*

The mental status examination is the most sensitive, available, and least expensive tool for detecting and tracking neuropsychiatric status in rheumatological disorders. Neuropsychological testing provides a more detailed, sensitive assessment of cognitive function, but it is not specific. Even in the absence of any rheumatological disorder, neuropsychiatric testing often reveals subtle cognitive abnormalities; consequently, such findings are not necessarily diagnostic of active neuropsychiatric rheumatological disease (Carbotte et al. 1995).

### *Laboratory Tests*

No laboratory test, or set of tests, is considered diagnostic of neuropsychiatric involvement in rheumatological disorders. Nevertheless, laboratory studies serve two purposes. First, they help rule out infection, as well as other complications of rheumatological disorders or their treatment that can present with neuropsychiatric symptoms. Second, positive laboratory results confirm the presence of rheumatological disease activity. Although neuropsychiatric involvement can pursue a clinical course somewhat independent of flares in other organs, high disease activity increases the likelihood of primary central nervous system (CNS) involvement, because the pathogenesis is shared. However, the absence of systemic disease activity does not preclude CNS involvement. Moreover, systemic disease activity seems to have little, if any, corre-

lation with certain neuropsychiatric symptoms, particularly fatigue and cognitive dysfunction (Carbotte et al. 1995; Waterloo et al. 2002).

Laboratory tests can also be useful in evaluating psychiatric symptoms in rheumatology patients with a history of a primary psychiatric illness such as schizophrenia or major depression. Primary psychiatric disorders do not cause elevations in erythrocyte sedimentation rate (ESR) or other markers of inflammation. Accordingly, if the psychiatric symptoms temporally coincide with a markedly increased ESR, then medical etiologies, particularly infection and CNS involvement, must be strongly considered.

When rheumatology patients have neuropsychiatric symptoms, lumbar puncture is indicated to rule out CNS infection and assess the degree of disease activity in the CNS. In patients without CNS infection, cerebrospinal fluid (CSF) pleocytosis and increased CSF protein are suggestive of CNS involvement by lupus or other rheumatological disease (West 1994). In addition, CSF studies should include oligoclonal bands, which are only present in a small number of disorders, including neurosyphilis, Lyme disease, multiple sclerosis, Sjögren's syndrome, and CNS SLE. A number of other CSF tests have been associated with neuropsychiatric SLE but are not widely available or timely (W. Cohen et al. 2004).

### *Electroencephalogram*

In patients with rheumatological disorders who also have neuropsychiatric symptoms, the electroencephalogram (EEG) is often abnormal but seldom useful (Waterloo et al. 1999), except in diagnosing subclinical seizure activity or differentiating hypoactive delirium (diffuse slowing on EEG) from depression (normal EEG).

### *Neuroimaging*

Although magnetic resonance imaging (MRI) is the best available imaging technique for identifying focal neurological lesions in patients with rheumatological disorders and neuropsychiatric symptoms, it is inherently limited because it detects only structural lesions, whereas the pathophysiology of the neuropsychiatric problems can be entirely functional. Also, MRI cannot reliably differentiate active from chronic lesions resulting from a previous neuropsychiatric insult (Sabbadini et al. 1999).

## Detecting, Diagnosing, and Quantifying Psychiatric Symptoms and Disorders

Despite their high prevalence and significant impact on the patient's illness and overall quality of life, psychiatric

disorders remain mostly unrecognized and undertreated in patients with rheumatological disorders. This underrecognition is partly attributable to a tendency to focus on the physical aspects of disease, coupled with limited resources in some health care systems. The problem of undertreatment of depression in rheumatological disorders is exacerbated by a misconception that because depression is understandable, occurring secondary to the pain and disability, treatment of the depression is not appropriate or necessary (Rifkin 1992). Furthermore, diagnosing depression in patients with rheumatological disorders is complicated because there is an overlap in symptoms of depression and rheumatological disorders (e.g., fatigue, weight loss, insomnia, and lack of appetite) such that the depression frequently goes unrecognized (Rifkin 1992).

Use of standardized psychiatric questionnaires (the Minnesota Multiphasic Personality Inventory, the Beck Depression Inventory [BDI], and the Center for Epidemiologic Studies Depression Scale) tends to overestimate the prevalence of depression, because many questionnaires include somatic symptoms that may be attributable to the rheumatological disorders (Callahan et al. 1991; Pincus et al. 1986). Scales that have little somatic content, such as the Geriatric Depression Scale (Sheikh and Yesavage 1989), the Hospital Anxiety and Depression Scale (HADS) (Zigmond and Snaith 1983), or disease-specific instruments (Smedstad et al. 1995) may aid accurate diagnosis of depression in such patients. These self-rated questionnaires may be used by rheumatologists or specialist nurses to identify probable cases of psychiatric disorder. With additional training in the use of follow-up questions to confirm cases of depression, rheumatologists can initiate antidepressant treatment where indicated, thus avoiding referrals to psychiatrists in uncomplicated cases.

Complex cases will require more detailed assessment by a psychosomatic medicine specialist. In addition to assessing the patient's current mental state, the specialist psychiatrist should explore the development of psychiatric symptoms and how these relate to the recent disease state and changes in management, availability of social support, psychosocial stresses resulting from pain and disability, and stresses independent of the illness. Inquiries about maladaptive coping strategies to physical symptoms (e.g., "I just lie down and wait for my symptoms to ease"; "I simply avoid activities that cause me pain") can identify fruitful targets for psychological interventions. Assessing past psychiatric history and family history will help identify which patients are most vulnerable to developing depression and other psychiatric disorders. Finally, investigating the patient's personal beliefs about the illness, such as the perceived causes, possible outcomes, and likelihood of

controlling disease progression through treatment, can identify psychological mechanisms by which psychiatric problems have arisen.

## General Principles of Treatment

---

### Primary Neuropsychiatric Involvement

When rheumatological diseases affect the CNS, the primary treatment is *corticosteroids* when the pathophysiology is thought to be neuronal injury or inflammation resulting from autoantibodies, and *anticoagulants* when hypercoagulability is involved (e.g., the anticardiolipin antibody syndrome). When corticosteroids are ineffective, other immunosuppressive agents may be helpful.

### Primary Psychiatric Disorders

Intervention studies have shown that psychological treatments, mostly cognitive and behavioral, are effective in reducing psychological distress and improving coping in subjects with rheumatological disorders (Bradley et al. 1987; Sharpe et al. 2001). In addition, such therapies may reduce pain and improve functioning, though it is unclear whether any of these effects is mediated by changes to the inflammatory state (Bradley et al. 1987; Sharpe et al. 2001).

Psychological interventions should always be considered in patients with rheumatological disorders who have psychiatric problems. Because of easier access, pharmacological interventions are more often used, with psychological therapies usually reserved for more complex cases. Cognitive-behavioral principles, however, can be employed by rheumatologists, specialist nurses, and physical or occupational therapists to optimize patients' care. As a matter of routine, newly diagnosed patients should be educated about the disease and its likely course—an approach that can facilitate adherence. Subjects with severe advanced disease might benefit from psychological adjuncts to physical management. Between these two extremes, maintaining an awareness of the importance of psychological processes in determining illness behavior might help the rheumatologist identify, treat, and make referrals for problems appropriately.

Lack of familiarity with antidepressant drugs among rheumatologists may also contribute to the undertreatment of depression. There is a wide choice of antidepressants currently available to clinicians, yet the majority of these drugs have not undergone assessment of efficacy in patients with physical illness. Current evidence from studies in psychiatric and other chronic pain patient populations indicates that various types of antidepressants,

when given in appropriate psychotherapeutic doses, have roughly equal efficacy in the treatment of depression (Anderson et al. 2000). However, they do differ in their analgesic efficacy, tolerability, and profile of drug interactions.

Tricyclic antidepressants (TCAs) with the least specific receptor activity, such as amitriptyline, appear to have the greatest analgesic efficacy (Onghena and Van Houdenhove 1992), even at low doses (e.g., 25 mg of amitriptyline) and independent of whether depression is present or not (Bromm et al. 1986). In higher doses, tolerability and safety are poor, particularly in the elderly. Newer drugs have comparable antidepressant efficacy, although their analgesic efficacy has yet to be established, and they are more expensive. In general, selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine or citalopram, in doses up to recommended maxima should be considered as first-line treatment for depression in RA (Anderson et al. 2000). Gradually introduced TCAs, such as amitriptyline or dothiepin (not available in United States), should be used in low doses (25–75 mg) for pain relief (Onghena and Van Houdenhove 1992). Combined use of TCAs and SSRIs greatly increases the risk of adverse events and should be avoided unless under expert guidance. Drug interactions may occur, although this is not a problem with first- and second-line treatments for RA.

Treatment of anxiety, mania, psychosis, delirium, and pain in rheumatological disorders is similar to their treatment in other medical diseases, following the principles reviewed in other chapters in this book (Chapter 6, “Delirium”; Chapter 11, “Mania, Catatonia, and Psychosis”; Chapter 12, “Anxiety Disorders”; Chapter 36, “Pain”).

## Rheumatoid Arthritis

---

Rheumatoid arthritis affects approximately 0.8% of the population (range=0.3% to 2.1%), with women being affected approximately three times more frequently than men. It is a chronic disorder characterized by persistent inflammatory synovitis. Though any synovial joint can be affected, the disease typically involves peripheral small joints in a symmetrical pattern. Inflammation of the synovium can result in destruction of joint cartilage and bony erosions, which can eventually result in destruction of the joint. Extra-articular manifestations are common, with some degree of extra-articular involvement being found in most patients. These extra-articular manifestations vary widely among patients but may include systemic symptoms (anorexia, weight loss, myalgia); more localized abnormalities such as rheumatoid nodules; or in-

involvement of the cardiovascular system (vasculitis, pericarditis), respiratory system (pleural effusions, pulmonary fibrosis), or CNS (spinal cord compression, peripheral neuropathy). The typical course of RA is prolonged, characterized by relapses and remissions. As the disease advances, progressive joint destruction results in limitations to joint movements, joint instability and deformities that increase pain, and functional disability.

The main aims of treatment of RA are 1) analgesia, 2) reduction of inflammation, 3) joint protection, 4) maintenance of functional ability, and 5) reduction of systemic manifestations. Pharmacological management involves a number of different types of drug treatment.

- Nonsteroidal anti-inflammatory drugs (NSAIDs) control symptoms and signs of local inflammation, although they do not appear to alter the eventual course of the disease.
- A number of drugs have been found that alter the course of the disease by reducing the inflammatory component of RA (e.g., methotrexate, antimalarials, minocycline, and sulfasalazine); gold and penicillamine are almost never used anymore.
- Corticosteroids can be used to reduce signs of inflammation by systemic administrations (oral or parenteral) or by local injection.
- Currently available biological response modifiers include the anti-TNF-alpha therapies—namely, etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), and an interleukin-1 (IL-1) receptor antagonist, anakinra (Kineret) (Olson et al. 2004).
- Immunosuppressive agents (azathioprine, leflunomide, cyclosporin, and cyclophosphamide) also reduce inflammation in RA, but because of toxicity, their use is limited to patients who are resistant to other treatments.

## Neuropsychiatric Disorders in Rheumatological Disorders

### *Epidemiology*

Neuropsychiatric disorders are common in patients with RA, as they are in most chronic illness populations. The wide variation in prevalence figures in the literature may be attributed to the use of self-rated questionnaire assessments to identify cases of psychiatric disorder (Creed 1990). More conservative figures, obtained by using standardized research interviews, indicate that about one-fifth of patients with RA have a psychiatric disorder. Using the Present State Examination, Murphy and colleagues (1988) interviewed a mixed group of inpatients and outpatients with definite or classic RA and found that 21% of subjects

had a psychiatric disorder: 12.5% were depressed, and the remainder were anxious. This study also revealed that a population of RA patients of approximately equal size (19%) had psychiatric symptoms, although they did not meet the criteria for a psychiatric disorder. These prevalence figures are consistent with those from other studies that used standardized research interviews (Frank et al. 1988).

### *Etiology*

Neuropsychiatric manifestations in RA can arise through four processes: 1) direct CNS involvement, 2) secondary effects of the illness or its treatments, 3) emotional reactions to chronic illness, and 4) comorbid primary psychiatric illness.

## Involvement of the Central Nervous System in Rheumatoid Arthritis

Despite its multisystem manifestations, neurological complications in RA are not common. When present, the most common is peripheral neuropathy due to entrapment resulting from synovial proliferation or vasculitis. Direct involvement of the CNS is rare. Atlanto-axial subluxation may occur, resulting in transverse myelitis, and is the most widely recognized CNS complication of RA.

Vasculitis in RA can involve cerebral vessels, resulting in cerebral ischemia or infarction, and has been associated with acute and chronic brain syndromes (Ando et al. 1995; Gobernado et al. 1984; Ohta et al. 1998; Singleton et al. 1995). Treatment with corticosteroids can usually alleviate vasculitis and edema, with resultant improvement in symptoms, but impairment from the infarction is permanent. Rarer CNS complications include transient ischemic attacks resulting from RA-associated thrombocytosis (Pines et al. 1982) and embolic phenomena as a consequence of RA-related granulomata in major arteries (Chatzis et al. 1999).

## Psychiatric Disorders as a Reaction to Illness

The vast majority of psychiatric disorders in patients with RA are emotional reactions to having RA. Patients experience life stress because of the burden not only of chronic physical symptoms but also of personal losses resulting from RA and associated disability. Albers et al. (1999) found that in 89% of RA patients, the disease adversely affected at least one domain of socioeconomic functioning (work, income, required rest time during day, leisure activity, transport mobility, housing, and social dependency), with 58% experiencing adverse effects in at least three domains. Other social impacts to consider are loss of

personal ambitions, loss of social role, loss of future financial security, relationship disturbances, and body image concerns. Social support that might help to offset the stress of RA may be less available because of limited mobility. Furthermore, RA patients may have fewer coping resources available to deal with comorbid illnesses and stresses unrelated to RA. The evidence for the associations of emotional reactions and the various aspects of RA are dealt with next.

## Psychological Symptoms and Clinical State

A large number of studies have examined the associations of depression with the physical symptoms of RA. Cross-sectional studies using self-report measures have shown that levels of depressive symptoms are associated with the severity of the pain experienced (Frank et al. 1988; Hurwicz and Berkanovic 1993; Peck et al. 1989; Smedstad et al. 1995; Wolfe 1999), and the degree of functional disability (Brown et al. 1989; Hurwicz and Berkanovic 1993; Pow 1987; Smedstad et al. 1996; Wolfe 1999). Some of the associations observed might be attributable to the use of depression measures such as the BDI, in which physical symptoms associated with the RA itself—for example, disturbed sleep, fatigue, and loss of appetite—are rated as indicators of depression. Exclusion of these somatic items leaves smaller though still significant associations between depression and the physical symptoms of RA (Peck et al. 1989).

Few longitudinal studies have examined whether changes in depression correlate with changes in the severity of RA symptoms. Wolfe et al. found that changes in depression were associated with changes in pain and disability, although only 17% of the variance in depression was accounted for by these two variables, indicating that the degree of association was weak (Wolfe and Hawley 1993).

The literature just cited indicates that psychological symptoms, particularly depression, are most marked in patients with worse pain and disability, although the strength of this association is modest at best. However, it is possible that these studies underestimate the strength of the association of physical symptoms and psychological problems. The measures used to assess physical state are generic assessments of functional ability. If depression is related to loss of function, the value or meaning of the lost activity to the individual could be important. In other words, generic measures provide a broad overview of function but may not be sensitive to what is important to the individual. Katz and Yelin (1995) performed an extremely detailed prospective longitudinal study of women with RA. Subjects were followed for 4 years to identify as-

pects of function that predicted the development of depression in the final year of the study. Although generic measures of function predicted a fourfold increase in depression, a 10% loss in activities that the individuals had identified as being important to them resulted in a sevenfold increase in depression in the subsequent year.

Furthermore, the vast majority of the research performed in this area has focused on ambulatory outpatients, probably for a combination of ethical and convenience reasons. It is possible that the association between physical and psychiatric symptoms is weak because of the mild to moderate nature of the symptoms in many of the patients studied. Mindham et al. (1981) conducted a prospective study involving a small number of patients with RA. They confirmed the positive association between symptoms of RA and the development of psychiatric symptoms considered to be of “pathological severity,” though this association was weak and nonspecific in the majority of their patients. Only in subjects with the most severe and disabling RA did they find an association between symptoms of RA and the development of several psychiatric symptoms together, indicating the development of a psychiatric disorder. Thus, the association between symptoms of RA and psychological symptoms may become more pronounced in subjects with the most severe disease.

## Role of Cognitive Factors

The way RA patients think about their illness is crucial to understanding the association of depression with pain and disability. Depression is associated with increased worry about illness and conviction of severe disease (Pilowsky 1993). Depressed RA patients perceive their illness as being more serious and feel hopeless about a cure compared with nondepressed RA patients (Murphy et al. 1999). Furthermore, depressed patients are more likely to have cognitive distortions relating to the RA (Smith et al. 1988). These associations remain significant in RA patients even after the extent of disease and pain levels are controlled, indicating that the association between depression and negative appraisals of health status is not simply the result of depressed people having more severe illness.

The way people think about or understand their illness is also important, because it influences the way RA patients cope with the illness. According to Leventhal's model, individuals hold personal representations and beliefs about their health and any threat posed to it (Leventhal et al. 1997). These personal representations have both cognitive and emotional components, are based on a lay knowledge or understanding of health and illness, and

thus may significantly differ from those of the consulting clinician. Patients' perceptions of a health threat initiate the use of coping strategies, the results of which are then appraised and may result in a change in the representations or a revision of the strategy. Coping strategies may be broadly described as adaptive if they result in normalization of a patient's life—that is, minimizing symptom impact—or maladaptive if they result in increased dependency. Depression is associated with impairment of general coping, especially at high levels of pain (Brown et al. 1989; Hurwicz and Berkanovic 1993).

Thus, psychiatric disorders, particularly depression, appear to be associated with a more negative appraisal of the illness and impairment in ability to cope with the illness. As such, these cognitive factors may act as mediators in the association between the physical symptoms of RA and psychiatric disorders. It should be recognized, however, that the amount of variance in depression accounted for by perceived control, coping ability, and cognitive distortions is small, with the majority being unexplained (Persson et al. 1999)

## Other Psychosocial Factors

A number of other psychosocial factors that may predispose any RA patient toward psychiatric problems have been suggested.

### *Neuroticism*

Some individuals are predisposed to experience and react to stress, including health stress, in a negative way. People with such negative affectivity, or *neuroticism*, have been shown to be more sensitive to physical sensations (Harkins et al. 1989; Larsen 1992), interpret physical sensations as threatening (Larsen 1992), experience more emotional distress regardless of the environment (Ormel and Wohlfart 1991), and choose less effective coping strategies (Bolger and Schilling 1991; Bolger and Zuckerman 1995). The importance of neuroticism has been confirmed in patients with RA. In a prospective study, RA patients completed daily reports on joint pain and mood for a period of 75 days. Those scoring higher on neuroticism experienced more chronic distress, regardless of their pain intensity (Affleck et al. 1992).

### *Social Support*

It is recognized that social support is associated with health and good quality of life in the general population (S. Cohen and Wills 1985). A number of studies have demonstrated that social support benefits patients with RA (Goodenow et al. 1990). In patients with RA, social support, and its actual or perceived availability, have been

shown to be associated with use of more adaptive coping strategies (Manne and Zautra 1989), greater perception of ability to control the disease (Spitzer et al. 1995), and less psychological distress (Affleck et al. 1988; Doeglas et al. 1994; Evers et al. 1997, 1998; Revenson et al. 1991). Not all social contacts are supportive, however, and critical or punishing comments are associated with increased psychological distress (Griffin et al. 2001; Kraaimaat et al. 1995; Revenson et al. 1991).

Rheumatoid arthritis has an adverse effect on the availability of social support to its patients, however. Patients with RA have been shown to have reduced social networks and social support (Fitzpatrick et al. 1991; Fyrand et al. 2000, 2001). This disruption of social support appears to be greatest in those with disease of greatest duration with most severe functional disability, possibly caused by a significant reduction in the availability of important others to patients with RA (Murphy et al. 1988).

### *Social Stresses*

Social stresses are recognized as being potent causes of depression in the general population. Particularly important in causing depression are those stresses in which the degree of threat to the individual is great—so-called severe events and marked difficulties (Brown and Harris 1979). As indicated previously, in addition to the burden of the symptoms, RA patients experience considerable hardship in association with their chronic illness. Social stresses independent of those of RA are also likely to contribute to the development of depression in RA patients, however. In fact, among ambulatory outpatients the stresses independent of RA may well have a greater importance in predicting depression than the RA-related stresses (Dickens et al. 2003). The findings of this study indicate that in patients with mild to moderate arthritis, RA-related life difficulties cause psychological distress that does not amount to a full-blown psychiatric disorder, perhaps because the degree of threat is not marked. The combination of RA-related and RA-independent stresses, however, is sufficient to cause a depressive disorder. Clearly, in subjects with the most severe, disabling arthritis, the situation is likely to be different, with RA-related difficulties alone being a sufficiently potent stress to result in depressive disorder (Mindham et al. 1981).

A number of studies have suggested that social stresses might play an important part in triggering the onset of RA in adults (G.H.B. Baker and Brewerton 1981; Hendrie et al. 1971; Rimon 1969; Shochet et al. 1969). All of these studies use unreliable retrospective measures that could be contaminated by the RA patients' effort to explain the onset of their disease by linking it spuriously with life events occurring around the time of the onset of

the symptoms: Three studies used unstructured interviews, and one used a simple scale. In the most careful research in this area (Conway et al. 1994), 60 consecutive outpatients with RA were studied with the most reliable method of assessing life events, the Life Events and Difficulties Schedule (Brown and Harris 1979). This semi-standardized research interview allowed the researcher to ask questions in detail about the timing of any life stresses, and the severity of the stress was rated by a panel blinded to the details of the illness. In this study there was no evidence of an excess of stressful events in the 12 months preceding the onset of RA. However, there was no control group in this study, and the researchers' findings relied on comparisons with so-called normal populations. More research is needed in this area.

### Impact of Mental Disorders

The mechanisms by which depression influences pain and disability are also poorly understood. Although depression and psychological stress have been shown to result in immune dysfunction (Herbert and Cohen 1993), there is no evidence to suggest that depression increases the pain and disability of RA by changing the underlying inflammatory activity. Studies suggesting that depression increases disease activity, or that psychological treatment reduces RA activity, have mostly relied on clinical assessments of disease activity such as counting tender joints (Bradley et al. 1987). Such clinical assessments rely on patient reports of tenderness and are vulnerable to the effects of depression, including pessimistic self-perception and the negative way patients react to their illness.

Few studies have shown that psychological interventions improve biological markers of disease activity in RA (e.g., ESR, C-reactive protein [CRP], or rheumatoid factors). In a recent blind, controlled trial of a cognitive-behavioral therapy (CBT) intervention for patients in an early stage of RA, those receiving adjunctive CBT versus standard treatment showed an improvement in CRP (but not ESR) immediately following therapy, but this effect was lost by 6 months (Sharpe et al. 2001). It remains unclear whether this was a direct effect of the CBT on inflammatory activity or a result of behavior-mediating factors, which seems more likely, such as improved compliance with treatment in the intensively followed-up group.

As mentioned previously, psychiatric disorders, particularly anxiety and depression, are associated with more negative illness cognitions in RA. As a result of these negative illness cognitions, health-seeking behaviors and health care utilization may increase as they do in other medical patients (Macfarlane et al. 1999; Manning and Wells 1992; Wells et al. 1989). Depressed RA patients are

more likely to report physical symptoms (Murphy et al. 1999), less likely to be reassured by a doctor (Pilowsky 1993), and less likely to comply with medications (DiMatteo et al. 2000). We know there is an immense variation in the health care costs among subjects that is not directly related to the severity of RA (Lubeck et al. 1986; Simon et al. 1995). Depression is likely to contribute to these hitherto unexplained costs. The impact of depression on indirect (social) costs is likely to be even greater (Yelin et al. 1979).

### Osteoarthritis

---

Osteoarthritis (OA) is the most common joint disease, with the idiopathic form being the most prevalent. Secondary OA arises most frequently as the result of trauma (acute or chronic), although it also may occur in a variety of metabolic and endocrine disorders. The prevalence of OA increases sharply with age: less than 2% of women younger than 45 years are affected, compared with 30% of those between 45 and 64 years of age and 68% of those older than 65 years.

The pattern of joint involvement varies with age and sex; OA involving the hip is more common in older men, whereas involvement of the interphalangeal joints and of the first metacarpophalangeal joint is more common in elderly women. Previous joint overload—in particular, repetitive incidences, as in vocational injuries—have a considerable influence on the distribution of joint involvement. Clinically affected joints are painful, especially on movement, and are stiff after a period of inactivity. In later stages of the disease, movements are limited, and joint instability may occur, which is exacerbated by atrophy of muscles adjacent to the affected joint.

There has been considerably less research interest in the causes, prevalence, and impact of psychological disorders in OA compared with those in other musculoskeletal disorders. Because direct involvement of the CNS is not a feature of primary OA, one can conclude that psychological disorders in patients with this disorder arise either as a reaction to the pain, disability, and life difficulties related to the OA or for reasons independent of the OA.

In regard to the prevalence of psychological disorders, depression was found to be no more common in a community sample of persons with OA than in the general population (Dexter et al. 1994). The extremely high prevalence of OA in the population means that a large proportion of those with the disease experience relatively minor pain and disability from their OA. These people are not troubled excessively by their OA, they do not seek medical care, and adverse psychological sequelae are not com-

mon. In a study of patients with a variety of musculoskeletal disorders who were attending a secondary care facility, patients with OA of the knee or hand tended to have slightly lower scores on an standardized assessment of depression compared with patients with other musculoskeletal disorders (Hawley et al. 1993). These results taken together indicate that OA is less closely associated with depression than is RA, although studies of patients with more advanced disease are required.

When depression does occur in patients with OA, it has been shown to be associated with a number of factors: younger age, less education, higher pain, and greater self-reported impact of the OA (Dexter et al. 1994; van Baar et al. 1998; Zautra et al. 2001). Other psychological factors such as anxiety and hopelessness have been shown to be associated with functional disability (Creamer et al. 2000).

Few intervention studies have examined the efficacy of antidepressants and psychological therapies in OA. Those that have been performed suggest that both antidepressants and cognitive-behavioral therapy are efficacious in the treatment of depression in patients with OA and that improvement in depression is associated with reduced pain and disability from the disease (Calfas et al. 1992; Lin et al. 2003).

## Systemic Lupus Erythematosus

SLE is an autoimmune disorder of unknown cause characterized by immune dysregulation with tissue damage caused by pathogenic autoantibodies, immune complexes, and T lymphocytes. Approximately 90% of cases are in women, usually of childbearing age. The incidence is 2.4 per 100,000 across genders and race, 9.2 for black women and 3.5 for white women; and prevalence rates are 90 per 100,000 for white women and 280 for black women. Asians are also more often affected than whites. At onset, SLE may involve one or multiple organ systems. Common clinical manifestations include cutaneous lesions (photosensitivity, malar or discoid rash, oral ulcers), constitutional symptoms (fatigue, weight loss, fevers), arthralgias and frank arthritis, serositis (pericarditis or pleuritis), renal disease, neuropsychiatric disorders, and hematological disorders (anemia, leukopenia). Autoantibodies are detectable at presentation in most cases. The spectrum of treatment options in SLE is similar to that in RA: namely, NSAIDs, antimalarials (e.g., hydroxychloroquine), corticosteroids, and other immunosuppressants (e.g., azathioprine, mycophenolate mofetil, methotrexate, cyclophosphamide). The role of biological response modifiers is currently under investigation, but none is now approved for this indication.

In addition, anticoagulants are used in SLE patients who have antiphospholipid antibodies if there is a history of arterial or venous thrombosis. The rate of 20-year survival has been reported to be 50%–70% (Lahita 2004) but is improving with newer immunosuppressive treatments.

## Psychiatric Manifestations

Neuropsychiatric symptoms of SLE were first reported in 1872 by Kaposi (1872). Depending on the diagnostic methodology used, neuropsychiatric manifestations have a prevalence of up to 75%–90% (Ainiala et al. 2001a; West 1994), ranging from stroke, seizures, headaches, neuropathy, transverse myelitis, and movement disorders, to cognitive deficits, depression, mania, anxiety, psychosis, and delirium. CNS involvement is a major cause of morbidity in SLE, second only to renal failure as a cause of mortality. The pathogenesis of neuropsychiatric syndromes in SLE is complex. For a more detailed review of psychiatric aspects of SLE, see W. Cohen et al. 2004.

### *Pathogenesis of Neuropsychiatric Manifestations*

Psychiatric syndromes in SLE can be caused by 1) direct CNS involvement; 2) infection, other systemic illness, or drug-induced side effects; 3) reaction to chronic illness; or 4) comorbid primary psychiatric illness.

### *Direct Pathophysiological CNS Effects*

Two major antibody-mediated mechanisms of CNS injury have been proposed: neuronal injury and microvasculopathy (Scolding and Joseph 2002). Autoantibodies may directly damage neurons by either causing cell death or transiently and reversibly impairing neuronal function. Antibody-mediated microvasculopathy seems to involve two processes: either endothelial damage (Wierzbicki 2000) or coagulation disturbances resulting from the prothrombotic effects of antiphospholipid (including anti-cardiolipin) antibodies (Gharavi 2001), both culminating in ischemia or infarction. These two pathogenic mechanisms may be mutually reinforcing, perpetuating the disease process. Microvascular endothelial injury in the CNS may increase the permeability of the blood-brain barrier, leading to influx of autoantibodies and further CNS damage.

Autoimmune antibodies seem to play a much larger role in direct CNS involvement (Jennekens and Kater 2002; Scolding and Joseph 2002) than does immune complex deposition. Antiribosomal-P antibodies have been associated with psychosis (Isshi and Hirohata 1998) and severe depression (Arnett et al. 1996), but not consistently (Gerli 2002). Antineuronal antibodies have been associated with psychosis, depression, delirium, coma, and cognitive dys-

function (West et al. 1995). In contrast, antiphospholipid antibodies (e.g., anticardiolipin) cause focal deficits (strokes) and cognitive dysfunction (Levine et al. 2002; Menon et al. 1999; West et al. 1995). Cytokines also appear to be involved in the pathogenesis of neuropsychiatric SLE, although their role remains unclear.

With the possible exception of cognitive dysfunction, all the major psychiatric manifestations of SLE (i.e., psychosis, depression, mania, anxiety, and delirium) exhibit a degree of reversibility, as does coma. Even the cognitive deficits sometimes respond to corticosteroids (Denburg et al. 1994; Hanly et al. 1997). Because psychiatric syndromes tend to resolve within 2–3 weeks with corticosteroid treatment (Denburger et al. 1994), they are probably caused by reversible or transient mechanisms rather than irreversible neuronal death. The reversibility of psychiatric dysfunction stands in contrast to most focal neurological events, which often have no more reversibility than atherosclerotic stroke and are associated with fixed lesions on neuroimaging. Similarly, in some patients, the progressive nature of cognitive impairment (Hanly et al. 1997; Menon et al. 1999), often with cerebral atrophy, suggests cumulative irreversible CNS damage.

Risk factors for direct CNS involvement in SLE include cutaneous vasculitis and antiphospholipid syndrome and its manifestations, especially arterial thromboses (Karassa et al. 2000). Patients with mainly articular manifestations or discoid rash have a much lower risk of neuropsychiatric lupus, as do those few who are antinuclear antibody (ANA)–negative and those with drug-induced SLE. Antiphospholipid antibodies may be the single strongest marker of CNS risk, because they are associated with stroke, cognitive dysfunction, and epilepsy (Herranz 1994; Sabet et al. 1998).

## Psychological Impact

Coping with SLE is particularly challenging because lupus is a chronic, often debilitating multisystem illness, and its course is unpredictable. Because SLE can involve almost any organ system or include vague systemic symptoms, the diagnosis is often elusive. The inability to make a diagnosis may erode the patient's confidence in the medical system, and when no etiology can be found, the physician may deem the illness psychogenic. Given that SLE can affect many organ systems, patients may worry that the illness pervades their entire body, even when the disease is limited. The diffuse nature of SLE distinguishes it from most other chronic, recurrent diseases, such as asthma or inflammatory bowel disease, which are primarily limited to one organ. SLE patients are often under the care of an entourage of specialists, which may frag-

ment care. One of the most stressful aspects of SLE is its unpredictable course, with sudden exacerbations, remissions, and variable prognoses, resulting in a profound loss of control, as well as a loss of ability to plan for the future.

Psychological reactions to having SLE are common and include grief, depression, anxiety, regression, denial, and invalidism. A feeling of isolation is reinforced by public ignorance about lupus. People with SLE may become socially withdrawn, especially if they are self-conscious about their appearance. Women with a malar rash or discoid lesions may feel branded as if by the "scarlet letter." (Perry and Miller 1992). The most prevalent fears of SLE patients are worsening disease, disability, and death. In particular, patients fear cognitive impairment, stroke, renal failure, and becoming a burden on their families (Liang et al. 1984). Although negative reactions to having SLE are common, at least 50% of patients experience positive reactions at some point during their illness (Liang et al. 1984).

## Stress and SLE

Although stress may cause a lupus flare, it is also likely, if not inevitable, that lupus flares cause stress. Several studies have provided support for stress-induced immune dysregulation in SLE. In response to acoustic, psychological, and exercise-induced stress, the normal increase in B- and T-suppressor or cytotoxic lymphocytes and decrease in T-helper lymphocytes are blunted in SLE patients, relative to healthy control subjects, patients with sarcoidosis, and others receiving corticosteroids (Ferstl et al. 1992; Hinrichsen 1989). Stress (because of public speaking) was associated with a transient increase in interleukin-4 (IL-4)–producing cells in SLE patients, but not in healthy control subjects. This immune response might precipitate a flare because IL-4–producing cells cause proliferation of activated B cells and, consequently, increased autoantibody production (Jacobs et al. 2001). In a 6-month prospective study of 41 patients with SLE, daily stress correlated positively with ANAs and anti-double-stranded DNA antibodies (Pawlak et al. 2003).

Whether stress precipitates onset or exacerbation of SLE symptoms has received relatively little study. There is only one controlled study demonstrating that 20 patients hospitalized for SLE had significantly greater stress prior to the onset of their illness than did the seriously ill hospitalized controls (Otto and Mackay 1967). Retrospective uncontrolled studies link lupus flares to preceding stress (Hall et al. 1981; Ropes 1976). However, in a naturalistic study after a severe earthquake in Los Angeles, none of the rheumatology patients studied (10 with SLE and 13 with rheumatoid arthritis) residing near the epicenter developed a significant flare of illness (Wallace and Metzger 1994).

## Classification of Psychiatric Disorders in Systemic Lupus Erythematosus

The literature on neuropsychiatric SLE has been plagued by terminology that has been imprecise and unstandardized. Terms such as “lupus cerebritis” have obfuscated our understanding because they imply a pathogenesis (inflammation) that remains unproven. Furthermore, because there is no gold standard for the diagnosis of neuropsychiatric SLE, ascertaining which conditions are direct CNS manifestations of SLE versus a reaction to illness has been controversial. To rectify these problems, the American College of Rheumatology (ACR) convened a committee to develop a standardized nomenclature for neuropsychiatric SLE, and guidelines were published in 1999 (American College of Rheumatology Ad Hoc Committee 1999). The guidelines defined neuropsychiatric lupus as “the neurological syndromes of the central, peripheral, and autonomic nervous systems, and the psychiatric syndromes observed in patients with SLE in which other causes have been excluded.” Psychiatric disorders included psychosis, acute confusional state, cognitive dysfunction, anxiety disorder, and mood disorders. Overall, the ACR criteria significantly broadened the spectrum of syndromes that can be considered neuropsychiatric SLE (American College of Rheumatology Ad Hoc Committee 1999). The criteria have good sensitivity but low specificity (Ainiala et al. 2001b), making them better suited for identifying all possible cases of neuropsychiatric SLE. A more fundamental problem with the ACR classification system is that it is difficult to apply clinically. To diagnose neuropsychiatric SLE as the cause of the psychiatric symptoms, one must exclude a primary psychiatric disorder. In contrast, in DSM-IV and its text revision, DSM-IV-TR (American Psychiatric Association 1994, 2000), a primary psychiatric disorder cannot be diagnosed unless medical disorders and substance use are ruled out as etiologies. Whereas medical disorders and substance use can be easily excluded, there are no clinical criteria or laboratory tests for excluding primary psychiatric disorders. For example, if a patient with SLE becomes depressed, it is unclear how one would rule out primary depression as the cause.

Cognitive dysfunction is the most common neuropsychiatric disorder in patients with SLE, occurring in up to 80% of patients (Ainiala et al. 2001a; Denburg et al. 1994). On neuropsychological testing, even patients who have never had overt neuropsychiatric symptoms are often found to have cognitive impairment. Patients with anticardiolipin antibodies have a three- to fourfold increased risk of cognitive impairment, which is often progressive (Hanly et al. 1997; Menon et al. 1999). Cognitive

impairment may be associated with lymphocytotoxic antibodies, CSF antineuronal antibodies, and pathological findings such as microinfarcts and cortical atrophy. Although cognitive dysfunction often fluctuates and is reversible (Hanly et al. 1997; Hay et al. 1994), presumably when attributable to edema and inflammation, it tends to be irreversible when secondary to multiple infarcts and may culminate in dementia.

Depression is the second most common neuropsychiatric disorder in SLE. The reported prevalence of depression has varied widely, depending on the diagnostic criteria, patient population, and study design. Using structured interviews, the prevalence of depression in SLE has been approximately 50% (Giang 1991). Depression may be a preexisting primary psychiatric disorder; an iatrogenically induced illness, particularly from corticosteroids; a reaction to having a chronic disease; and, possibly, a direct CNS manifestation of lupus. The question of whether depression is a direct manifestation of CNS SLE or a reaction to the stress and multiple losses associated with having a chronic debilitating illness remains unresolved (for a review of the evidence, see W. Cohen et al. 2004). Diagnosing depression in SLE is confounded by the overlap between depressive symptoms and those associated with SLE or its treatment. Hypothyroidism should be ruled out, because it can mimic depression and is more common in SLE than in the general population.

Anxiety is quite common in SLE patients, often as a reaction to the illness. The question of whether anxiety is attributable to direct CNS involvement in SLE or simply a reaction to chronic illness remains controversial, as with depression. In patients with SLE, the most common cause of mania is corticosteroid therapy. Psychosis in SLE patients can be a manifestation of direct CNS involvement, and in some but not all studies, it has been linked to antiribosomal P antibodies. Distinguishing psychosis caused by CNS lupus from corticosteroid-induced psychosis presents a major diagnostic challenge (see the following section). Delirium, referred to as “acute confusional state” in the ACR criteria, is common in severe SLE and is a result of CNS lupus, medication, or medical disorders, as shown in Table 25–1. Personality changes have been reported in SLE patients whose disease has damaged the frontal or temporal lobes, and symptoms are typical of those resulting from pathology in those brain regions.

## Prevalence of Neuropsychiatric Disorders

Estimates of the prevalence of neuropsychiatric disorders in SLE have ranged from 17% to 91% (Ainiala et al. 2001b; Brey et al. 2002; W. Cohen et al. 2004). This variation is a

Comorbid psychiatric illness

*Note.* CNS = central nervous system.

consequence of multiple factors: 1) lack of standardized terminology, 2) changing terminology over time, 3) differences in diagnostic methods, 4) variations in which disease entities are considered direct manifestations of CNS SLE versus a reaction to a chronic unpredictable illness, 5) differences in study population, 6) differences in specialty of investigator, 7) inclusion or exclusion of mild psychiatric symptoms, and 8) inclusion or exclusion of particular CNS neurological disorders, as well as the arbitrariness of separating them from psychiatric disorders.

Using the ACR nomenclature, two studies, a cross-sectional Finnish population-based study (Ainala et al. 2001b) and a cohort study of predominantly Mexican Americans (Brey et al. 2002), examined the prevalence of neuropsychiatric syndromes in outpatients with SLE. Overall, 80%–91% of patients had at least one neuropsychiatric disorder, and the prevalence rates in the two studies were similar for individual neuropsychiatric syndromes. Cognitive dysfunction was the most common neuropsychiatric condition, occurring in 79%–80% of patients; however, less than a third of those patients had moderate to severe impairment. Major depression occurred in 28%–39%; mania or mixed episodes, in 3%–4%; anxiety, in 13%–24%; and psychosis, in 0%–5%. Acute confusional state occurred in 7% of the Finnish patients with SLE; it was not reported in the Mexican American cohort. Although comparable prevalence studies have not been reported for acutely ill inpatients with neuropsychiatric SLE, the incidence of psychosis and delirium is likely to be substantially higher.

## Detection of CNS Systemic Lupus Erythematosus

The general principles of treatment discussed earlier in this chapter are applicable to neuropsychiatric SLE, but there are also relevant laboratory tests specific to SLE. In SLE, complement levels (C3, C4, CH50) and anti-DNA antibodies are elevated during disease flares (West et al. 1995). Serum ANA titers need not be obtained in SLE because they do not seem to correlate with systemic or CNS lupus activity. Testing for antiphospholipid antibodies (including lupus anticoagulant and anticardiolipin) is crucial, particularly in patients with focal symptoms, because the results may determine treatment and prognosis (Gharavi 2001; Levine et al. 2002). Unlike antiphospholipid antibody-negative patients, those with antiphospholipid syndrome are treated primarily with anticoagulation rather than corticosteroid or cytotoxic therapy. Antiribosomal-P antibodies have been linked to psychosis, but their usefulness is limited by their low positive predictive value: 13%–16% for psychosis and depression (Arnett et al. 1996). Other serum autoantibodies, including antineuronal, antineurofilament, and antiganglioside antibodies, have not proven to be diagnostic markers for CNS lupus (Bruyn 1995; Hanly 2001; Sibbitt et al. 1999; West et al. 1995).

## Corticosteroid-Induced Psychiatric Symptoms

Corticosteroids have been shown to cause a variety of psychiatric syndromes. However, such symptoms in SLE patients are usually not attributable to corticosteroids. First, severe psychiatric syndromes were reported historically in SLE prior to the introduction of corticosteroids and occur in SLE patients who have not received corticosteroids. Second, psychiatric symptoms in SLE are more frequent and severe than in other disorders treated with comparable doses of corticosteroids. Third, psychiatric symptoms in SLE are often ameliorated, not worsened, by maintenance or an increase in high-dose corticosteroids. In contrast, a reduction in steroid dosage often does not alleviate psychiatric symptoms and may exacerbate them. Finally, in SLE patients who have had a previous psychotic episode while taking corticosteroids, retreatment with steroids usually does not precipitate a recurrence of the psychosis (M. Baker 1973).

Distinguishing corticosteroid-induced psychiatric reactions from a flare of CNS lupus is one of the most challenging aspects of treating SLE. Helpful distinguishing features are summarized in Table 25–2 (Kohen et al. 1993). Given the risk of untreated CNS lupus, and the likelihood that corticosteroids will alleviate such flares

**TABLE 25–2. Differentiating CNS lupus flares from corticosteroid-induced psychiatric reactions**

	<b>Active primary CNS lupus</b>	<b>Corticosteroid-induced psychiatric reaction</b>
<b>Onset</b>	After ↓ corticosteroid dosage or ongoing low-dose treatment	Generally <2 weeks after ↑ corticosteroid dosage (~90% within 6 weeks)
<b>Corticosteroid dosage</b>	Variable	Rare if <40 mg/day, common if >60 mg/day
<b>Psychiatric symptoms</b>	Psychosis, delirium > mood disorders, cognitive impairment (new onset)	Mania, mixed states, or depression (often with psychotic features) >> delirium, psychosis
<b>SLE symptoms</b>	Often present, may coincide with onset of psychiatric symptoms	Often present, but precede onset of psychiatric symptoms
<b>Labs</b>	↑ Indices of inflammation	No specific lab findings
<b>Response to corticosteroids</b>	Improvement	Exacerbation of symptoms
<b>Response to ↓ corticosteroid dose</b>	Exacerbation	Improvement

*Note.* CNS = central nervous system; SLE = systemic lupus erythematosus.

*Source.* Adapted from Kohen M, Asheron RA, Gharavi AE, et al.: “Lupus Psychosis: Differentiation From the Steroid-Induced State.” *Clinical and Experimental Rheumatology* 11:323–326, 1993. Used with permission.

and only temporarily exacerbate corticosteroid-induced psychiatric reactions, an empirical initiation or increase of corticosteroids is often the most prudent intervention (Denburg et al. 1994; McCune 1988). (Corticosteroid-induced psychiatric reactions are discussed in-depth later in this chapter.)

## Pregnancy in Women With Systemic Lupus Erythematosus

Women may be at increased risk of SLE flares (usually mild) during pregnancy, especially in the second and third trimesters, and during the postpartum period (Khamashta et al. 1997; Ruiz-Irastorza 1996). Some patients with antiphospholipid syndrome have been advised to forego reproduction because of the risk of thrombosis, preeclampsia, and fetal demise (now uncommon because of anticoagulation therapy). Family tension may escalate when a patient wants to (or her partner wants her to) risk jeopardizing her health by becoming pregnant, despite admonitions about possible worsening renal or heart failure, hypertension, or stroke.

## Differential Diagnosis of Psychiatric Disorders

### *Other Medical Disorders*

A wide variety of diseases can mimic neuropsychiatric SLE. One group of diseases, associated with a medium to high ANA titer (>1:160), includes Sjögren’s syndrome and mixed or undifferentiated connective tissue disease. A second group of diseases, associated with a low ANA titer

(<1:160), includes multiple sclerosis and, less commonly, ANA-positive rheumatoid arthritis, sarcoidosis, and hepatitis C. A third group of diseases, characterized by a negative ANA, may also be mistaken for CNS lupus. This group includes polyarteritis nodosa, microscopic angiitis, Wegener’s granulomatosis, chronic fatigue syndrome, fibromyalgia, temporal arteritis, and Behçet’s disease.

### *Psychotropic Drug–Induced Positive ANA*

Patients who are receiving antipsychotic drugs, particularly phenothiazines such as chlorpromazine, may have positive ANAs and antiphospholipid antibodies (Canoso et al. 1990; Yannitsi et al. 1990). Drug-induced lupus has also been reported with other psychotropic drugs, including carbamazepine, divalproex, other anticonvulsants, and lithium, (Wallach 2000). In drug-induced lupus, CNS manifestations are rare (Stratton 1985). If the offending drug is discontinued, the lupus symptoms typically resolve within weeks, although the ANA may remain positive for over a year.

### *Somatization Disorder (“Psychogenic Pseudolupus”)*

Systemic lupus erythematosus can be misdiagnosed in “somatizing” patients with multisystem complaints and mildly positive tests for ANAs, which are common in young women.

### *Factitious Systemic Lupus Erythematosus*

Factitious SLE appears to be rare, but several cases have been reported (Tlacuilo–Parra et al. 2000). Patients have simulated hematuria by pricking their finger surrepti-

tiously to add trace amounts of blood to urine specimens, injected themselves with feces or other contaminants to cause infections, or applied rouge to their cheeks to simulate a malar rash. One patient feigned proteinuria by inserting a packet of protein into her bladder. These patients had no serological evidence of an autoimmune disorder.

## Sjögren's Syndrome

---

Sjögren's syndrome is characterized by lymphocytic infiltration of the exocrine glands. It can occur alone (primary Sjögren's) or in association with another autoimmune rheumatic disease. It is associated with a medium to high ANA titer ( $>1:160$ ), and positive anti-double-stranded DNA antibodies. Although Sjögren's syndrome may be difficult to distinguish from CNS SLE (and the two syndromes may overlap), establishing a specific diagnosis is less crucial clinically, because the treatment is the same. While the most common symptoms result from drying of the eyes, mouth, and upper respiratory and urogenital tracts, systemic manifestations can occur in up to one-third of patients. In general these extraglandular manifestations are rare in secondary Sjögren's syndrome but are relatively common in primary Sjögren's syndrome. These extraglandular manifestations of primary Sjögren's syndrome have been shown to involve the CNS in approximately 25% of patients (Alexander et al. 1981, 1982, 1988a; Provost et al. 1987). Rates of CNS involvement are even greater in subjects with cutaneous vasculitic features (up to 70% showing CNS signs) (Alexander et al. 1988b). Unlike SLE, there is no clear association between the CNS involvement and titers of auto-antibodies (Moll et al. 1993; Spezialetti et al. 1993).

The nature of CNS involvement can be focal (cerebellar ataxia, vertigo, ophthalmoplegia, cranial nerve involvement) or diffuse (encephalopathy, aseptic meningoencephalitis, dementia or psychiatric manifestations). Focal lesions are visible on MRI scanning and most frequently involve the white matter (periventricular and subcortical) in the frontal and temporal lobes (Alexander et al. 1988a). Cognitive deficits were found to be common, with more than 80% of subjects with primary Sjögren's syndrome reporting subjective cognitive deficits (Alexander et al. 1988a). Objective cognitive deficits were confirmed in 85% of those with subjective problems: Impairment in attention and concentration were most common (63% of subjects with neuropsychiatric involvement), with deficits in short-term memory and verbal fluency also being detected. Of those with recognized neuropsychiatric manifestations, 25% had progressive dementia, although it should be recognized that the number of sub-

jects was small, and subjects were recruited based on having neuropsychiatric symptoms.

Psychiatric manifestations do occur and usually take the form of affective disturbance (depression, hypomania, anxiety) and somatization (Alexander et al. 1988a). The exact prevalence of psychiatric complications is not clear because most studies have investigated small populations with unreliable questionnaire assessments.

## Systemic Sclerosis (Scleroderma)

---

Systemic sclerosis is a chronic disorder of unknown etiology. The condition is characterized by thickening of the skin as a result of the accumulation of fibrotic connective tissue and damage to the microvasculature. Multiple body systems can be involved, including the gastrointestinal tract, heart, lungs, and kidneys. Of all the connective tissue disorders, systemic sclerosis is considered to be the least likely to cause CNS damage (Hietaharju et al. 1993). The exact prevalence of CNS involvement in systemic sclerosis is not clear because previous studies have mostly investigated small samples of nonrepresentative patients. In a recent study, all patients with a diagnosis of systemic sclerosis in an area of Finland over an 11-year period were traced, and 16% were found to have neurological involvement (Hietaharju et al. 1993).

Psychiatric symptoms are common, with up to half of patients reporting symptoms of depression, and about 20% scoring in the moderate to severe range on the BDI (Roca et al. 1996). Symptoms of anxiety, hostility, somatization, and sensitivity have been shown to be higher in those with systemic sclerosis than in healthy control subjects (Angelopoulos et al. 2001). Body image dissatisfaction is common in these patients and is likely to increase distress and psychosocial impairment in this group (Benrud-Larson et al. 2003).

There is no known treatment to prevent progression of scleroderma (although some medications alleviate symptoms), and the prognosis can be poor because of renal failure and pulmonary hypertension. Some patients have severe pain secondary to digital ischemia. Anxiety about prognosis and depression as a consequence of disfigurement (skin thickening, discoloration, and telangiectasias on face) and pain are common in patients with scleroderma.

## Temporal (Giant-Cell) Arteritis

---

Temporal (giant-cell) arteritis, a granulomatous arteritis of unknown etiology, predominantly affects those over

the age of 60. Although almost any large artery may be involved, most of the clinical features arise because of involvement of the carotid artery and its branches. Extradural arteries are most commonly involved, leading to the typical clinical picture of headache, superficial pain, or sensitivity in skin overlying inflamed vessels (e.g., pain on combing hair). Pain overlying the temporal artery with loss of pulsations is characteristic of temporal arteritis. Pain in the face, mouth, and jaw may occur, the latter characteristically being worse on eating (jaw claudication). Visual problems occur in 25% of untreated patients, and avoidable blindness may occur if treatment with corticosteroids is delayed. In 50% of patients, pain and tenderness occur in the proximal limb muscles without signs of joint effusion, which constitutes the diagnosis of polymyalgia rheumatica. Systemic features such as weight loss and malaise can occur.

Neuropsychiatric manifestations of temporal arteritis arise because of the involvement of arteries supplying blood to the CNS. The insults to the CNS in temporal arteritis can be ischemic (either permanent or transient) or hemorrhagic. The clinical characteristics of the presentation depend on the nature and extent of the brain areas affected. Resultant impairments can be focal (e.g., cerebrovascular accidents leading to specific motor or sensory deficit) or diffuse, resulting in impairment of consciousness. Other neuropsychiatric manifestations include affective symptoms (Johnson et al. 1997). Visual hallucinations have been reported as occurring in up to 80% of patients, who progress to develop permanent visual loss (Nesher et al. 2001).

Treatment with high-dose steroids is commenced as soon as the diagnosis is made on clinical grounds, before results of arterial biopsy are available, to prevent progression of the disease resulting in irreversible blindness or other serious CNS damage.

## Polymyositis

---

Polymyositis is a disease of unknown etiology that results in inflammation of the muscles. The disease can occur on its own or as part of other rheumatological diseases. The clinical picture is typically that of symmetrical, proximal muscle weakness. Involvement of cardiac (arrhythmias, cardiac failure), gastrointestinal tract (dysphagia, reflux, constipation), and respiratory muscles (breathlessness and respiratory failure) can occur. Vasculitis can occur, affecting the CNS and resulting in neuropsychiatric manifestations. As with SLE and temporal arteritis, the clinical features of neuropsychiatric involvement secondary to vasculitis depend on the site and extent of the vasculitic le-

sions. In 20% of patients, an underlying malignancy is present (most commonly bronchus, breast, stomach, or ovary). Thus neuropsychiatric manifestations may occur as the result of secondary spread of malignancy to the CNS.

## Polyarteritis Nodosa

---

Polyarteritis nodosa (PAN) is a systemic, necrotizing arteritis affecting small and medium-sized vessels, often related to hepatitis B virus infection. Although multiple organ systems can be damaged in this disease, direct involvement of the CNS is rare and usually occurs after the disease is well established. Small cerebral infarcts are the most common neuroradiological findings, although intracranial aneurysms and intracranial hemorrhage have been reported (Iaconetta et al. 1994; Oran et al. 1999).

## Behçet's Disease

---

Behçet's disease (Sakane et al. 1999) is an idiopathic inflammatory disorder with incidence primarily in Asia and highest incidence in Turkey. In Europe, most cases are in Turkish immigrants. The most common symptoms include oral and genital ulcers, uveitis, and skin lesions. Behçet's can be life-threatening. Neuropsychiatric involvement occurs in 10%–20% of cases. Acutely, aseptic meningitis or meningoencephalitis may occur. Later manifestations include personality change, meningoencephalitis, and motor signs. Depression and anxiety are common (Calikoglu et al. 2001). In terminal Behçet's, one-third of patients have dementia (Kaklamani et al. 1998). Differential diagnosis includes other autoimmune disorders, multiple sclerosis, and herpes simplex infections. Brain imaging and CSF studies are abnormal but not specific. Acute neuropsychiatric symptoms respond to corticosteroids, but chronic progressive CNS disease does not.

## Wegener's Granulomatosis

---

Wegener's granulomatosis, an uncommon disorder of unknown etiology, is characterized by a granulomatous vasculitis, predominantly affecting the upper and lower respiratory tracts together with glomerulonephritis. Necrotizing vasculitis is the hallmark of this disorder, involving both small arteries and veins. As the result of vasculitis and granuloma formation, virtually any organ in the body can be involved including the brain and CNS. Literature relating to the neuropsychiatric manifestations is sparse.

## Secondary Causes of Neuropsychiatric Symptoms in Rheumatological Disorders

### Infection, Other CNS or Systemic Illness, and Drug-Induced Side Effects

Neuropsychiatric symptoms are often secondary to complications of the rheumatological disorder or its treatment, especially infection. Because a number of the rheumatological disorders or their treatments can be associated with immune dysregulation or immunosuppression, these disorders predispose individuals to CNS and systemic infections. These infections can simulate direct involvement of the CNS by the primary disease process as in, for example, neuropsychiatric lupus (West et al. 1995). Infections causing these secondary neuropsychiatric complications include cryptococcal, tubercular, and meningococcal infections and *Listeria meningitis*; herpes encephalitis; neurosyphilis; CNS nocardiosis; toxoplasmosis; brain abscesses; and progressive multifocal leukoencephalopathy (see also Chapter 27, "Infectious Diseases"). Other etiologies of neuropsychiatric manifestations in rheumatological disorders include uremia, hypertensive encephalopathy, cerebral lymphoma, and medication side effects, as well as comorbid medical or psychiatric disorders and psychological reactions to illness (see Tables 25–1 and 25–3).

### Corticosteroid-Induced Psychiatric Syndromes

Corticosteroids have psychiatric adverse effects, including mania, depression, mixed states, psychosis, anxiety, insomnia, and delirium. A previous psychiatric reaction to corticosteroids does not necessarily predict recurrent reactions with subsequent steroids. Mild psychiatric side effects include insomnia, hyperexcitability, mood lability, mild euphoria, irritability, anxiety, agitation, and racing thoughts. Mood disorders, including mania, are the most common psychiatric reaction to corticosteroids. Patients may experience both mania and depression during a single course of corticosteroid therapy. Affective symptoms are often accompanied by psychotic symptoms. The psychiatric symptoms induced by corticosteroids most often resemble those of bipolar disorder (Brown and Suppes 1998). Delirium and psychosis (without mood symptoms) are less common. Cognitive dysfunction also has been reported and may be attributable to corticosteroid-induced cortical atrophy and loss of hippocampal neurons (Sapolsky 2000; Wolkowitz 1997).

**TABLE 25–3. Psychiatric side effects of medications used in treating systemic lupus erythematosus**

Medication	Psychiatric side effects
NSAID (high dose)	Depression, anxiety, paranoia, hallucinations, hostility, confusion, delirium, ↓ concentration
Sulfasalazine	Insomnia, depression, hallucinations
Corticosteroids	Mood lability, euphoria, irritability, anxiety, insomnia, mania, depression, psychosis, delirium, cognitive disturbance
Gold	None reported
Penicillamine	None reported
Leflunomide	Anxiety
Azathioprine	Delirium
Mycophenolate mofetil	Anxiety, depression, sedation (all rare)
Cyclophosphamide	Delirium (at high doses) (rare)
Methotrexate	Delirium (at high doses) (rare)
Cyclosporine	Anxiety, delirium, visual hallucinations
Tacrolimus	Anxiety, delirium, insomnia, restlessness
Immunoglobulin (intravenous)	Delirium, agitation
LJP-394 <sup>a</sup>	None reported
Hydroxychloroquine	Confusion, psychosis, mania, depression, nightmares, anxiety, aggression, delirium

*Note.* NSAID=nonsteroidal anti-inflammatory drug.

<sup>a</sup>B-cell tolerogen–anti-anti-double-stranded DNA antibodies.

The incidence of corticosteroid-induced psychiatric symptoms is dose-related: 1.3% in patients receiving less than 40 mg/day of prednisone, 4.6% in those receiving 41–80 mg/day, and 18.4% in those receiving greater than 80 mg/day (Boston Collaborative Drug Surveillance Program 1972). For the majority of patients, the onset of psychiatric symptoms is within the first 2 weeks (and in 90%, within the first 6 weeks) of initiating or increasing corticosteroid treatment.

The preferred treatment for corticosteroid-induced psychiatric reactions is tapering of corticosteroids, if possible, resulting in greater than 90% response rate. However, rapid tapering or discontinuation of corticosteroids can also induce psychiatric reactions by precipitating a flare of the rheumatological disease, iatrogenic adrenal insufficiency, or possibly corticosteroid-withdrawal syndrome. Corticosteroid-withdrawal syndrome is manifested by headache, fever, myalgias, arthralgias, weakness, anorexia, nausea, weight loss, and orthostatic hypotension and sometimes depression, anxiety, agitation, or psychosis (Wolkowitz 1989). Symptoms respond to an increase or resumption of corticosteroid dosage. Adjunctive treatment with antipsychotics, antidepressants, and mood

stabilizers can be helpful, depending on the particular psychiatric symptom constellation.

Other drugs used in treating rheumatological disorders may also cause psychiatric side effects, especially hydroxychloroquine (see Table 25–3).

# 26 Chronic Fatigue and Fibromyalgia Syndromes

---

Michael C. Sharpe, M.A., M.D., F.R.C.P., M.R.C.Psych.

Patrick G. O'Malley, M.D., M.P.H.

**IN THIS CHAPTER**, we review two symptom-defined somatic syndromes: chronic fatigue syndrome (CFS) and fibromyalgia syndrome (FMS). The central feature of CFS is the symptom of severe chronic, disabling fatigue that is typically exacerbated by exertion and unexplained by any other medical condition. The central feature of FMS is widespread pain with localized tenderness that similarly is unexplained by any other diagnosis. Although these syndromes have different historical origins, it is increasingly recognized that they have much in common (Sullivan et al. 2002). Therefore, in this chapter we consider them together.

CFS, FMS, and other symptom-defined somatic syndromes are conditions whose homes in medicine (as functional syndromes) and in psychiatry (as somatoform disorders) are both rather temporary structures located in unfashionable areas of their respective communities. These functional disorders (Wessely et al. 1999) are, however, of central concern to psychosomatic medicine. Other functional or medically unexplained syndromes are covered elsewhere in this volume, including noncardiac chest pain (see Chapter 19, "Heart Disease"), hyperventilation syndrome (see Chapter 20, "Lung Disease"), irritable bowel and functional upper gastrointestinal disorders (see Chapter 21, "Gastrointestinal Disorders"), idiopathic pruritus (see Chapter 29, "Dermatology"), migraine (see Chapter 32, "Neurology and Neurosurgery"), chronic pelvic pain and vulvodynia (see Chapter 33, "Ob-

stetrics and Gynecology"), and several other pain syndromes (see Chapter 36, "Pain"). Somatization is also discussed (see Chapter 13, "Somatization and Somatoform Disorders").

## General Issues

---

### Symptom or Disorder?

Although CFS and FMS are often regarded as discrete conditions, the severity of the symptoms of fatigue and pain is continuously distributed in the general population (Croft et al. 1996; Pawlikowska et al. 1994), and the case definitions also can be regarded as simply defining cutoff points on these continua.

### Organic or Psychogenic?

The history of CFS and FMS has been notable for its vigorous disputes about whether these disorders are organic or psychogenic (Asbring and Narvanen 2003). The extreme organic position argues that they eventually will be found to be as firmly based in disease pathology as any other medical condition. Attempts to establish a conventional pathology (e.g., inflammation in muscles in fibromyalgia and chronic infection in CFS) have not yet succeeded, however. An extreme psychogenic view is that these syndromes are pseudodiseases, not rooted in biol-

---

We are grateful to the following for helpful comments on earlier versions of the chapter: Dr. Peter White, Dr. Leslie Arnold, Professor Simon Wessely, Professor Gijs Belijenbergh, Professor Dan Clauw, and Dr. Robert Perry.

ogy but rather representing social constructions based on psychological amplification of normal somatic sensations such as tiredness and pain. Neither of these extreme positions is sustained by the evidence or helpful for patients. In clinical practice, an extreme organic position encourages patients to search for a doctor who will find the pathology and prescribe the right medication while they adapt themselves to a chronic disease. The extreme psychological view ignores the demonstrable physiological disturbances associated with these conditions and, if perceived as dismissive and rejecting, paradoxically can encourage the patients in a defensive entrenchment of the belief that they really do have an untreatable disease (Haddler 1996b). An etiologically neutral and integrated perspective that recognizes these functional disorders as real and that also acknowledges the likely contribution of biological, psychological, and social factors is the best basis for clinical practice (Engel 1977).

## Medical or Psychiatric Diagnosis?

In parallel with the debate about etiology is an argument about whether these conditions are most appropriately regarded as medical or as psychiatric. For the same symptoms, the medical diagnosis is CFS (chronic fatigue and immune dysfunction syndrome; myalgic encephalomyelitis or encephalopathy—see “History” subsection in the following section “The Syndromes”) or FMS, and the psychiatric diagnosis is often an anxiety, mood, or somatoform disorder. However, it can be argued that neither alone is adequate. Proper use of the DSM-IV-TR (American Psychiatric Association 2000) axes allows the patient to be given both a medical (Axis III) and a psychiatric (Axis I) diagnosis. The final diagnosis may be, for example, FMS and generalized anxiety disorder (GAD). Ultimately, a classification that avoids two diagnoses being given for the same symptoms is required. This is a task for the authors of the forthcoming DSM-V (Mayou et al. 2003).

## The Syndromes

---

### Chronic Fatigue Syndrome

#### *History*

It has been convincingly argued that CFS is not a new illness. A very similar, if not identical, condition was described as *neurasthenia* more than 100 years ago and probably much earlier (Wessely 1990). The term *chronic fatigue syndrome* was coined in 1988 to describe a condition characterized by chronic disabling fatigue, with

many other somatic symptoms and strict psychiatric exclusions (Holmes et al. 1988). The authors of this early definition anticipated that a specific disease cause, possibly infectious, would be found, but this has never been established.

The term *chronic fatigue syndrome* subsumed a multitude of previous terms used to describe patients with similar symptoms. These include *chronic Epstein-Barr virus infection* (see Chapter 27, “Infectious Diseases”), *myalgic encephalomyelitis*, *neurasthenia* (still a specific diagnosis in ICD-10 [World Health Organization 1992]), and *postviral fatigue syndrome*. Arguments persist about the similarity of these conditions to CFS. Patient advocacy groups in particular have been very vocal and politically active in arguing that CFS is an inadequate description of their illness and that a name such as *myalgic encephalomyelitis or encephalopathy* or *chronic fatigue and immune dysfunction syndrome*, which emphasizes a biological pathology, is more appropriate. The new terminology of CFS did, however, have the important advantage for researchers of being clearly operationally defined and provided a basis for replicable scientific research.

#### *Definition*

Several operational diagnostic criteria for CFS have been published. The first (noted in the preceding subsection, “History”) (Holmes et al. 1988) were in practice found to be excessively cumbersome and restrictive. Furthermore, it was found that requiring multiple somatic symptoms and fatigue selected patients more rather than less likely to have psychiatric diagnoses, which, combined with the strict psychiatric exclusions, made the condition very rare. Consequently, simpler and less exclusive Australian (Lloyd et al. 1988) and British (Oxford) (Sharpe et al. 1991) case definitions were published. The most recent criteria (shown in Table 26–1) were based on an international consensus and were published in 1994. These remain the most widely used (Fukuda et al. 1994), although they are likely to be clarified and revised (Reeves et al. 2003). The different definitions have been a source of confusion and dispute, but it should be remembered that all have been constructed by committees to aid research. Clinical practice therefore should not necessarily be bound by them.

#### *Clinical Features*

The clinical presentation of the individuals whose symptoms meet the criteria for CFS is heterogeneous, although the core symptoms of fatigue exacerbated by exercise, subjective cognitive impairment, and disrupted and unrefreshing sleep are almost universally described,

**TABLE 26–1. Diagnostic criteria for chronic fatigue syndrome****Inclusion criteria**

1. Clinically evaluated, medically unexplained fatigue of at least 6 months' duration that is
  - Of new onset (not lifelong)
  - Not the result of ongoing exertion
  - Not substantially alleviated by rest
  - Associated with a substantial reduction in previous level of activities
2. The occurrence of four or more of the following symptoms:
  - Subjective memory impairment
  - Sore throat
  - Tender lymph nodes
  - Muscle pain
  - Joint pain
  - Headache
  - Unrefreshing sleep
  - Postexertional malaise lasting more than 24 hours

**Exclusion criteria**

- Active, unresolved or suspected medical disease
- Psychotic, melancholic, or bipolar depression (but not uncomplicated major depression)
- Psychotic disorders
- Dementia; anorexia or bulimia nervosa
- Alcohol or other substance misuse
- Severe obesity

*Source.* Adapted from Fukuda et al. 1994.

and some degree of widespread pain is common. Patients often report marked fluctuations in fatigue that occur from week to week and even from day to day. Most patients are not so disabled that they cannot attend an outpatient consultation, although some describe difficulty walking or cannot attend an outpatient consultation without the aid of wheelchairs and other appliances. Other patients remain bedridden, unable to visit the clinic, and represent an important and neglected group.

The symptom of fatigue is subjective, and a poor correlation exists between the feeling of fatigue and objectively measured performance (Welford 1953). If patients with CFS are asked to perform exercise tests, they may not show the expected decrement but rather report greater effort and increased fatigue, both at the time of the test and over the following days. Similarly, standard neuropsychological testing usually has normal results but is often accompanied by complaints of greater effort (Vercoleyen et al. 1998). Some evidence indicates that more complex cognitive tests do show deficits, although these usually appear less severe than that expected from the pa-

tient's subjective complaints and are difficult to distinguish from those associated with depression (Wearden and Appleby 1996). In summary, the core clinical features of CFS are physical and mental fatigue exacerbated by physical and mental effort. These are subjective phenomena, often less evident on objective testing. Although some may interpret this observation as evidence of exaggeration of disability, such findings also can be interpreted as indicating the essentially subjective and sensory nature of this condition.

## Fibromyalgia

### History

In 1904, Gowers first coined the term *fibrositis* to describe a chronic widespread pain thought to be caused by inflammation of muscles. However, as with CFS, specific disease pathology in muscle has not subsequently been confirmed. In 1990, the American College of Rheumatology (ACR) adopted the operationally defined and descriptive term *fibromyalgia* as an alternative to *fibrositis* (Wolfe et al. 1990). Other terms have been used, such as *chronic widespread pain* and *myofascial pain syndrome*. As with CFS, the new definition facilitated replicable research and has been widely adopted.

### Definition

A variety of different diagnostic criteria for fibromyalgia have been proposed. The ACR criteria published in 1990 are the most widely accepted (Wolfe et al. 1990). These specify widespread pain of at least 3 months' duration and tenderness at 11 or more of 18 specific sites on the body. The ACR criteria are shown in Table 26–2.

**TABLE 26–2. American College of Rheumatology 1990 criteria for fibromyalgia**

1. History of widespread pain. Pain in the right and left side of the body, pain above and below the waist, axial skeletal pain (cervical spine or anterior chest or thoracic spine or low back). In this definition, shoulder and buttock pain is considered as pain for each involved side. "Low back" pain is considered lower-segment pain.
2. Pain, on digital palpation, must be present in at least 11 of 18 specified tender point sites. Digital palpation should be performed with an approximate force of 4 kg. For a tender point to be considered "positive," the patient must state that the palpation was painful. "Tender" is not to be considered "painful."

*Source.* Adapted from Wolfe et al. 1990.

A particular feature of the FMS criteria is the specification of examination findings as well as of symptoms. A standardized method of eliciting these “tender points” has been defined (i.e., the application of pressure with the thumb pad perpendicular to each defined site with increasing force by approximately 1 kg/second until 4 kg of pressure is achieved, which usually leads to whitening of the thumbnail bed). Despite the apparent precision of this clinical sign, both the specificity of the locations and the uniqueness of the proposed tender points to FMS have been questioned (Croft et al. 1996; Wolfe 1997).

### **Clinical Features**

The core features of fibromyalgia are chronic widespread pain and musculoskeletal tenderness (muscle, ligaments, and tendons). Pain occurs typically in all four quadrants of the body and the axial skeleton but also can be regional. Fatigue, sleep disturbance, and subjective cognitive impairment (memory and concentration) are common associations. As with CFS, the report of pain is essentially a subjective phenomenon and may not be reflected in attempts to assess physical and mental performance objectively.

Patients have a range of associated disability, although most patients are able to attend outpatient services. The symptoms of FMS overlap considerably with those of other rheumatological conditions. Up to 25% of the patients with systemic inflammatory conditions (such as systemic lupus erythematosus and rheumatoid arthritis) can meet ACR criteria for fibromyalgia in the initial stages, thus creating a diagnostic dilemma for the clinician faced with a patient who has an undifferentiated constellation of chronic musculoskeletal symptoms (see subsection “Identifying Medical and Psychiatric Conditions” later in this chapter).

### **Primary or Secondary?**

Both CFS and FMS are typically diagnosed when the patient has no evidence of another medical condition. This makes it easy to define the symptoms as unexplained by another condition. However, similar symptoms are often found in patients with other medical diagnoses. For example, symptoms of FMS have been reported in patients with systemic lupus erythematosus (Buskila et al. 2003) and rheumatoid arthritis (Wolfe et al. 1984), and symptoms of CFS have been reported in disease-free cancer patients (Servaes et al. 2002) and in patients with multiple sclerosis (Vercoulen et al. 1996a). The terms *primary* (occurring in the absence of another condition) and *secondary* (accompanying a medical condition) have been used to describe these findings. The terminology is, however, con-

fusing and arguably more a matter of differential diagnosis than of comorbidity (see subsection “Association With Other Symptom-Defined Syndromes” later in this section). It is best avoided.

### **Same or Different?**

Many studies have shown an overlap in the symptoms of patients with a diagnosis of FMS and those with a diagnosis of CFS if these are specifically asked about. Put simply, CFS is fatigue with pain, and FMS is pain with fatigue. A latent class analysis of the symptoms of more than 600 patients failed to identify separate syndromes (Sullivan et al. 2002). Not only are the symptoms similar, but a patient who has received the diagnosis of one of these conditions is also likely to meet the diagnostic criteria for the other. Of 163 consecutive female patients with CFS enrolled at a tertiary care clinic, more than a third also met criteria for FMS (Ciccone and Natelson 2003). Consequently, most authorities now accept that important similarities exist between CFS and FMS (Aaron and Buchwald 2003; Wessely et al. 1999). One potential difference between FMS and CFS is the presence of so-called tender points in the former. However, tender points also are often found in patients with CFS. Whether they will be found ultimately to be distinct entities, overlapping conditions, or aspects of the same condition remains both unclear and controversial.

### **Association With Other Symptom-Defined Syndromes**

Studies that have assessed the comorbidity of FMS and CFS with other symptom-defined syndromes (also known as medically unexplained symptoms or functional somatic syndromes) also have found high rates of migraine, irritable bowel syndrome, pelvic pain, and temporomandibular joint pain. These syndromes, like CFS and FMS, are also associated with high lifetime rates of comorbid mood and anxiety disorders (Hudson and Pope 1994). Other similarities are also seen between FMS, CFS, and these disorders, including a female predominance, association with childhood abuse, and response to similar treatments. This observation raises the possibility not only that CFS and FMS are similar but also that all the functional syndromes have more in common than previously thought by the specialists who diagnose each (Sullivan et al. 2002; Wessely et al. 1999). It has been further suggested that these syndromes, along with mood and anxiety disorders, share a common psychological and central nervous system (CNS) pathophysiology (Clauw and Chrousos 1997).

## Association With Psychiatric Disorders

In clinical practice, many but not all patients with CFS and FMS can be given a psychiatric diagnosis. Most will meet criteria for a depression or an anxiety syndrome. Those who do not are likely to meet DSM criteria for a somatoform disorder or merit an ICD-10 diagnosis of neurasthenia (Sharpe 1996). The more somatic symptoms the patient has, the more likely a diagnosis of depression or anxiety is (Skapinakis et al. 2003). Precise prevalence rates of psychiatric disorder do, however, depend on the nature of the patient population studied and the diagnostic criteria used. Several factors may influence the estimates obtained. First, compared with a community sample, patients attending clinics are likely to be more disabled and distressed and therefore to have more depression and anxiety. Second, some symptoms (such as fatigue, sleep disturbance, and poor concentration) overlap with the symptoms of depression and anxiety, and the observed prevalence of psychiatric disorders will depend on whether all symptoms are counted toward a diagnosis of psychiatric disorder or whether those considered medically explained by CFS or FMS are excluded. Third, it has been argued that atypical presentations of depression (Van Hoof et al. 2003) and anxiety (Kushner and Beitman 1990) are common in these groups, adding further unreliability to the estimates quoted in the following subsections.

### *Depression*

Fatigue is strongly associated with depression. The international World Health Organization (WHO) study of more than 5,000 primary care patients in several countries (Sartorius et al. 1993) found that 67% of the patients with CFS (defined from survey data) also had an ICD-10 depressive syndrome (Skapinakis 2000). Studies of clinic attenders with CFS reported that more than 25% have a current DSM major depression diagnosis, and 50%–75% have a lifetime diagnosis (Afari and Buchwald 2003). Population studies also find an elevated prevalence, although a lower rate than in some clinic studies (Taylor and Jason 2003).

Chronic pain is also strongly associated with depression in the general population (Ohayon and Schatzberg 2003) (see also Chapter 36, “Pain”). In FMS, a study of attenders at a specialist clinic reported that 32% had a depressive disorder (22% major depression) (Epstein et al. 1999). An increased prevalence of lifetime and family history of major depression also has been reported in FMS (Hudson and Pope 1996). As with CFS, the prevalence of depression is probably lower in patients with FMS in the general population (Clauw and Crofford 2003).

### *GAD, Panic Disorder, and Posttraumatic Stress Disorder*

Anxiety disorders have been relatively neglected in association with CFS and FMS. One study reported GAD in as many as half of the clinic patients with CFS or FMS when the hierarchical rules that subsume it under major depression were suspended (Fischler et al. 1997).

Panic disorder is especially common in patients with medically unexplained symptoms. A prevalence of 7% has been reported in clinic patients with FMS (Epstein et al. 1999), and the prevalence was 13% in one study of CFS (Manu et al. 1991). Panic should be suspected when symptoms are markedly episodic.

The prevalence of posttraumatic stress disorder (PTSD) has been reported to be higher in patients with CFS (Taylor and Jason 2002) and FMS (Cohen et al. 2002) than in the general population, and PTSD is associated with a report of previous abuse (see “Abuse” subsection in the “Etiology” section later in this chapter).

### *Somatoform Disorders*

Somatoform disorders are descriptive diagnoses primarily defined by somatic symptoms not explained by a medical condition. Hence, replacing a diagnosis of CFS or FMS with a somatoform one may simply be relabeling. Furthermore, the choice of diagnosis depends on one’s beliefs about the nature of these conditions. If one regards CFS and FMS as medical conditions, then the symptoms will not be counted toward a diagnosis of a somatoform disorder, whereas if one regards CFS and FMS as medically unexplained syndromes, then they will be counted toward a diagnosis of a somatoform disorder (Johnson et al. 1996). Some patients will meet the criteria for hypochondriasis because of persistent anxious concern about the nature of their illness. Others may meet the criteria for somatization disorder because of a long history of multiple symptoms. Patients with FMS are likely to meet the criteria for somatoform pain disorder. Most patients with CFS and FMS who do not meet the criteria for anxiety, depression, or these more specific disorders will fit the undemanding criteria for a diagnosis of undifferentiated somatoform disorder.

### *Summary*

Depressive and anxiety disorders are relatively common in patients with CFS and FMS. There is some suggestion that anxiety is associated more with pain, and depression with fatigue (Kurtze and Svebak 2001). This association with psychiatric disorders appears not to be explained simply by overlapping symptoms, because it remains high even when fatigue is excluded from the diagnostic criteria for major depression (Kruesi et al. 1989). The occurrence

of depression or anxiety disorders in patients with CFS or FMS cannot be attributed entirely to referral bias because the rate is still elevated, although less so, in community cases. Also, it does not appear that depression can be explained entirely as a reaction to disability, because it has been found to be more common than in patients with disabling rheumatoid arthritis (Katon et al. 1991; Walker et al. 1997a). However, many patients with CFS and FMS do not have depressive and anxiety syndromes, even after detailed assessment (Henningesen et al. 2003). Whether these patients are given appropriate diagnoses of a somatoform disorder is controversial.

It has been proposed that depression, anxiety, CFS, and FMS have shared risk factors. These may include both genetics (Hudson et al. 2003) and adverse experiences such as abuse and victimization (Van Houdenhove et al. 2001b). The lack of acceptance by others of the suffering associated with these medically ambiguous conditions also may contribute to emotional distress (Lehman et al. 2002).

The relation between symptom syndromes defined by psychiatry and those of CFS and FMS is an intimate and complex one. It can be conceived of either as psychiatric comorbidity with a medical condition or as different perspectives on the same condition. Whichever view one takes, the importance of making the psychiatric diagnosis in patients with CFS and FMS is its implications for treatment.

## Epidemiology

---

### Prevalence of Fatigue and Chronic Fatigue Syndrome

Fatigue is common, but CFS as currently defined is relatively rare. A large survey of 90,000 residents in Wichita, Kansas, which used rigorous assessment and exclusion criteria, found that 6% of the population had fatigue of more than 1 month's duration, but only 235 per 100,000 (or 0.2%) had CFS (Reyes et al. 2003). It should be noted, however, that the application of current diagnostic criteria (Fukuda et al. 1994) excluded numerous patients, mainly because of diagnoses of rheumatoid arthritis and psychiatric disorder.

### Prevalence of Pain and Fibromyalgia Syndrome

The studies of prevalence of pain and FMS have reported similar findings (Makela 1999). Chronic pain is common and has been reported in as many as 10% of the general population (Croft et al. 1993). However, FMS defined according to the ACR criteria has an estimated prevalence of only 2% (Wolfe et al. 1995) to 4% (K.P. White et al.

1999). The observation that FMS appears to be more common than CFS (Bazelmans et al. 1997) may indicate that chronic pain states are more common than chronic fatigue states but also may simply reflect the requirement in the CFS diagnostic criteria for a longer duration and greater disability from the condition (see Tables 26–1 and 26–2).

## Associations

### *Gender*

Both CFS and FMS are more common in women. The female-to-male ratio for CFS has been reported to be about 4:1 (Reyes et al. 2003) and for FMS, 8:1 (Wolfe et al. 1995), although this increased female preponderance in FMS may be primarily associated with tender points rather than with pain (Clauw and Crofford 2003).

### *Age*

The most common age at onset for both CFS and FMS is between 30 and 50 years. However, patients who present with FMS are on average 10 years older (Reyes et al. 2003; K.P. White et al. 1999). These syndromes are also diagnosed, although controversially, in children. A recent epidemiological study from the United Kingdom found a prevalence of CFS of only 0.002% in 5- to 15-year-olds (Chalder et al. 2003). CFS and FMS are also diagnosed in the elderly, but the frequency of other chronic medical conditions complicates the differential diagnosis.

### *Socioeconomic Status*

Both CFS and FMS are more prevalent in persons of lower socioeconomic status and in those who have received less education (Jason et al. 1999; K.P. White et al. 1999). CFS is 50% more common in semiskilled and unskilled workers than in professionals.

### *International and Cross-Cultural Studies*

It is often noted that the diagnoses of CFS and FMS are almost entirely restricted to Western nations, whereas the symptoms of fatigue and pain are universal. It is unclear to what extent this reflects differing epidemiology or simply different diagnostic practice. For example, fatigue in France may be diagnosed as a condition called *spasmophilia*. In the Far East, neurasthenia remains a popular diagnosis and accordingly is still listed in the ICD-10 diagnostic classification. The WHO Collaborative Study of Psychological Problems in General Health Care conducted in 14 countries reported wide variations in the prevalence of both persistent pain (including both medically explained and medically unexplained pain) and fatigue (Gureje et al. 2001; World Health Organization 1995).

**Disability and Work**

FMS and CFS are both associated with substantial self-reported loss of function and substantial work disability (Assefi et al. 2003). Unemployment in patients with CFS and FMS attending specialist services in the United States is as high as 50% (Bombardier and Buchwald 1996).

**Prognosis**

The prognosis for patients with CFS or FMS is variable and typically has a chronic but fluctuating course. Rehabilitative therapy improves outcome (see subsection “Specialist Nonpharmacological Treatments” later in this chapter).

Prospective studies of CFS and FMS in the general population report that in about half the cases, the syndrome is in partial or complete remission at 2–3 years (Granges et al. 1994; Nisenbaum et al. 2003). Poor outcome in CFS and FMS is predicted by longer illness duration, more severe symptoms, older age, depression, and lack of social support (van der Werf et al. 2002), and in CFS, by a strong belief in physical causes (Joyce et al. 1997). Severely disabled patients attending specialist clinics have a particularly poor prognosis for recovery (Hill et al. 1999; Wolfe et al. 1997).

**Etiology**

The precise etiology of CFS and FMS remains unknown. A wide range of etiological factors have been proposed, but

none has been unequivocally established. The available evidence may be summarized as suggesting that a combination of environmental factors and individual vulnerability initiates a series of biological, psychological, and social processes that lead to the development of CFS or FMS (see Table 26–3). These factors are discussed in the following subsections as predisposing factors, precipitating factors, and perpetuating factors. It is worth mentioning that, with notable exceptions, the preponderance of research in this area is based largely on small, case-control studies (typically 10–20 patients per case and control group) with insufficient power to control for confounding variables, thereby limiting the ability to draw strong causal inferences about any of the findings reported below.

**Predisposing Factors****Biological Factors**

**Genetics.** Modest evidence from family and twin studies suggests that genetic factors play a part in predisposing individuals to CFS and to FMS. In CFS, a small study found that individuals whose family member had CFS were more likely to have the condition (Walsh and Bennett 2001). In a study of 146 female–female twins, one of whom had CFS, the concordance was 55% in monozygotic and 20% in dizygotic twins (Buchwald et al. 2001), suggesting both moderate heritability and the importance of environmental factors. In FMS, a similar familial clustering was reported (Buskila and Neumann 1997), as well as a possible link with human leukocyte antigen types (Yunus et al. 1999).

**TABLE 26–3. Possible etiological factors to consider in a formulation of chronic fatigue**

	<b>Predisposing</b>	<b>Precipitating</b>	<b>Perpetuating</b>
<b>Biological</b>	Genetics	Acute infection, disease, or injury	Neuroendocrine changes Immunological changes Deconditioning Sleep disorder
<b>Psychological</b>	Personality	Perceived stress	Depression Fixed disease attribution Catastrophizing Low self-efficacy Avoidance of activity
<b>Social</b>	Lack of support	Life events	Information Lack of legitimacy of illness Social or work stress Occupational and financial factors

### ***Psychological and Social Factors***

**Personality and activity.** Clinicians often claim a predisposing “obsessional” personality type, but this theory has been little studied. The clinical observation that CFS and FMS patients lead abnormally active lives before becoming ill has received limited empirical support (Van Houdenhove et al. 2001a).

**Abuse.** Childhood and adult neglect, abuse, and maltreatment have been reported by some, but not all, studies to be more common in both FMS and CFS groups than in medical comparison groups (Van Houdenhove et al. 2001b). In FMS, a particular association with abuse in adulthood has been noted (Walker et al. 1997b). Both psychological and biological etiological mechanisms have been suggested, and particular association with comorbid posttraumatic stress disorder and anxiety has been noted (Taylor and Jason 2002).

**Social status.** Low social status and lower levels of education are risk factors for both CFS and FMS (see subsection “Socioeconomic Status” in the “Epidemiology” section earlier in this chapter).

### **Precipitating Factors**

Precipitating factors trigger the illness in vulnerable persons.

### ***Biological Factors***

**Infection.** Some evidence indicates that infection can precipitate CFS, and some, but less, evidence indicates that infection also may trigger FMS (Rea et al. 1999). Specific infections have been found to be associated with the subsequent development of CFS in 10%–40% of patients. These infections are Epstein-Barr virus (P.D. White et al. 2001), Q fever (Ayres et al. 1998), viral meningitis (Hotopf et al. 1996), and viral hepatitis (Berelowitz et al. 1995). The etiological mechanism to explain this association remains unclear but may include both immunological factors and an acute reduction in activity (P.D. White et al. 2001) (see subsection “Perpetuating Factors” later in this section).

**Injury.** The role of physical injury in the etiology of CFS and FMS has been controversial, in part because of the implications for legal liability and compensation. Limited evidence indicates that both conditions may be precipitated by injury, particularly to the neck. If a link exists, it is stronger for FMS (Al Allaf et al. 2002).

### ***Psychological and Social Factors***

**Life stress.** Clinical experience indicated that patients often report the onset of CFS and FMS as occurring during or after a stressful period in their lives. The evidence for life stress or life events being a precipitant of FMS and CFS is, however, both limited and retrospective (Anderberg et al. 2000; Theorell et al. 1999). One of the best studies so far published examined 64 patients and a similar number of matched control subjects. An excess of severe life events and difficulties was found in the CFS patients for the year prior to onset. More specifically, a certain type of life event called a *dilemma* (defined as an event when the person had to choose between two equally undesirable responses to circumstances) was found in a third of the patients with CFS and none of the control subjects (Hatcher and House 2003).

### **Perpetuating Factors**

Perpetuating factors are those that maintain a condition once it is established. They are clinically the most important because they are potential targets for treatment.

### ***Biological Factors***

**Chronic infection.** There has been much interest in the potential role of ongoing infection and in associated immunological factors, especially in CFS. It was previously thought that chronic Epstein-Barr virus was a cause of CFS, but that hypothesis has been rejected. There have been numerous reports of evidence of chronic infection with other agents in both CFS and FMS, but none has been substantiated.

**Immunological factors.** Immunological factors, especially cytokines, also have been much investigated in CFS and FMS, not only because of the possible triggering effect of infection but also because administration of immune active agents, such as interferons, is recognized as a cause of fatigue and myalgia (Vial and Descotes 1994) and because similar symptoms in conditions such as hepatitis C have been associated with changes in measured cytokines (Thompson and Barkhuizen 2003). Various minor immune abnormalities have been reported in patients with CFS and FMS. However, a recent systematic review found no evidence of any consistent immune abnormality in CFS (Lyll et al. 2003). The hypothesis that CFS is associated with immune activation therefore remains tantalizing but unproven.

**Myopathic or biochemical abnormalities and physiological deconditioning.** The bulk of evidence indicates that there are no proven pathological or biochemical abnormalities of

muscle or muscle metabolism, either at rest or with exercise, other than those associated with deconditioning. *Deconditioning* describes the physiological changes that lead to the loss of tolerance of activity after prolonged rest (e.g., as a result of pain). It has been found in many, but not all, patients with CFS (Bazelmans et al. 2001; Fulcher and White 2000) and also in FMS (Valim et al. 2002). Deconditioning offers a potential biological explanation for exercise-induced fatigue and worsening or persistent muscle pain in patients with CFS and FMS and also provides a rationale for treatment with graded activity (see subsection "Specialist Non-pharmacological Treatments" later in this chapter).

**Sleep abnormalities.** Patients with CFS and FMS typically complain of unrefreshing and broken sleep, a symptom that has been objectively confirmed with polysomnography. Abnormalities in sleep have been claimed to be of major etiological importance, especially in FMS. Early work (Moldofsky et al. 1975) reported a specific sleep electroencephalogram abnormality of alpha wave intrusion into slow wave sleep (so-called alpha-delta sleep) and suggested that this was a cause of the myalgia. However, attempts to replicate this finding in both FMS and CFS have produced inconsistent results, and its specificity to chronic pain remains unclear (Rains and Penzien 2003).

**Neuroendocrine changes.** One of the best-supported biological abnormalities reported to be associated with both CFS and FMS is changes in neuroendocrine stress hormones. A repeated observation has been of a tendency to low blood levels of cortisol and a poor cortisol response to stress (Parker et al. 2001). This finding differs from what would be expected in depression (in which blood levels of cortisol are typically elevated) but is similar to that reported in other stress-induced and anxiety states. It is not known whether this is a primary abnormality or merely a consequence of inactivity or sleep disruption, however.

Patients with FMS also have an elevated level of substance P in their cerebrospinal fluid (Russell et al. 1994). A similar finding has been made in patients with other chronic pain syndromes such as osteoarthritis. However, elevated substance P has not been found in CFS patients (Evangard et al. 1998).

**Blood pressure regulation.** Failure to maintain blood pressure when assuming erect posture (orthostatic intolerance), and particularly a pattern in which the heart rate increases abnormally (postural orthostatic tachycardia syndrome), have been reported in both CFS (Rowe et al. 1995) and FMS (Bou-Holaigah et al. 1997). These findings have been interpreted as indicating abnormal autonomic nervous system function. However, postural hypotension

occurs after prolonged inactivity (Sandler and Vernikos 1986), and its specificity to CFS and FMS is unclear.

**CNS structure.** The brains of patients with CFS and FMS are probably structurally normal, although minor abnormalities have been reported in a minority of patients with CFS (Cook et al. 2001). A small proton magnetic resonance imaging (MRI) study has suggested a deficiency of brain choline in CFS patients compared with healthy control subjects (Puri et al. 2002).

**CNS function.** The use of functional brain imaging has great potential to elucidate the biology of these conditions but remains in its infancy. A recent study in FMS examined abnormal pain sensitivity (allodynia) by comparing brain activation in 16 patients with FMS and 16 control subjects during the application of pressure to their thumb-nail beds. Similar pressures resulted in more widespread activation in FMS. This finding was interpreted as supporting the hypothesis that a central augmentation of pain processing occurs in FMS (Gracely et al. 2002).

An early single photon emission computed tomography (SPECT) study (Costa et al. 1995) and a positron emission tomography (PET) study (Tirelli et al. 1998) reported reduced brain stem perfusion in patients with CFS. However, another study that found fewer differences when CFS patients were compared with depressed patients reminds us of the need for careful control for variables such as depression (Machale et al. 2000). As with pain, more widespread cerebral activation is seen in CFS patients than in control subjects when performing a fatiguing cognitive task (Schmaling et al. 2003),

Although tantalizing, these functional brain imaging findings must be regarded as preliminary. Furthermore, evidence of changes in brain activation or brain reorganization must not be taken to mean that the symptoms are necessarily based in fixed neurological pathology; behavioral rehabilitation and drug therapy can potentially reverse such changes (Flor 2003).

### ***Psychological and Social Factors***

There is good evidence that psychological and behavioral factors play a major role in perpetuating CFS and FMS.

**Illness beliefs.** Some of the striking aspects of CFS and FMS are the concern, and often strong beliefs, of many patients about the causes of such illnesses. Three categories of illness beliefs are considered here: 1) cause (attributions), 2) significance of symptoms (catastrophizing), and 3) what one can do despite symptoms (self-efficacy).

Although the cause of CFS and FMS is unknown, many patients, and especially those seen in specialist clinics,

strongly attribute their symptoms to a physical disease (Neerincx et al. 2000). A systematic review of prognostic studies in CFS found that such strong attributions predicted a poorer outcome (Joyce et al. 1997). The mechanism of this effect is unclear. It may be that such an attribution favors a focusing of attention on symptoms, more passive coping, and greater inactivity (Heijmans 1998), or, alternatively, that such an attribution leads to nonparticipation in potentially effective psychological and behavioral treatment.

Catastrophizing is a tendency to make excessively negative predictions about symptoms, such as “If I do more, my pain or fatigue will keep getting worse and worse.” Catastrophizing has been observed in patients with CFS (Petrie et al. 1995) and FMS (Hassett et al. 2000) and is associated with increased symptom vigilance, avoidance of activity, and more severe disability. Furthermore, a reduction in the belief that activity is damaging is associated with recovery during rehabilitative therapy (Deale et al. 1998), suggesting that it may be a critical psychological target for effective rehabilitation.

Self-efficacy—the belief that one can do something, despite symptoms—has been found to be low and to be associated with more severe disability in patients with CFS (Findley et al. 1998), FMS (Buckelew et al. 1996), and chronic pain (Asghari and Nicholas 2001). Achieving an increase in self-efficacy is another potential target for treatment that aims to improve function.

**Behavioral factors.** Patients cope with their symptoms in different ways. The way in which a patient copes will be influenced by his or her illness beliefs (Silver et al. 2002). Of particular interest is coping by avoiding any activity that the patient fears will exacerbate symptoms. This fear–avoidance phenomenon is well established in chronic pain patients (Philips 1987) and also has been observed in CFS (Afari et al. 2000) and in FMS (Davis et al. 2001). Objective assessment also confirms that patients with CFS and FMS show reduced overall activity, with most patients oscillating between activity and rest, and a quarter being more pervasively inactive. This reduced activity produces deconditioning; gradually increasing activity is a treatment task.

Another potentially important coping behavior is the focusing of attention on symptoms—so-called symptom focusing or symptom vigilance (Roelofs et al. 2003). This behavior is, not surprisingly, associated with catastrophizing beliefs and greater perceived symptom intensity; it offers another target for treatment.

**Social factors.** Patients’ beliefs about their illness and associated coping behavior will be influenced by informa-

tion received from others. A striking social aspect of CFS and FMS is the high level of activity in patient support and advocacy organizations mainly over the Internet (Ross 1999). Studies from the United Kingdom have reported that patients who are members of a support group have a poorer outcome, despite similar illness duration and disability (Sharpe et al. 1992), and a poorer response to rehabilitation (Bentall et al. 2002). It is now unknown whether this reflects self-selection into such groups or the effect of the group on patients’ beliefs, coping, and willingness to engage in rehabilitation. Other social factors include the experience of repeated questioning of the legitimacy of one’s illness by doctors and others that probably serves to drive some patients to join advocacy organizations. Perhaps unsurprisingly, the acquisition of a disability pension is also associated with a worse prognosis (Wigers 1996).

## Summary

In summary, the evidence suggests that patients are predisposed to develop CFS and FMS by some combination of genetics, previous experience, and possibly lack of social support. Many patients with CFS have a history of preceding infection, and many patients with FMS point to an accident, injury, or trauma as the triggering event. Others can identify no precipitant. Most research has been into factors associated with established illness, so-called perpetuating factors, because these are both clearly more accessible to study and more relevant to treatment of established cases. Many biological factors have been investigated, with interest initially being directed at peripheral nerves and muscles and subsequently focusing on the CNS and its neuroendocrine and autonomic outputs. Also, some tantalizing findings have suggested but not yet established the role of immune factors. The physiological effects of inactivity seem to be important. Substantial evidence indicates the importance of psychological and behavioral factors, especially the fear of exacerbating symptoms and the associated avoidance of activity in both FMS and CFS. Social factors are more difficult to study but often are of striking importance clinically.

## Models of Chronic Fatigue and Fibromyalgia Syndromes

---

The findings discussed in the previous section can be amalgamated into models. Three main models can be discerned that correspond approximately to biological, psychological, and social perspectives, although, in reality, all three are probably relevant.

## Biological Model

It is well known that the immune system and the CNS and endocrine system interact and also have reciprocal relations with sleep and activity. It is thus possible to construct a tentative biological model in which these systems interact to perpetuate the illness (Moldofsky 1995). There seems to be stronger evidence for the role of infection in triggering CFS and for the role of trauma and changes in central pain processing in FMS. However, it is unclear whether these represent real differences or simply differences in the hypotheses pursued by researchers.

## Cognitive-Behavioral Model

Whatever the biological aspects of these conditions, cognitive-behavioral models assume that the symptoms and disability are perpetuated, at least in part, by psychological, behavioral, and social factors. Biological factors are assumed to be either only partially responsible for the illness or largely reversible (Surawy et al. 1995). The cognitive-behavioral models for chronic pain and CFS have much in common (Philips 1987). Both emphasize the importance of fear of symptoms leading to a focusing on the symptoms, helplessness, and avoidance of activity. This model provides the rationale for behavioral and cognitive-behavioral approaches to rehabilitation (see section "Management" later in this chapter).

## Social Model

The social model emphasizes the role of social factors in shaping the illness. A fight for the legitimacy of the syndrome as a chronic medical condition is central (Banks and Prior 2001). Patient advocacy has been strongly hostile to psychological and psychiatric involvement, probably because it is seen as undermining legitimacy. The social model proposes that patient organizations, while providing valuable social support, can also shape patients' illness beliefs, medical care, and disability payment seeking in ways that are not conducive to recovery (Shorter 1997).

## Diagnostic Evaluation

---

Effective management of patients with possible CFS or FMS requires that 1) alternative medical and psychiatric diagnoses are considered and 2) the patient receives a comprehensive assessment so that collaborative management may be planned.

## Identifying Medical and Psychiatric Conditions

### *Medical Differential Diagnosis*

The medical differential diagnosis for CFS and FMS is a long one because many diseases present with pain and/or fatigue (Sharpe and Wilks 2002; Yunus 2002) (Table 26-4). Both a physical and a mental status examination must be performed in every case to determine any alternative medical and psychiatric diagnoses. As with many chronic diseases, particularly rheumatological conditions, time is often the principal arbiter because the conditions evolve clinically. For symptoms in general, 75% of the patients presenting to primary care improve within 2-4 weeks (Kroenke 2003). Thus, it makes sense to rely on an initial 4- to 6-week wait to clarify whether the symptoms will persist (Kroenke and Jackson 1998). For persistent symptoms, most of the common medical disorders can be diagnosed from a standard history, physical examination, and basic laboratory studies.

**Routine investigations.** Initial investigation depends on the clinical signs, symptoms, and temporal nature of symptoms. When symptoms exceed 4-6 weeks, an initial basic screening workup is appropriate. If there are no specific indications for special investigations, the following have been found to be adequate as screening tests: thyrotropin, erythrocyte sedimentation rate (sensitive for any condition with systemic inflammation), complete blood count, basic chemistries, and withdrawal of some medications (particularly statins or 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors; typical resolution of symptoms in 4-6 weeks).

**Special investigations.** Special investigations should be carried out only if clearly indicated by history or examination. Immunological and virological tests are generally unhelpful as routine investigations and remain research tools. Sleep studies can be useful in excluding other diagnoses, especially when the fatigue is characterized by sleepiness. Diagnoses include sleep apnea, narcolepsy, nocturnal myoclonus, and periodic leg movements during sleep (see Chapter 16, "Sleep Disorders"). Once symptoms become chronic (>3 months) and remain unexplained, the general approach is to avoid excessive testing, establish regular follow-up, screen for depressive and anxiety disorders, and focus on symptom management.

**Medical misdiagnosis.** Those concerned about missing a serious medical diagnosis can be reassured that in most cases, the primary care physician's initial judgment in this

**TABLE 26–4. Medical differential diagnosis for patients with chronic fatigue syndrome (CFS) and fibromyalgia syndrome (FMS)**

Relative frequency	Diagnoses	Syndrome	Differentiating clinical features	Initial workup
Very common (~1 per 100)	Thyroid disorders	CFS, FMS	Hypothyroidism: cold intolerance, slowed relaxation phase of reflexes, weight gain, elevated cholesterol Hyperthyroidism: heat intolerance, tremor, weight loss	Thyrotropin
	Medications (statins)	CFS, FMS	Symptom resolution with withdrawal of medication	Creatine kinase, aldolase
	Sleep apnea	CFS, FMS	Daytime somnolence, motor vehicle accidents, witnessed nighttime apnea and snoring, hypertension	Sleep study
	Spinal stenosis	FMS	History of osteoarthritis, degenerative disc disease, back pain with radiculopathy, sensory and/or motor deficits, pseudoclaudication	Nerve conduction study, electromyogram, magnetic resonance imaging of spine if neurological deficits
Common (~1 per 1,000)	Anemia	CFS	Pallor	Complete blood cell count
	Chronic infection: HIV, hepatitis C, endocarditis, osteomyelitis, Lyme disease, occult abscess	CFS, FMS	Infection-specific risk factors and signs (e.g., sexual habits, diabetes, fevers, murmur)	Serology, erythrocyte sedimentation rate, liver function tests, serial blood cultures, bone scan, indium scan
	Polymyalgia rheumatica	FMS	>60 years old	Erythrocyte sedimentation rate
	Cancer	CFS	Pallor, anemia, anorexia, weight loss, cachexia	Complete blood cell count, albumin, age-appropriate cancer screening studies
	Pulmonary condition: asthma, obstructive lung disease, interstitial lung disease	CFS	Shortness of breath, prominent exertional symptoms, smoking history, hypoxia	Chest X ray, pulmonary function tests, oxygenation saturation with exercise
	Symptomatic hyperparathyroidism	CFS	Bone pain, nephrolithiasis, pancreatitis, renal insufficiency	Serum calcium and parathyroid hormone
Uncommon (~1 per 2,500–100,000)	Systemic lupus	FMS	Malar rash, joint pain	Antinuclear antibody, double-stranded DNA
	Rheumatoid arthritis	FMS	Symmetric synovitis, morning stiffness	Rheumatoid factor
	Polymyositis, dermatomyositis, myopathy	CFS, FMS	Proximal muscle weakness	Antinuclear antibody, creatine kinase, aldolase
	Myasthenia gravis, multiple sclerosis	CFS	Neurological findings: extinguishing strength with repetitive movements, ptosis, swallowing difficulties, optic neuritis, sensory deficits	Tensilon test, acetylcholine receptor antibodies, magnetic resonance imaging of brain
	Narcolepsy	CFS	Drop attacks, falling asleep during daily activities	Sleep study
	Inflammatory bowel disease (Crohn's)	CFS	Diarrhea, weight loss, fever, anemia	Serial fecal occult blood with endoscopy if positive

regard is likely to be accurate (Khan et al. 2003). However, some evidence shows that CFS and FMS may be overdiagnosed by primary care physicians (Fitzcharles and Boulos 2003), and psychiatrists should feel able to request second medical opinions.

### *Psychiatric Differential Diagnosis*

Underdiagnosis of psychiatric disorders is particularly common (Torres-Harding et al. 2002), probably reflecting a focus of the initial medical assessment on somatic symptoms and a tendency to disregard mood changes as simply being a consequence of these symptoms. The most important psychiatric diagnoses to consider are depressive and anxiety disorders because of their frequency and their implications for treatment. Depression may be masked and require expert assessment if it is to be detected. Panic attacks with agoraphobia may cause intermittent severe fatigue and disability. Somatoform disorders are common but have fewer implications for management. A diagnosis of somatization disorder indicates a poorer prognosis, and hypochondriasis indicates special attention to repeated reassurance seeking, which may perpetuate fears of undiagnosed disease (Sharpe and Williams 2001).

### Assessment of the Illness

Other than to make diagnoses, the aims of the assessment are to 1) establish a collaborative relationship with the patient, 2) elicit the patient's own understanding of his or her illness and how he or she copes with it, and 3) identify current family and social factors such as employment and litigation that may complicate management. It is important to inquire fully about the patient's understanding of his or her illness (e.g., "What do you think is wrong with you?" or "What do you think the cause is?"). Patients may be fearful that their symptoms indicate a progressive, as yet undiagnosed, disease or that exertion will cause a long-term worsening of their condition. A formulation that identifies potential predisposing, precipitating, and perpetuating factors (see Table 26-3) is valuable both in providing an individualized explanation to the patient and for targeting interventions.

## Management

---

### Diagnosis, Formulation, and Management Plan

#### *Forming a Therapeutic Relationship With the Patient*

The patient often will have seen many other doctors and will have experienced problematic interactions with them

(Asbring and Narvanen 2003). Other doctors may have offered overly biomedical or overly psychological explanations or even dismissed the patient completely.

#### *Explaining Psychiatric Involvement*

Psychiatrists' involvement in management may be interpreted by the patient as indicating that his or her condition is considered to be "all in his or her head." It is often best to begin with a somatic assessment and only then to introduce discussion of psychological factors. This can be done in a nonblaming and normalizing way. For example; "You have clearly had a terrible time made worse by not being believed. It is entirely understandable that this has gotten you down." It is generally unhelpful to force a psychiatric diagnosis on an unwilling patient. It is also important to explain how treatments commonly associated with psychiatry (particularly antidepressants and cognitive-behavioral therapy [CBT]) do not necessarily imply that the person is mentally ill. Rather, they can be explained as ways of normalizing brain and bodily function in conditions that are exacerbated by stress (Sharpe and Carson 2001).

#### *Giving the Diagnosis*

It is important to give the patient a positive diagnosis supplemented with an etiological formulation. Some controversy exists about whether giving patients a diagnosis of CFS or FMS is helpful or harmful (Finestone 1997). Some who believe that a diagnosis is helpful argue that it enables patients to both conceptualize their illness and communicate about it with others (Sharpe 1998). Others who are concerned about the potentially harmful effect of diagnosis argue that it medicalizes and pathologizes symptoms in a way that can exacerbate social and occupational disability (Hadler 1996a). It is our clinical experience that a positive diagnosis linked to an explanation of the potential reversibility of symptoms and a management plan to achieve this is an essential starting point for effective management.

#### *Offering an Explanation*

The explanation ideally should be scientifically accurate, acceptable to the patient, and congruent with the management plan. It can be explained that although the specific causes of CFS or FMS remain unknown, a combination of vulnerability and environmental stress likely to involve the brain and endocrine system is most likely. One such explanation is that the illness is a disorder of brain function rather than *structure*—that is, a functional nervous disorder (Stone et al. 2002).

### ***Explaining the Management Plan***

The management plan should be explained to the patient as following from the formulation, focusing on illness perpetuating factors and consisting of elements to 1) relieve symptoms such as depression, pain, and sleep disturbance with agents such as antidepressants; 2) assist the patient's efforts at coping by stabilizing activity and retraining the body to function effectively (graded exercise, CBT); and 3) assist the patient in managing the social and financial aspects of his or her illness and, when possible, remaining in or returning to employment (problem solving).

### **General Measures**

#### ***Providing Advice on Symptom Management***

One of the most important interventions the clinician can make is to encourage and guide patients in the active self-management of the illness. Such advice will include the importance of being realistic about what they are able to accomplish without giving up hope for improvement in the future. It should involve advice on the pros and cons of self-medication, particularly with analgesics, and also might require a discussion of the potential benefits and risks of iatrogenic harm associated with seeking treatment from other practitioners, both conventional and alternative. The overall aim is to encourage the patients to feel that they can do things to manage the condition themselves, to accept the reality of their illness while still planning positively for the future, and to be cautious about seeking potentially harmful and expensive treatments.

#### ***Managing Activity and Avoidance***

Once activity is stabilized and large fluctuations between excessive rest and unsustainable activity are reduced, gradual increases in activity can be advised. It is critical, however, to distinguish between carefully graded increases carried out in collaboration with the patient and a forced or an overambitious exercise regimen.

#### ***Managing Occupational and Social Factors***

Patients who continue working may be overstressed by the effort of doing this. Those who have left work may have become inactive and demoralized and may not wish to return to the same job. These situations require a problem-solving approach to consider how to manage work demands, achieve a graded return to work, or plan an alternative career. Ongoing litigation is potentially a complicating factor because it reinforces (and may reward) the patient for remaining symptomatic and disabled. A large trial in Canada that randomized patients either to litigation or to no-fault compensation for whiplash injury

found that symptoms lasted longer in the former group (Cassidy et al. 2000).

### **Pharmacological Therapies**

Most pharmacological treatment studies in CFS and FMS have focused on antidepressants, although various other agents have been advocated.

#### ***Antidepressants***

Antidepressant drug treatment is indicated by the fact that 1) many patients with CFS or FMS have depressive and anxiety syndromes and 2) these agents reduce pain and improve sleep, even in the absence of depression. However, the evidence that antidepressants lead to an overall improvement in CFS and FMS is mixed, with the evidence being better for FMS (O'Malley et al. 2000) than for CFS (Reid et al. 2003).

The tricyclic antidepressants (TCAs) are probably more effective than the selective serotonin reuptake inhibitors (SSRIs) for relieving pain (Fishbain 2003) and for inducing sleep. Small doses (e.g., 25–50 mg of amitriptyline) are often adequate for these purposes (Arnold et al. 2000; O'Malley et al. 2000), but full doses are required to treat major depression.

Cyclobenzaprine, a tricyclic agent chemically similar to amitriptyline but used as a "muscle relaxant" rather than as an antidepressant, has been found to be effective in improving symptoms in FMS, especially pain and sleep disturbance (Tofferi et al. 2004).

SSRIs are generally better tolerated than TCAs. In CFS, fluoxetine was found in a large trial to be no more effective than placebo (Vercoulen et al. 1996b). In FMS, one recent study found that patients who received fluoxetine (mean dose = 45 mg) experienced a greater reduction in pain, fatigue, and depressed mood than did those who received placebo (Arnold et al. 2002); however, in a small previous trial, fluoxetine at a dosage of 20 mg/day did not have the same effect (Wolfe et al. 1994).

Other antidepressant agents also have been tried. Venlafaxine, a dual serotonin-norepinephrine reuptake inhibitor (SNRI), is useful for pain and has been reported as showing initial promise in both FMS (Dwight et al. 1998) and CFS (Goodnick 1996). Moclobemide, a reversible inhibitor of monoamine oxidase A, has been reported to be of no benefit in FMS but of some value in increasing energy in CFS (Hickie et al. 2000).

#### ***Other Pharmacological Agents***

Patients with FMS and CFS frequently use nonsteroidal anti-inflammatory drugs (NSAIDs) to relieve pain. No evidence from clinical trials indicates that NSAIDs are ef-

fective when used alone, although they may be of some benefit in FMS when combined with amitriptyline (Goldenberg et al. 1986).

Opiates are occasionally used for pain in FMS and CFS. However, no trials of their use have been done, and a major concern is the development of dependence.

As with opiates, great caution is required with benzodiazepines because of the risk of dependence in patients with chronic conditions. TCAs are probably preferable to benzodiazepines for treating insomnia, and the chronic use of benzodiazepines should be reserved for patients with intractable anxiety.

Given the finding of low serum levels of cortisol, it is not surprising that corticosteroids have been tried. Prednisone was found to be ineffective in FMS (Clark et al. 1985). Hydrocortisone was reported to produce some benefit in CFS but was not recommended because of the long-term risks of adrenal suppression (Cleare et al. 1999). In CFS, fludrocortisone has been used in patients with orthostatic hypotension but has not been found to be of value (Rowe et al. 2001).

Serotonin<sub>3</sub> receptor antagonists (e.g., ondansetron and tropisetron) have analgesic effects (Kranzler et al. 2002). A randomized, placebo-controlled, double-blind trial in FMS found short-term benefit only with the lowest dosage (5 mg/day) (Farber et al. 2001). Trials of longer duration are needed.

Gabapentin has substantial analgesic effects, but its mechanism of action is unknown. There are only anecdotal reports of its successful use in FMS. Pregabalin, a drug still in clinical development that has pharmacological properties similar to those of gabapentin, also may have potential efficacy.

Amphetamines have been used in CFS with some evidence of short-term efficacy (Olson et al. 2003) but are not widely used because of the risk of dependence.

### Summary

It is wise to exercise caution when prescribing pharmacological therapy for CFS and FMS. The mainstay of therapy continues to be the so-called antidepressant drugs, which may be helpful for mood, pain, and sleep but have limited effect on overall outcome. TCAs are preferred for nighttime sedation and pain, but greater tolerability may mean that an SSRI or an SNRI is preferable as first-line treatment. In current clinical practice, although patients often receive low doses of antidepressants, higher doses may be required to achieve a therapeutic response. The increased interest in pharmacological treatment of functional syndromes in the past few years will likely expand treatment options, and several medications in clinical development show promise, including duloxetine, milna-

cipran, and pregabalin. However, the available evidence suggests that drug therapy has a limited role in the management of these conditions.

### Specialist Nonpharmacological Treatments

If the patient does not respond to, or requires more active treatment than, the general and pharmacological management described above, referral for specialist therapy should be considered. For most patients, a rehabilitative outpatient program based on appropriately managed increases in activity, either as graded exercise therapy (GET) or as CBT, is indicated. Some patients may require inpatient multidisciplinary rehabilitation, although evidence of its efficacy is inadequate (Karjalainen et al. 2000).

#### *Graded Exercise Therapy*

Graded exercise therapy is a structured progressive exercise program administered and carefully monitored by an exercise therapist. It also may be given in individual or group form, but the evidence is best for individually administered treatment (Fulcher and White 1998).

Graded exercise therapy follows the basic principles of exercise prescription for healthy individuals, adapted to the patient's current capacity. The initial exercise intensity and duration are determined on an individual basis and may be done via heart rate monitoring. Most patients can begin at an intensity of 40% of their maximum aerobic capacity, which approximately equates to 50% of their estimated individual heart rate reserve added to their resting heart rate (e.g., if the maximum heart rate is 180 beats/minute [bpm] and the resting heart rate is 80 bpm, the heart rate reserve is 100 bpm, and the exercise target heart rate is  $80 + (0.5 \times 100) = 130$  bpm). This heart rate should not be exceeded; if it is, the patient should stop exercising for 1–2 minutes and then resume. Patients who are very disabled, or who have extremely low exercise tolerance to begin with, should begin with 2 weeks of stretching alone without aerobic activity and then should adopt alternate-day aerobic exercise before building up frequency, duration, and then intensity. The important principle is to calculate exercise capacity conservatively to start with, as well as to ensure that the patient will try that which is proposed.

At each clinic visit, joint planning of the exercise prescription for the following 1–2 weeks is completed. The initial aim is to establish a regular pattern of exercise (usually walking), with exercise 5 days/week. Home exercise sessions should initially last between 5 and 15 minutes, depending on ability and exercise tolerance. The duration is increased by 1–2 minutes/week up to a maximum of 30 minutes per homework session. Then, the intensity of

exercise can be increased to a target heart rate of 60% and then 70% of the patient's heart rate reserve added to his or her resting heart rate. Patients will respond differently; some will take a lot longer to adapt to each new level, whereas others will have to be held back, particularly those who have been active sports participants in the past. Those patients who are inclined to overexert themselves in an attempt to speed up the recovery process should be monitored carefully because this can be a contributing factor in nonrecovery or relapse.

Graded exercise therapy has been found in systematic review to be of benefit in both CFS and FMS. In FMS, four high-quality aerobic training studies (total 227 patients) reported significantly greater improvements in aerobic performance, tender point pain pressure threshold, and pain with exercise than with comparison treatments (Busch et al. 2002).

In CFS, three high-quality trials (total 340 patients) all found benefits over comparison treatments in symptoms and disability. However, the number of dropouts in one study was substantial (Whiting et al. 2001). Of particular interest is a trial of brief simple education about the physiology and rationale of exercise that found the education to be as effective as CBT (Powell et al. 2001).

### ***Cognitive-Behavioral Therapy***

There are a variety of types of CBT (Williams 2003). Here, we refer to a collaborative psychologically informed type of rehabilitation that aims to achieve both graded increases in activity and changes in unhelpful beliefs and concerns about symptoms. It also may include problem solving for life and occupational dilemmas. It can be given in an individual or a group form, although more evidence exists for the efficacy of individual therapy (Sharpe 1997).

The procedure is 1) to elicit nonjudgmentally the patient's own illness model, appraisal of his or her situation, and the ways in which he or she copes; 2) to introduce the possibility of alternatives; and 3) to help the patient select the beliefs and coping behaviors that are most helpful by conducting behavioral experiments. The key question for the behavioral experiment is "Is it possible for me to make changes in my behavior that will allow me to achieve my goals?" The patient is encouraged to think of the illness as real but reversible by his or her own efforts rather than (as many patients do) as a fixed, unalterable disease. The ability to make changes is a test of these alternative hypotheses. The aim of behavior change is to achieve specific goals. Problem solving is used to address relevant occupational and interpersonal difficulties. A typical therapy takes place over 14 sessions (the first 90 minutes, the rest 50 minutes), the first 4 sessions being weekly and thereafter biweekly over 5 months.

In CFS, individually administered CBT has now been found to be effective in two systematic reviews, with approximately two-thirds of the patients showing significant improvement. Three high-quality trials (total 164 patients) found improvement in both symptoms and disability and concluded that CBT appears to be an effective and acceptable treatment for adult outpatients with CFS (Price and Couper 2003; Whiting et al. 2001).

Although CBT is an established treatment for chronic pain (Morley et al. 1999) (see also Chapter 36, "Pain"), in FMS, only group CBT has been adequately evaluated in randomized trials. One trial reported no benefit (Vlaeyen et al. 1996), but a more recent study did find a clear advantage of group CBT over usual medical care (Williams et al. 2002). Further evaluation of the intensive individual CBT shown to be effective in CFS is required in FMS.

### **Patients Who Do Not Respond to Treatment**

Most patients respond to some degree to rehabilitative therapies, but many will achieve only partial improvement, and some will fail to improve at all. In such cases, the management is the same as that for other chronic conditions—to maximize functioning and quality of life while minimizing the risk of iatrogenic harm. Although it is desirable that all patients should have a trial of rehabilitative treatment, a balance has to be struck between heroic efforts at therapy and acceptance of chronic illness. Many physicians are reluctant to accept chronic disability in these patients, perhaps because they do not regard these conditions as true diseases. Pushing patients beyond their capabilities may only demoralize them or cause them to retreat further into invalidism. For such patients, regular follow-up from a single physician is often the best form of management.

### **Conclusion**

---

Although peripheral to both internal medicine and psychiatry, somatic syndromes such as chronic fatigue syndrome and fibromyalgia are core to the practice of psychosomatic medicine. A willingness and ability to integrate biological, psychological, and social factors is essential to both an adequate understanding of these syndromes' etiology and their effective management. The challenge that these syndromes present to the more narrow paradigms of the biomedical and psychopathological perspectives makes them an effective Trojan horse for those who seek to persuade others of the benefits of much greater integration of medical and psychiatric theory and practice.

## Infectious Diseases

---

James L. Levenson, M.D.

Robert K. Schneider, M.D.

**PSYCHIATRIC SYMPTOMS ARE** part of the clinical presentation of many systemic and central nervous system (CNS) infectious processes. Recently, several factors have combined to increase the prevalence and significance of infectious diseases. Rapid cultural and economic changes affecting regional and international mobility, sexuality, and other behaviors have led to worldwide spread of new epidemics (e.g., HIV, severe acute respiratory syndrome [SARS] [Cheng et al. 2004]) and more limited spread of previously geographically isolated diseases (e.g., cysticercosis). Infectious diseases have been considered as contributing to the pathogenesis of psychiatric disorders (e.g., viral antibodies in schizophrenia). Causal links between specific infections and a subset of psychiatric syndromes (e.g., pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection [PANDAS]) provide intriguing models of etiology. Controversy surrounds some attributions of psychopathology to infectious pathophysiology (e.g., Lyme disease, Epstein-Barr virus [EBV]).

As a result of these developments, consulting psychiatrists should carefully consider relevant aspects of patients' histories, including immune status, regions of origin and residence, travel, high-risk sexual behaviors, occupation, and recreational activities. Physicians must consider which infectious diseases are endemic in the practice area and in the areas where the patient has traveled or resided. Similar psychiatric symptoms might suggest possible Lyme disease in a hiker in the northeastern United States and neurocysticercosis in an immigrant from Central America.

Many brain diseases or injuries, as well as the effects of aging, render patients more vulnerable to neuropsychiatric effects of even minor metabolic or toxic insults and similarly to adverse effects of even limited infectious dis-

eases. For example, a simple upper respiratory or bladder infection may cause only discomfort in an otherwise healthy individual but agitation, irritability, and frank delirium in the elderly, especially in patients who also have dementia. In a study of elderly patients admitted to a psychogeriatric inpatient unit with delirium and a coincident urinary tract infection, as well as underlying dementia in more than 70%, two-thirds had resolution of delirium with treatment of the urinary tract infection (Manepalli and Grossberg 1990). The reasons that older age and brain disease would make patients vulnerable to delirium with minor infections are not understood but may involve changes in immune function (Prio et al. 2002) and the blood-brain barrier.

Psychological factors may significantly affect the risk for and course of infectious diseases, with HIV as the most studied example (see Chapter 28, "HIV/AIDS"). Psychological factors have been shown to influence other infectious diseases as well, including the common cold (Takkouche et al. 2000), pneumonia (Mehr et al. 2001), genital herpes (Levenson et al. 1987), hepatitis B and C infection (Osher et al. 2003), and recurrent urinary tract infections (Hunt and Waller 1992). Several studies have convincingly shown that psychological stress suppresses the secondary (but not primary) antibody response to immunization (S. Cohen et al. 2001).

We divide this chapter into bacterial, viral, fungal, and parasitic infections, followed by psychiatric side effects of antimicrobial drugs and their interactions with psychotropic medications. We end the chapter by discussing fears of infectious disease and psychiatric aspects of immunization. HIV and AIDS are covered in Chapter 28. In the current chapter, we focus on psychiatric aspects of all other infectious diseases.

## Occult Infections

Occult infections, irrespective of location, by definition are concealed or mysterious, often requiring diligent detective work. Such infections may occur essentially anywhere in the body (see Table 27–1). Psychiatric symptoms may result from even a small focus of chronic infection (e.g., Becarevici 1988; Yamasaki et al. 1997). The psychiatric symptoms most likely to be present are subtle cognitive dysfunction or mood change (e.g., irritability) consistent with a mild encephalopathy, but depression, psychosis, and delirium also may occur.

The diagnosis is suggested by secondary signs of infection, specifically temperature dysregulation, or increases in white blood cell count, granulocyte count, or sedimentation rate. A careful history and physical examination may identify overlooked clues to guide the search (e.g., chronic toothache or lymphadenopathy). If repeat history and physical examination are not fruitful, other studies may be needed (e.g., chest X rays, computed tomography [CT] scans, ultrasounds). Nuclear medicine studies may be useful in a “shotgun” search for a site of infection, but they have a high frequency of false-positive and false-negative results.

## Bacterial Infections

### Bacteremia and Sepsis

*Bacteremia* literally means entry of bacteria into the bloodstream, whereas *sepsis* refers to the systemic inflammatory response to bacteremia. Systemic symptoms of sepsis, including CNS symptoms, result from many different mechanisms, including bacterial toxins, release of cytokines, hyperthermia, shock (poor perfusion), acute renal insufficiency, pulmonary failure (“shock lung”), coagulopathy, disruption of the blood-brain barrier, and spread of the organism into the CNS and other organs. An acute change in mental status may be the first sign of impending sepsis and may precede the development of fever. Any patient who has an abrupt change in mental status in concert with a shaking chill should be presumed to have a high risk for impending sepsis. Diagnosis focuses on culturing the organism from blood or the primary site of infection.

Septic encephalopathy occurs more frequently than is generally assumed. Its severity is associated with the severity of overall illness, and it is often part of multiorgan failure (Zauner et al. 2002). Standard treatment is broad-spectrum antibiotics at first and is then tailored to the identified organism and its antimicrobial susceptibilities. Recent evidence suggests that the use of low-dose corti-

**TABLE 27–1. Occult infections that may cause psychiatric symptoms**

Sinusitis
Chronic otitis
Abscess (e.g., dental, lung, intra-abdominal, retroperitoneal, perirectal)
Bronchiectasis
Endocarditis
Cholecystitis
Parasitosis
Urinary tract infection
Pelvic inflammatory disease
Osteomyelitis
Subclinical systemic infections (e.g., HIV, tuberculosis)

costeroids may improve outcomes (Annane 2001; Schelling et al. 2001). Symptoms of posttraumatic stress disorder recently have been recognized as very common following septic shock (Schelling et al. 2001).

### Toxic Shock Syndrome

Toxic shock syndrome (TSS) typically occurs in otherwise healthy people with intact immune systems. TSS is typically caused by either *Staphylococcus aureus* (Lowy 1998) or *Streptococcus pyogenes*, with the latter much more common currently. TSS generally manifests with rapid onset of fever, rash, and hypotension (shock) and is a multisystem disease with at least three organ systems involved, very often including the CNS. Most cases of TSS are associated with a wound and/or foreign body. Most staphylococcal TSS occurs in young menstruating white women (the proportion of menstrual cases has decreased following removal of superabsorbent tampons from the market) but can occur at any age, even in early childhood (Broome 1989; Van Lierde et al. 1997). Staphylococcal TSS is most likely caused by the production of a toxin (TSS toxin 1) that acts as a superantigen, a substance that rapidly initiates a multisystem inflammatory response (Stevens 1996). There is a great peril in missing this diagnosis because TSS often occurs in healthy, young women; the onset of the disease is fast; and early morbidity and mortality are high. TSS should be suspected in any patient with a recent wound who acutely develops unexplained pain, lethargy, and confusion and may occur even when a surgical wound appears not to be inflamed.

There may be a prodromal period of 2–3 days of malaise, myalgia, and chills followed by confusion and lethargy. Early CNS symptoms may include confusion, weakness, and headache. These early features rapidly progress to hypotension and shock. Following recovery, CNS se-

quelaes may persist for years and include deficits in memory, computation, and concentration (Rosene et al. 1982). It is unclear to what extent these sequelaes are a result of the toxin or the shock.

Clinical suspicion is necessary for early diagnosis of staphylococcal TSS. No tests are available for the antigen, and cultures of blood, cerebrospinal fluid (CSF), and throat usually have negative results. In contrast, blood cultures are positive in 60% of the cases of streptococcal TSS (Stevens 1989). Treatment includes aggressive supportive care, removal of the foreign body, drainage of the abscess, and antibiotics. Experimental antitoxin agents are being explored.

### Pediatric Autoimmune Neuropsychiatric Disorder Associated With Streptococcal Infection

PANDAS is a fascinating etiological model of psychiatric illness (Swedo 2002). Sir William Osler (1894) had first noted "a certain perseverativeness of behavior" among patients with Sydenham's chorea (a complication of rheumatic fever). A century later, investigators at the National Institute of Mental Health found that approximately 70% of the children with Sydenham's chorea had obsessive-compulsive symptoms shortly before the chorea began (Swedo et al. 1998).

PANDAS is not a diagnosis but an acronym for the clinical characteristics of a subgroup of children whose obsessive-compulsive and tic disorders seem to have been triggered by an infection with group A beta-hemolytic streptococci (GABHS). The syndrome is defined by early childhood onset of symptoms; an episodic course characterized by abrupt onset of symptoms with frequent relapses and remissions; association with neurological signs, especially tics; and temporal association with GABHS infections (most commonly pharyngitis) (Swedo et al. 1997). The best way to show the association between recent GABHS infection and PANDAS symptoms is to document a rapid rise in antistreptococcal (ASO) titers associated with symptom onset or exacerbation and a decrease in titers associated with symptom resolution or improvement. Children with PANDAS also may have behavioral symptoms (e.g., attention deficits and hyperactivity) (Perlmutter et al. 1998; Schneider et al. 2002; Swedo et al. 1998). GABHS may play a role in Tourette's syndrome as well (Church et al. 2003). Adult onset of illness fulfilling criteria for PANDAS has been reported (Bodner et al. 2001), and obsessive-compulsive disorder (OCD) and tics are more common in first-degree relatives of PANDAS probands (Lougee et al. 2000).

In addition to ASO titers, a throat culture should be obtained, keeping in mind that some children who have GABHS infection may not have a sore throat (Swedo et al. 1998). Prompt antibiotic treatment may prevent the expected rise in ASO titers. Although PANDAS is conceptualized as an autoimmune disorder, antibiotics active against GABHS may be beneficial in reducing current symptoms (Murphy and Pichichero 2002) but have not been shown to have prophylactic value in PANDAS patients (Garvey et al. 1999). Randomized clinical trials of antibiotic treatment are under way, and immunomodulatory treatments are also being investigated (Perlmutter et al. 1999).

### Bacterial Endocarditis

Bacterial endocarditis may cause neuropsychiatric symptoms at all stages of the disease, via focal, systemic, and CNS disease processes. Osler first described the triad of fever, heart murmur, and cerebral infarction in 1885. Endocardial infections are focal infections that usually occur on one of the valves of the heart. Rheumatic heart disease was originally the typical cause of the predisposing cardiac abnormality. Its incidence has decreased, while the incidence of senescent valvular disease, prosthetic valve placement, and intravenous drug use have increased, thus changing the risk factors in the developed world. Malaise and fatigue may represent early symptoms before progression of the infection is evident. CNS symptoms are related to 1) occlusion of cerebral arteries by septic emboli (Singhal et al. 2002); 2) expansion, leakage, or rupture of mycotic aneurysms; and 3) direct infection of meninges or brain abscess. Neuropsychiatric deficits resulting from septic emboli will reflect which cerebral vessels have been affected. The most common psychiatric symptoms are those of diffuse encephalopathy, which may occur at any stage of infection. Their onset may be insidious to acute, paralleling the course of the endocarditis (chronic, subacute, acute).

Diagnosis is based on clinical history and physical examination, particularly looking for new or changing heart murmurs, signs of microembolism (splinter hemorrhages, retinal hemorrhages, microscopic hematuria), plus positive blood cultures in a patient with fever. Cardiac echocardiography is important for evaluation of valvular abnormalities. Magnetic resonance imaging (MRI) scans are more sensitive than CT scans in detecting cerebral infarction. Treatment is based on blood culture results. The choice of antibiotics and length of parenteral treatment required vary according to the specific organism, its antibiotic susceptibilities, whether it is the first or a recurrent episode, whether a prosthetic heart valve is present, and other factors (Bertorini and Gelfand 1990; Lerner 1985).

## Rocky Mountain Spotted Fever

The etiological agent for Rocky Mountain spotted fever (RMSF) is *Rickettsia rickettsii*. RMSF is a tickborne disease with a seasonal distribution paralleling human contact with ticks, peaking May through September. Its name is misleading because half of the United States cases are in the South Atlantic region, and rickettsial spotted fevers occur worldwide. After the tick bite, *R. rickettsii* enters vascular endothelial cells, proliferates, and disseminates, causing a diffuse vasculitis in many organs. RMSF typically (although not invariably) includes fever and a rash characterized by erythematous macules that later progress to maculopapular lesions with central petechiae. Initially appearing as a nonspecific severe febrile illness, the diagnosis is seldom suspected until the rash appears. CNS involvement occurs in 25% of cases, including lethargy, confusion, and occasionally fulminant delirium. Subtle changes such as irritability, personality changes, and apathy may occur before the rash, particularly in children. Abnormalities on CT or MRI of the brain may include infarctions, cerebral edema, meningeal enhancement, or prominent perivascular spaces, but 80% of RMSF patients with normal scans have symptoms of encephalopathy as well (Bonawitz et al. 1997). Cognitive dysfunction persisting months after resolution of the acute illness has been reported (Bergeron et al. 1997).

*R. rickettsii* may be detected by direct immunofluorescence of skin biopsies, but serology is the usual diagnostic method; confirmation requires convalescent titers. Because mortality is high in untreated patients, a provisional clinical diagnosis (e.g., fever, rash in the appropriate season, and geographic setting) is sufficient to initiate definitive antimicrobial therapy. Only half of these patients report exposure to ticks. Response to the treatment is quick and usually heralded by defervescence and mental clearing (Woodward 1992).

## Typhus Fevers

Typhus fevers are caused by two species of *Rickettsia*. *R. prowazekii* is the cause of mouseborne and squirrelborne typhus. *R. typhi* is the cause of fleaborne typhus. Mouseborne typhus usually occurs in epidemics related to war or famine when communal hygiene deteriorates. Fleaborne typhus is associated with fleas found on rodents. The annual disease frequency in the United States was 2,000–5,000 cases in the 1940s. It is now fewer than 100, with most in Texas. This dramatic change is a result of the initiation of rat control programs. Clinical manifestations, diagnosis, and treatment of typhus are similar to those of RMSF. The psychiatric manifestations are confu-

sion, lethargy, and particularly headache in a febrile illness with rash. Typhus has been implicated as a cause of febrile cerebrovasculitis in the United States (Hechemy et al. 1991). The delirium of typhus and typhoid has been classically described as having a peculiar preoccupied nature, with patients picking at the bedclothes and imaginary objects (Verghese 1985). In fact, the word *typhus* in Greek means “cloud” or “mist,” a term Hippocrates used to describe clouded mental status in patients with unremitting fevers.

## Typhoid Fever

Typhoid fever is an enteric fever caused by salmonellae. The incidence of typhoid fever has steadily declined in the United States over the last century primarily because of improved sanitation. Typhoid fever is still endemic in many places in the world. Sixty percent of the cases in the United States are acquired outside the country, most often in Mexico and India.

Abdominal pain, headache, and fever are the classic presentation. However, when typhoid fever is endemic or not treated promptly, psychiatric symptoms appear. *Salmonella typhi* enters a bacteremic phase, and the typhoid bacilli can localize in the CNS. The high fever and electrolyte imbalances also may cause encephalopathy, with delirium reported in up to 75% of the cases in some parts of the world (Aghanwa and Morakinyo 2001; Ali et al. 1997) and very infrequently (2%) in others (Parry et al. 2002). Mental symptoms such as indifference, listlessness, and dullness are common at presentation (Farmer and Graeme-Cook 1999), but psychosis remains a frequent complication (Parry et al. 2002). Published cases have described persistent psychiatric symptoms, including irritability, personality change, hallucinations, and even psychosis requiring electroconvulsive therapy, after definitive treatment (Breakey and Kala 1977). Most symptoms in survivors completely resolve following treatment. Diagnosis is made by isolation of the typhoid bacilli. The treatment of choice is a fluoroquinolone or ceftriaxone.

## Tetanus

Tetanus is uncommon in the United States but remains internationally significant. *Clostridium tetani* produces a potent neurotoxin called *tetanospasmin*, which is the cause of tetanus. The greatest risk factor for tetanus remains lack of up-to-date immunization. In the United States, 60% of the cases occur in people older than 60 years, with older women especially at risk. The first mass vaccinations were offered during World War II, and many women never received vaccination then (Srewe and Spivack 1994).

Infections generally occur because an open wound comes into contact with soil contaminated with spores from *C. tetani*. After initial inoculation, tetanospasmin is disseminated via blood, lymph, and nerves and produces symptoms by binding to receptors at the neuromuscular junction.

The classic symptom is muscle stiffness, particularly in the muscles of mastication, thus the descriptive term *lockjaw*. If the muscle stiffness extends across the entire face, risus sardonicus occurs, an expression of continuous grimace. Also, stiffness may progress to the entire body if left untreated.

Tetanospasmin may enter the CNS, causing encephalopathic symptoms. Diagnosis is based on the clinical manifestations and a history of likely exposure. On initial presentation, patients with tetanus have been given misdiagnoses of an anxiety disorder or a conversion disorder (Treadway and Prange 1967), although more commonly, a conversion disorder is mistakenly thought to be possible tetanus (Barnes and Ware 1993). If the patient had received neuroleptics or antiemetics, one could easily mistake the symptoms as drug-induced acute dystonia. Treatment is aimed at reducing exposure to the neurotoxin and includes tetanus immunoglobulin, debridement of the wound, and administration of high-dose penicillin G. Infection does not always result in immunity, so active immunization is needed following treatment for the infection (Gray 1997).

## Brucellosis

Brucellosis is a worldwide zoonosis caused by species of *Brucella*, gram-negative intracellular coccobacilli. They infect many animals, but most human cases are acquired from consumption of unpasteurized dairy products from sheep or goats. It has become rare in developed countries (about 100 cases per year in the United States) but is likely underdiagnosed because of the nonspecificity of symptoms. Brucellosis occurs at any age, with insidious or abrupt onset, affecting any organ system, and hence is notorious for mimicking other diseases. Signs of acute brucellosis include fever, diaphoresis, headache, and myalgia. Chronic brucellosis is not always preceded by acute symptoms. Its manifestations include fatigue, depression, and multiple chronic pains, so it is not surprising that patients' symptoms are frequently misdiagnosed as primary psychiatric illness (Sacks and Van Rensburg 1976). Protean complications in many different organs have been reported. CNS involvement occurs in about 5% of cases and may present as meningitis, psychosis, or cranial nerve dysfunction (Bodur et al. 2003; Mousa et al. 1986). Diagnosis is confirmed by isolation of the organism or sero-

logical testing. Treatment regimens usually include multiple antibiotics.

## Syphilis

Syphilis is a chronic systemic disease caused by the spirochetal bacterium *Treponema pallidum*. Although *T. pallidum* was not identified until 1905, syphilis was described in the medical literature before the sixteenth century. A hundred years ago, syphilis was the leading diagnosis in psychiatric inpatients; the incidence declined as the antibiotic era began. The rates of syphilis increased in the 1990s, exceeding the rates in the previous 40 years, probably linked to the global pandemic of HIV infection. With the current trend, psychiatrists must relearn this disease.

The clinical manifestations are varied and mimic those of other diseases. Syphilis was the original "great imitator." In adults, syphilis passes through several stages. *Primary syphilis* develops first as a small papule at the site of inoculation that develops into an ulcer called a chancre. If left untreated, the chancre will disappear, but about 6–24 weeks after the initial infection, *secondary syphilis* occurs with a variety of symptoms. During this stage, multiple organ systems, including the CNS, may become involved. Most symptoms are constitutional (malaise, fatigue, anorexia, and weight loss). Skin, gastrointestinal tract, lymphatics, bones, kidneys, and eyes all may be affected. Most syphilitic meningitis occurs within the first year of infection. Symptoms of headache, stiff neck, nausea, and vomiting prevail, and focal neurological findings may be present. Often, signs and symptoms of secondary syphilis disappear, and the infection becomes latent.

*Tertiary syphilis* refers to infection years to decades after initial infection. It has been divided into three types: late benign (gummatous), cardiovascular syphilis, and neurosyphilis. Gummatous and cardiovascular forms were very prevalent before antibiotics; neurosyphilis is now the predominant form of tertiary syphilis (Gliatto and Caroff 2001). A recent resurgence of neurosyphilis has occurred in persons with HIV infection, although during the period 1985 to 1992 in San Francisco, California, neurosyphilis in AIDS was a rare event (Flood et al. 1998).

Neurosyphilis is divided into asymptomatic, meningeal, meningovascular, and parenchymatous forms. Meningeal syphilis may occur early in the course (as noted earlier in this subsection) or late. Meningovascular syphilis typically occurs 4–7 years after infection. Presenting symptoms of neurosyphilis include changes in memory and personality, dizziness, and other encephalopathic symptoms that can mimic atherosclerotic disease (e.g.,

transient ischemic attack, multi-infarct dementia). Parenchymatous neurosyphilis syndromes are tabes dorsalis and general paresis. Tabes dorsalis occurs 20–25 years after infection and results from demyelination of the posterior columns and dorsal roots. Paresthesias, Argyll Robertson pupils (pupils that accommodate but do not react to light), impotence, incontinence, and truncal ataxia may develop. General paresis is an insidious dementia that can include seizures and personality deterioration. This form of syphilis presents 15–20 years after infection and if untreated may be fatal. In our clinical experience, the infection has “burned out” in some patients; they manifest dementia, have positive CSF and serum serology, and yet show no clinical response to penicillin G.

Diagnosis relies on serological testing because *T. pallidum* cannot be cultivated on artificial media. However, in primary and secondary syphilis, dark-field microscopy of material from chancres, condylomata, and mucous patches usually identifies a large number of organisms.

Except in populations where syphilis is common, it is not cost-effective to screen all new psychiatric patients for syphilis (Banger et al. 1995; Roberts et al. 1992); screening should focus on patients with unexplained cognitive dysfunction or other neurological symptoms accompanying the psychopathology. The most frequently used tests and their sensitivities are shown in Table 27–2.

Serological testing is based on two types of antibody response to the syphilitic infection: nontreponemal antibodies and antitreponemal antibodies. The Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) are the most commonly used tests that detect nontreponemal (nonspecific) antibodies. The reactivity of these tests depends on the stage of the disease. In secondary syphilis and early latent syphilis, the nontreponemal tests show reactivity 95%–100% of the time. However, the reactivity in primary syphilis and tertiary syphilis is 76% and 70%, respectively. The fluorescent treponemal antibody absorption (FTA-ABS) test is more

sensitive and more specific. This test is used to confirm the diagnosis when syphilis is suspected and a nontreponemal test was nonreactive and to confirm a positive nontreponemal test result. The FTA-ABS test is not used as a screening test because its false-positive rate is as high as 1%. Another treponemal test is the microhemagglutination assay of *T. pallidum* (MHA-TP). This assay is used as a confirmatory test, typically after a positive RPR test result (Hicks 2004).

False-positive nontreponemal tests (i.e., positive VDRL or RPR and negative FTA-ABS and no clinical evidence of disease) are divided into acute (those that revert to normal in less than 6 months) and chronic (those that persist for longer than 6 months). Acute false-positive results occur after some immunizations, during acute infections, and during pregnancy. Chronic false-positive results occur in individuals with autoimmune disease (e.g., lupus), in narcotic-addicted persons, in persons with leprosy, and in the elderly (Relman and Swartz 1998).

Treatment requires penicillin at varying dosages depending on the stage. If a definitive diagnosis cannot be made, it is prudent to treat presumptively.

## Lyme Disease

Lyme disease is caused by the spirochete *Borrelia burgdorferi*, which is transmitted by deer ticks. The risk of contracting Lyme disease from a single tick bite is 3% (Nadelman et al. 2001). Lyme disease occurs worldwide; it is the most common tickborne disease in the United States, with four times as many cases as reported in Europe. Disease onset is marked by erythema migrans, a characteristic (more than 90% of cases) large, spreading rash with central clearing. Acute disseminated disease includes fatigue, arthralgia, headache, fever, and stiff neck. If untreated, Lyme disease may disseminate to other organs and produce subacute or chronic disease. Neurological symptoms occur in about 15% and may include

**TABLE 27–2. Sensitivity (%) of diagnostic tests of serum<sup>a</sup> in different stages of syphilis**

Stage of disease	Screening <sup>b</sup>		Confirmatory <sup>c</sup>	
	RPR or VDRL	FTA-ABS	TPI	MHA-TP
Primary	75	85	40	80
Secondary and early latent	95–100	100	98	100
Late latent and tertiary	70	99	95	98

Note. RPR=rapid plasma reagin; VDRL=Venereal Disease Research Laboratory; FTA-ABS=fluorescent treponemal antibody absorption; TPI = *Treponema pallidum* immunofluorescence assay; MHA-TP=microhemagglutination assay of *Treponema pallidum*.

<sup>a</sup>Sensitivity and specificity cannot be determined on cerebrospinal fluid because no gold standard exists.

<sup>b</sup>Detects nontreponemal antibodies.

<sup>c</sup>Detects treponemal antibodies. Typically, a laboratory performs one of these tests when a screening test result is positive.

cranial neuropathies (most often, the facial nerve), meningitis, or painful radiculopathy (Rahn and Evans 1998). If still untreated, patients may develop chronic neuroborreliosis, including a mild sensory radiculopathy, cognitive dysfunction, or depression. Typical symptoms of chronic Lyme encephalopathy include difficulty with concentration and memory, fatigue, daytime hypersomnolence, irritability, and depression. Rarely, Lyme disease has included chronic encephalomyelitis. While these chronic syndromes are not distinctive, they are almost always preceded by the classic early symptoms of Lyme disease, such as erythema migrans, arthritis, cranial neuropathy, or radiculopathy (Rahn and Evans 1998).

The clear relation between another spirochetal disease, syphilis, and psychopathology makes the possibility of *B. burgdorferi* causing psychiatric syndromes an area of interest and controversy. Many different psychiatric symptoms have been reported to be associated with Lyme disease, including depression, mania, delirium, dementia, psychosis, obsessions or compulsions, panic attacks, catatonia, and personality change (Tager and Fallon 2001). However, association does not allow one to infer causation by Lyme. Evaluation of patients with Lyme disease at 10- to 20-year follow-up showed no significant differences in symptoms or neuropsychological testing compared with control subjects without Lyme disease. Although symptoms such as pain, fatigue, and difficulty with daily activities are common in patients who received treatment for Lyme disease years earlier, the frequencies of such symptoms are similar in control subjects without Lyme disease (Seltzer et al. 2000).

The differential diagnosis of neuroborreliosis in a patient presenting with fatigue, depression, and/or impaired cognition includes fibromyalgia, chronic fatigue syndrome, other infections (e.g., babesiosis or ehrlichiosis), somatoform disorders, depression, autoimmune diseases, and multiple sclerosis (Schneider et al. 2002; Tager and Fallon 2001).

Unfortunately, Lyme disease has been grossly overdiagnosed in patients with nonspecific cognitive, affective, or other psychiatric symptoms. As noted earlier in this section, numerous reports in the literature attribute a wide variety of psychiatric symptoms to neuroborreliosis on the basis of positive serological testing. As explained later in this section, this is inappropriate. Adverse consequences of overdiagnosis include reinforcement of somatization and the creation of invalidism. Overdiagnosis leads to overtreatment. The diagnosis of an infection that can be treated with antibiotics can be very appealing to patients for whom depression or somatoform disorder is an unacceptable diagnosis, but this leads to inappropriate diagnostic procedures and inappropriate extended pre-

scription of antibiotics for a putative chronic CNS infection. Chronic antibiotic prescription is not benign and may lead to secondary infections, antibiotic resistance, and drug toxicity (Rahn and Evans 1998). Even in patients with classic symptomatic Lyme disease confirmed by serological testing, persisting symptoms are usually explained by some illness other than chronic borreliosis if these patients have received adequate antibiotic therapy (Kalish et al. 2001; Seltzer et al. 2000).

Diagnosis is based on the characteristic clinical features. Serological testing (enzyme-linked immunosorbent assay followed by Western blot) can support the diagnosis but should never be the primary basis (Rahn and Evans 1998). False-negative and false-positive results are common with serological testing. Even a true-positive test result simply indicates that the patient has had Lyme disease at some point in life, but no conclusion about current disease activity or extent of infection can be drawn. In chronic neuroborreliosis, increased CSF protein and antibody to the organism occur in more than 50% of the patients. Electroencephalograms (EEGs) are typically normal, whereas MRI shows nonspecific white matter lesions in about 25%. Neuropsychological assessment is useful in measuring cognitive dysfunction, but the findings are not specific (Ravdin et al. 1996).

Treatment is straightforward for acute Lyme disease (see Wormser et al. 2000). Neither serological testing nor antibiotic treatment is cost-effective in patients who have a low probability of having the disease (i.e., nonspecific symptoms, low incidence region) (Nichol et al. 1998). Two controlled trials found no benefit of extended intravenous or oral antibiotics in patients with well-documented, previously treated Lyme disease who had persistent pain, neurocognitive symptoms, or dysesthesia, often with fatigue (Klempner et al. 2001). A vaccine was developed that provided some protection (Steere et al. 1998) but was removed from the market in 2002.

## Leptospirosis

Leptospirosis is another protean spirochetal disease. It was previously thought of as a rural, tropical disease, but it occurs globally in rural and urban areas (Vinetz 2001), even in the American inner city (Vinetz et al. 1996). The organism is spread through the urine of many species of mammals. Most infections resemble influenza and are relatively benign. The more severe form of leptospirosis is a multiorgan disease affecting liver, kidneys, lung, and brain (meningoencephalitis, aseptic meningitis). Confusion and delirium are common, and mental status changes are the strongest predictor of mortality (Ko et al. 1999).

## Bacterial Meningitis

Bacterial meningitis is an acute illness associated with significant morbidity and mortality. Psychiatric symptoms play an important role in its presentation. Irrespective of the organism, most cases of bacterial meningitis result from hematogenous spread of bacteria from a primary site to the subarachnoid space. Once the organism crosses the blood-brain barrier at the choroid plexus and enters the subarachnoid space, host defenses become activated. Psychiatric symptoms may result by several mechanisms, including toxic effects of the organism, mediators of inflammation, cerebral edema, and hypoxia.

The classic sign of meningeal inflammation is nuchal rigidity. Headache, nausea, vomiting, confusion, lethargy, and apathy also may occur. Psychiatric symptoms are the result of encephalopathy. As in other infections, encephalopathy may present subtle changes in personality, mood, motivation, or mentation. Symptom severity generally correlates with the magnitude of the host's immune response (Weinstein 1985). When the patient cannot mount a full inflammatory response, the classic symptoms may not occur. In infants, the elderly, or immunocompromised patients, the only clinical signs may be irritability or minor changes in mentation or personality (Segreti and Harris 1996).

Once clinically suspected, the diagnosis is usually confirmed by examination of the CSF, which typically shows pleocytosis, low glucose, high protein, and evidence of the offending organism on appropriate staining. Although neuroimaging is routinely performed to rule out other CNS processes, it rarely establishes the diagnosis of bacterial meningitis. Morbidity and mortality of bacterial meningitis increase with delay in the initiation of effective antibiotic treatment (Gray 1997).

Initially, antibiotics are chosen to cover a broad range of organisms common to the population to which the patient belongs (e.g., age and immune status). Recent developments affect medication choice. The *Haemophilus influenzae* type B and the pneumococcal conjugate vaccines have greatly reduced cases of meningitis caused by these agents (Schuchat et al. 1997; Whitney et al. 2003), and penicillin resistance has emerged in *Streptococcus pneumoniae* infections.

## Cat-Scratch Disease

Cat-scratch disease (CSD), which is caused by *Bartonella henselae*, usually presents as self-limiting lymphadenopathy in young people following a cat scratch or bite. Encephalopathy is one of the common complications, with almost all cases reported in children. Patients with CSD encephalopathy present with combative behavior, leth-

argy, and seizures, and significant fever may be absent. Diagnosis is made by serology and/or biopsy of skin or lymph node. Antibiotic treatment is indicated in CSD with encephalopathy, although most CSD cases resolve spontaneously without it (Carithers and Margileth 1991; Windsor 2001).

## Bacterial Brain Abscess

The portals of entry for organisms causing brain abscesses are similar to those in bacterial meningitis. In fact, brain abscesses frequently occur as a complication of bacterial meningitis, although they also are a frequent complication of infective endocarditis. The classic triad of headache, fever, and focal neurological deficits has been described for the diagnosis of brain abscess, but these symptoms occur in fewer than half of the patients who have a brain abscess. Seizures are common. Various psychiatric symptoms may occur, depending on the size and location of the abscess(es), how irritating the organism is, and the extent of the inflammatory response. Disordered mood, cognitive dysfunction, psychosis, and aggression are the most common psychiatric complications (Chang et al. 1997; Douen and Bourque 1997).

Mortality rates have markedly declined as a result of improved neuroimaging and antimicrobials, but morbidity remains high. Early detection and aggressive treatment are necessary to further reduce morbidity and mortality. Neuroimaging can be very helpful in the diagnosis of brain abscess, unlike in bacterial meningitis. Neuroimaging can show focal abscesses in the CNS with very good sensitivity. Effective treatment includes empirical antibiotics that cross the blood-brain barrier, with primary excision or aspiration of the abscess usually required. After successful treatment of the infection, psychiatric symptoms may persist.

## Tuberculous Meningitis

Tuberculosis remains a major world health problem, endemic in many developing countries. Where AIDS is prevalent, the epidemiology of tuberculosis has markedly changed. Tuberculosis now represents the most common serious HIV-related complication worldwide. Where tuberculosis is not endemic, the diagnosis of tuberculous meningitis is often not considered because the clinical manifestations are often nonspecific. Early diagnosis of tuberculous meningitis is essential because delay in treatment is associated with high morbidity and mortality. Tuberculous meningitis is caused by bacilli discharged from small tuberculous lesions adjacent to the meninges. These small tuberculous lesions arise early via hematogenous

spread following a primary pulmonary infection or as a consequence of reactivation.

Early symptoms of tuberculous meningitis are non-specific and include low-grade fever, generalized malaise, fatigue, and mild headache. Over the course of a week, there is progression to high-grade fever, severe nuchal rigidity, confusion, and delirium. Persons with HIV, the elderly, substance abusers, and others with impaired immunity are more likely to present without nuchal rigidity and headache. In such patients, the symptoms will tend to be most nonspecific, with a higher risk of missing the correct diagnosis while attributing the symptoms to more common diagnoses such as alcohol withdrawal.

Confirming the diagnosis can be difficult. The organisms are difficult to detect in the CSF, so diligent search is needed to identify them when present. Early in the course when symptoms are mild, CSF glucose may be unchanged and protein only marginally elevated. As the disease progresses, glucose declines drastically, and protein becomes markedly elevated, with white blood cell counts typically between 50 and 200 per cubic millimeter (predominantly lymphocytes). Later complications include cerebral vasculitis and cranial nerve involvement. Diffuse meningeal involvement by tuberculosis may be seen on MRI (Gray 1997).

Strong suspicion of tuberculous meningitis calls for early multidrug treatment because it is better to have temporarily treated a few patients needlessly than to miss prompt treatment in those who really have the disease. Regimens of multiple antitubercular drugs should be used until sensitivities are determined after cultures. In many parts of the world today, including the United States, multidrug-resistant tuberculosis is present, requiring different drug combinations.

## Viral Infections

---

The overwhelming majority of viral infections are asymptomatic or mild and do not receive medical attention. Many viruses are difficult to detect, most infections are difficult to treat, and none are cured by treatment. Viruses can produce psychiatric symptoms by primary CNS involvement, from secondary effects of immune activation, or indirectly from systemic effects. One serious sequela of several viral infections is acute disseminated encephalomyelitis; patients with this condition can present with encephalopathy, acute psychosis, seizures, and other CNS dysfunction. Active demyelination is widespread, and the disease may be difficult to distinguish from multiple sclerosis (Nasr et al. 2000). Despite viral syndromes' ubiquity and frequent nonspecificity, it is important for psychiatrists to know particular viral syndromes.

## Epstein-Barr Virus

EBV, one of the herpesviruses, causes an acute lymphoproliferative disease called *infectious mononucleosis* ("mono"), common in children and young adults. The prodromal stage of infectious mononucleosis is characterized by headache, fatigue, and malaise, with progression to fever, sore throat, and lymphadenopathy. Diagnosis is based on the combination of typical clinical symptoms and a positive heterophil antibody test (Monospot) result. Because the Monospot test is an antibody measure, it may have false-negative results in immunosuppressed patients. Therapy is supportive, and most cases completely resolve, although some may take several months. Fatigue commonly persists for a few months, but this can occur with other viral infections as well (White et al. 1998). In the rare, more severe form of infectious mononucleosis, anemia, leukopenia, eosinophilia, thrombocytopenia, pneumonitis, hepatosplenomegaly, uveitis, and an abnormal pattern of serum globulins occur.

In patients with chronic fatigue and malaise, the differential diagnosis may include depression or chronic EBV infection. Because EBV may persist lifelong in a latent state following acute infection, periodic reactivation may occur. Patients with latent EBV infection typically report overwhelming fatigue, malaise, depression, low-grade fever, lymphadenopathy, and other nonspecific symptoms. Often, there are no other findings with these patients. This picture is essentially that of chronic fatigue syndrome, even though only a small fraction of chronic fatigue symptoms are attributable to EBV infection. In the past, patients with chronic fatigue caused by depression or somatoform disorder who resisted considering a psychiatric diagnosis (and sometimes their physicians) often pursued an explanation in chronic EBV infection. They found (erroneous) confirmation in a positive Monospot test result; it is erroneous because the test result remains positive long after complete resolution of uncomplicated infectious mononucleosis in youth, often for life. With wider recognition of the limitations of Monospot testing, this misdiagnosis is now very infrequent (but see earlier discussion in "Lyme Disease" subsection).

The role of the psychiatrist is to help the infectious disease clinician or primary care provider distinguish which patients have a primary psychiatric diagnosis (mood, anxiety, or somatoform disorders). Chronic EBV infection should never be diagnosed solely on the basis of a positive Monospot test result. The absence of any objective findings (e.g., significant lymphadenopathy, atypical lymphocytes, lymphocytosis, elevated sedimentation rate, fever, hepatosplenomegaly) increases the likelihood of a primary psychiatric diagnosis, but the diagnosis should be based on positive

criteria, never made only by exclusion of an identifiable diagnosis such as EBV. As in other postviral syndromes, antidepressant therapy is often helpful if depression exists in the recovery phase of infectious mononucleosis.

## Cytomegalovirus

Like EBV, cytomegalovirus (CMV) is a common herpesvirus, and most infections are subclinical. CMV infection occurs in a broader age group than does EBV. Seroprevalence in adults older than 35 years has ranged from 38% in Rochester, New York, to 99% in Tanzania (Hoeprich et al. 1994). In adults, CMV can produce a syndrome identical to infectious mononucleosis, except that heterophil antibody testing is negative in CMV, and a sore throat is usually absent. CMV also may cause hepatitis, retinitis, colitis, and pneumonitis. In immunocompromised patients, CMV has been implicated as a cause of depression or dementia. CMV should always be considered in the differential diagnosis of acute depression or cognitive dysfunction in the first few months after organ transplantation. CMV is referred to as the “most important pathogen affecting transplant recipients,” potentially causing immunosuppression or allograft rejection (Fishman and Rubin 1998). Diagnosis is most accurate when CMV can be recovered in body fluids. Antiviral agents (e.g., acyclovir, ganciclovir) are helpful, but significant side effects can occur (Hibberd et al. 1995). Antidepressant therapy may be needed if the patient develops a postviral mood disorder.

## Viral Meningoencephalitis

Most viruses that cause encephalitis cause meningitis as well. Enteroviruses, mumps, and lymphocytic choriomeningitis primarily affect the meninges, with enteroviruses responsible for most identifiable cases. Patients with viral meningitis (often referred to as *aseptic meningitis*) present with headache, fever, nuchal rigidity, malaise, drowsiness, nausea, and photophobia. Typically, the CSF shows pleocytosis, elevated protein, and no evidence of an organism. Treatment is generally supportive. Antiviral drugs such as acyclovir are being increasingly used, most effectively for herpes encephalitis. Correct early diagnosis is critical to a successful outcome (Deresiewicz et al. 1997).

## Arboviruses

Arboviruses (short for arthropod-borne viruses) are the most common cause of viral encephalitis worldwide (Solomon 2004). Of the arbovirus diseases, Japanese encephalitis is the most common worldwide and annually causes 10,000 deaths in Asia. In the United States, the four major types

are St. Louis encephalitis, eastern equine encephalomyelitis, western equine encephalomyelitis, and California encephalitis. Recently, West Nile virus has appeared in the United States. West Nile virus is a flavivirus like the virus in Japanese encephalitis and has a similar clinical course (Solomon 2003). Most arboviruses are mosquito-borne. Arboviral encephalitis typically appears in the summer or fall in children (Japanese encephalitis) or young adults (West Nile virus and St. Louis encephalitis), with abrupt onset of fever, headache, nausea, photophobia, and vomiting, and may be fatal. Reduced level of consciousness, flaccid paralysis resembling poliomyelitis, parkinsonism, and seizures are common (Solomon 2004). Occasionally, patients with viral encephalitis may present initially with psychopathology without neurological symptoms. Caroff et al. (2001) reviewed 108 published cases of psychiatric presentation, classified as psychosis (35%), catatonia (33%), psychotic depression (16%), or mania (11%). Patients in such cases often receive misdiagnosis and inappropriate treatment, and Caroff et al. (2001) noted that patients with viral encephalitis are more vulnerable to adverse effects of neuroleptics, including extrapyramidal side effects, catatonia, and neuroleptic malignant syndrome. Although no specific treatment is available for arboviral encephalitis, rapid diagnosis is important for public health measures, mosquito control, and, ideally, vaccines. Although a vaccine exists for Japanese encephalitis, access is limited (Monath 2002). For those who survive, outcomes vary from complete recovery to serious neuropsychiatric sequelae.

## Dengue

Dengue, another disease caused by an arbovirus, is transmitted by mosquitoes, endemic in 100 countries, and encountered in temperate developed countries mainly in travelers and new immigrants (Castleberry and Mahon 2003). The virus causes three syndromes: 1) the relatively more benign dengue fever, which is a painful influenza-like illness, and the serious forms, 2) hemorrhagic dengue and 3) dengue shock syndrome; the latter two are rare in travelers. However, neuropsychiatric symptoms were noted in 14% of the tourists who returned to France with dengue (Badiga et al. 1999). In the more serious endemic dengue infections, meningoencephalitis is common, with confusion, delirium, and seizures (Pancharoen and Thisyakorn 2001).

## Herpes Simplex Virus

Herpes encephalitis is caused by invasion of the brain by herpes simplex type 1 virus in 90% of herpes encephalitis cases. Symptoms may include personality change, dysphasia, seizures, autonomic dysfunction, ataxia, delirium,

psychosis, and focal neurological symptoms. Herpes simplex virus (HSV) encephalitis differs from arboviral encephalitis by causing more unilateral and focal findings, with a predilection for temporoparietal areas of the brain. HSV encephalitis is more likely to cause focal seizures, olfactory hallucinations, and personality change (Whitley et al. 1982). HSV is the most common identified cause of viral encephalitis simulating a primary psychiatric disorder (Caroff et al. 2001). CSF typically shows pleocytosis, red blood cells (because of the hemorrhagic nature of HSV encephalitis), and elevated protein. Glucose is usually normal. EEG is a sensitive (but not specific) diagnostic test, showing periodic temporal spikes and slow waves as opposed to more diffuse changes usually seen in other forms of viral encephalitis (Smith et al. 1975). MRI may show diffuse inflammation, particularly in the temporoparietal areas. Serological evaluation is helpful only retrospectively. Brain biopsy is reliable and has a high yield and low complication rate. Diagnosis based on symptoms and signs alone misses 50% of the cases. Rapid diagnosis is essential because only early treatment improves outcome. Acyclovir is the drug of choice. One possible sequela of HSV encephalitis is the Klüver-Bucy syndrome, which includes oral touching compulsions, hypersexuality, amnesia, placidity, agnosia, and hyperphagia (Hart et al. 1986).

### Varicella/Herpes Zoster

The varicella/herpes zoster virus causes chickenpox in children and herpes zoster in adults. Most cases of encephalopathy in children with varicella infection have been due to Reye's syndrome, although the virus itself can cause encephalitis. The most common neurological sequela of herpes zoster is postherpetic neuralgia (see Chapter 36, "Pain") (Gnann and Whitley 2002). Comorbid psychopathology is common in postherpetic neuralgia, especially depression (Clark et al. 2000), and may influence the choice of treatment for the neuropathic pain (e.g., tricyclic antidepressant vs. anticonvulsant). Weeks or months after recovery from herpes zoster, encephalitis or arteritis may appear. In immunocompetent hosts, it is usually a granulomatous arteritis affecting large vessels, producing strokelike symptoms. In immunosuppressed patients, the vasculitis mostly affects small vessels, producing headache, altered mental status, fever, seizures, and focal deficits (Gilden et al. 2000).

### Postencephalitis Syndromes

Following recovery from acute viral encephalitis, psychiatric sequelae are common and constitute a major cause of

disability, especially mood disorders. Depression, hypomania, irritability, and disinhibition of anger, aggression, or sexuality have been frequently noted months after recovery, and psychosis occurs rarely (Caparros-Lefebvre et al. 1996). Depressive symptoms may respond to treatment with antidepressants or stimulants. Hypomania, irritability, and disinhibition have benefited from mood stabilizers, and behavior modification also may be helpful for aggressive and sexual behaviors (Boulais et al. 1976; Vallini and Burns 1987).

The global pandemic encephalitis in 1917–1929 known as *encephalitis lethargica* (von Economo's disease) had an acute encephalitic phase during which lethargy, psychosis, and catatonia were common. This period was followed by a chronic postencephalitic syndrome, including parkinsonism, mania, depression, and apathy in adults (Cummings et al. 2001; Dolan and Kamil 1992) and conduct disorder, emotional lability, and tics in children, with relatively little cognitive impairment (Cummings et al. 2001; Hokkanen and Launes 1997).

### Viral Hepatitis

Some viruses—including hepatitis A, B, and C; EBV; and CM—cause acute or chronic hepatitis. Hepatitis C infection is very common in the chronically mentally ill (Dinwiddie et al. 2003; Osher et al. 2003; Rosenberg et al. 2003). Fatigue, malaise, and anorexia are usually prominent in viral hepatitis and may lead to a misdiagnosis of depression. However, fatigue in chronic hepatitis is more closely correlated with depression and other psychological factors than is severity of hepatitis (McDonald et al. 2002). Depression is frequently comorbid, especially in the chronic forms of hepatitis B infection (Kunkel et al. 2000) and C (Gallegos-Orozco et al. 2003), but whether the etiology of depression in hepatitis C infection is really viral has been questioned (Wessely and Pariente 2002). Subtle cognitive dysfunction not attributable to depression, substance abuse, or hepatic encephalopathy has been documented in hepatitis C infection, and the virus has been identified in brain, suggesting that cerebral infection also may occur (Forton et al. 2002). Complicating the diagnostic picture further, treatment with interferon causes depression itself in 20%–40% of patients (Bonaccorso et al. 2002; Dieperink et al. 2003). Depression has been the most common adverse effect leading to cessation of interferon treatment. Depression associated with hepatitis or interferon is amenable to treatment with antidepressants (Kraus et al. 2002; Levenson and Fallon 1993), allowing continuation of interferon in most patients (Schaefer et al. 2003). Therefore, depression should not be considered a contraindication to interferon therapy.

Dosing should be adjusted downward if the patient has impaired liver function.

## Rabies

Rabies is a viral infection of mammals transmitted by bite. In the United States, nondomesticated animals (i.e., bats, raccoons) account for most cases of rabies because domesticated animals are vaccinated (Kauffman and Goldmann 1986). In contrast, India has no vaccination program, and 15,000 deaths each year have been attributed to rabies infection (Miller and Nathanson 1977). Transmission to humans is rare but has been misdiagnosed as an anxiety disorder (Centers for Disease Control 1991) or alcohol withdrawal (Centers for Disease Control and Prevention 1998).

Initial symptoms are nonspecific and include generalized anxiety, fever, depression, hyperesthesia, and dysesthesia, especially at the site of inoculation. In the most recent United States case, “mild personality changes” preceded more suggestive symptoms such as unsteady gait and slurred speech by more than a week (Centers for Disease Control and Prevention 2003). The rabies virus has a proclivity for attacking the limbic system; thus, delusions may result. The initial phase is followed by an excitatory phase, when the classic symptom of hydrophobia may occur. Hydrophobia is an aversion to swallowing liquids (not a phobia of water) secondary to the spasmodic contractions of the muscles of swallowing and respiration, resulting in pain and aspiration. The final phase is a progressive, general, flaccid paralysis that progresses relentlessly to death. Both rabies and the rabies vaccine may cause delirium (Leung et al. 2003).

No effective treatment exists for rabies once symptoms are evident (Fishbein and Robinson 1993). After a bite by an infected animal, the rabies vaccine should be given as soon as possible because outcome is related to the proximity in time to the bite.

## Prion Diseases

---

Prions are proteinaceous agents that cause spongiform changes in the brain. Prion diseases are rare and universally fatal, with an incubation period of months to years—hence, the term *slow viruses* (see also Chapter 32, “Neurology and Neurosurgery”). Kuru occurs only in Papua, New Guinea. It is spread by the cannibalistic consumption of dead relatives during mourning rituals. Scrapie is a spongiform encephalopathy found in sheep. Although known to have been present in Great Britain for almost three centuries, scrapie has never been shown to cause disease in humans.

Bovine spongiform encephalopathy (“mad cow disease”) appears to have been transmitted to cattle by the practice of feeding cattle recycled sheep by-products.

Creutzfeldt-Jakob disease (CJD) occurs sporadically and sometimes familiarly in humans. It also has been transmitted by intracerebral electrodes, grafts of dura mater, corneal transplants, human growth hormone, and gonadotropin, but iatrogenic transmission is now rare (Ironsides 1996; Tyler 2003). CJD is a severe dementia accompanied by psychosis, affective lability, and dramatic myoclonus that rapidly progresses to rigid mutism and then death. In the last few years, mainly in Great Britain, there have been 139 cases of “new-variant” CJD (nvCJD) with distinct differences from CJD.

nvCJD patients are younger than CJD patients (average age=26 vs. 60 years). In most cases of nvCJD, psychiatric symptoms appear several months before any neurological symptoms, including depression, irritability, anxiety, and apathy (Spencer et al. 2002; Tyler 2003). Although bovine spongiform encephalopathy and nvCJD are temporally and geographically associated, a causative link has not been proven. The EEG is usually abnormal in both forms of CJD, but definitive diagnosis requires brain biopsy.

Fatal familial insomnia is an even rarer prion disease in which progressive insomnia (and sometimes behavior change) appears months before any cognitive, autonomic, or motor symptoms develop. Despite its name, the disease also occurs through sporadic mutation. Patients with this disorder may be given misdiagnoses of mood, anxiety, or somatoform disorders (Mastrianni et al. 1999; Taberner et al. 2000).

## Fungal Infections

---

The frequency of fungal infection has steadily increased over the last three decades, coincident with the growing number of immunosuppressed patients who are surviving longer than in the past. An aging population, an increased number of malignancies, the spread of AIDS, the use of immunosuppressive and cytotoxic drugs, the use of intravenous catheters, hyperalimentation, illicit drug use, extensive surgery, and the development of burn units also have contributed to the increased frequency of fungal infection (Hawkins and Armstrong 1984). CNS symptom development depends on the size and shape of the fungi. The smallest fungi have access to the cerebral microcirculation and infect the subarachnoid space. Large hyphae obstruct large and intermediate arteries, giving rise to extensive infarcts (e.g., aspergillosis). Fungi with pseudohyphae occlude small blood vessels, producing small infarcts

tions and microabscesses (e.g., *Candida*). Most fungi are opportunistic (as in aspergillosis, mucormycosis, and candidiasis), whereas others are pathogenic (as in coccidioidomycosis and cryptococcosis) irrespective of the host's defenses (Chimelli and Mahler-Araújo 1997).

## Aspergillosis

*Aspergillus*, an opportunistic organism, infects only debilitated patients. *Aspergillus* genus is commonly found in soil. CNS involvement usually follows infection of the lungs or gastrointestinal tract. Symptoms of confusion, headache, and lethargy often accompany focal neurological signs.

## Cryptococcosis

Cryptococcosis is an infection caused by *Cryptococcus* species, a pathogen distributed worldwide, found in bird excreta, the soil, and other animals. *Cryptococcus* may act as a solo pathogen, but in up to 85% of cases, it is associated with another illness, especially AIDS. The portal of entry is usually the respiratory tract from which hematogenous spread occurs, although at the time of presentation, pulmonary infection may not be evident. This pathogen has a predilection for the subarachnoid space (Sabetta and Andriole 1985).

*Cryptococcus* is the most common form of fungal meningitis. It is typically insidious in onset and slowly progressive. Headache is present in up to 75% of the cases, varying from mild and episodic to progressively incapacitating and constant. Other signs include cerebellar, cranial nerve, and motor deficits; irritability; psychosis; and lethargy, which may progress to coma. Remission and relapse are common in untreated patients. Isolation of the fungi provides definitive diagnosis. Serological testing of patients with cryptococcal meningitis identifies cryptococcal antigen in serum, CSF, or both 90% of the time. Treatment is typically a prolonged course of an antifungal agent.

## Coccidioidomycosis

Coccidioidomycosis is restricted to warm, dry areas such as the southwestern United States, Mexico, and parts of South America (particularly Argentina and Paraguay). Its spores are inhaled in infected dust. Initial infection produces a mild febrile illness, often followed by pulmonary symptoms (Chimelli and Mahler-Araújo 1997). Dissemination beyond the lung is relatively rare, and the CNS is not the most common extrapulmonary site. When it does occur, CNS infection is typically insidious in onset, 1–3

months after initial infection (Castleman and McNeely 1971), with severe headache associated with confusion, restlessness, hallucinations, lethargy, and transient focal signs (Bañuelos et al. 1996). Neuroimaging and serological testing of the CSF confirm the diagnosis. Amphotericin is the treatment of choice.

## Histoplasmosis

Histoplasmosis is a common respiratory infection found throughout the world and is especially common in the central United States. *Histoplasma capsulatum* is inhaled with dust contaminated with chicken, bird, or bat excreta. Most infections are asymptomatic and involve the lungs or the reticuloendothelial system. Two peaks of increased incidence occur—in infancy and in the fifth and sixth decades. CNS involvement is rare but is of insidious onset. After a few weeks of irregular fever and persistent cough, extreme nervousness and irritability progress to marked lethargy and, if untreated, coma (Tan et al. 1992).

## Blastomycosis

*Blastomyces dermatitidis* is an uncommon mycotic infection that rarely causes CNS infections. Blastomycosis is endemic with histoplasmosis in the central United States. The most common CNS manifestations are stiff neck and headache, eventually progressing to confusion and lethargy.

## Mucormycosis

*Mucormycosis* refers to any infection caused by a member of the family Mucoraceae, opportunistic fungi found in common bread and fruit molds. Mucormycosis is notorious for causing an acute fulminant infection in diabetic patients and patients with neutropenia. *Mucor* directly invades tissue and disseminates by attacking contiguous structures. Any diabetic patient with a purulent, febrile infection of the face or nose should be emergently evaluated for mucormycosis, because it may rapidly erode into the orbit and cerebrum in a matter of hours. Early mild encephalopathy (Crowley and Wilcox 1996) may quickly progress to severe delirium. Aggressive debridement and intravenous antifungal medication are required.

## Candidiasis

*Candida* causes limited local infections (cutaneous, vaginal, oral) in immune-competent hosts, typically after broad-spectrum antibiotics. Disseminated candidiasis occurs only in immunocompromised patients. Psychiatric

symptoms occur from the toxic effects of fungemia or from direct invasion of the CNS. Cerebral lesions generally occur late in the course of disseminated candidiasis. *Candida* may cause meningitis, microabscesses, macroabscesses, or vasculitis in the CNS. The nonspecific signs include confusion, drowsiness, lethargy, and headache. Sometimes *Candida* can be cultured from blood or CSF, but most cases of CNS candidiasis are not discovered until autopsy. Suggestive neuroimaging findings and isolation of *Candida* from a non-CNS site in an immunocompromised patient should prompt treatment with appropriate antifungal agents.

An alternative medicine belief is that occult systemic *Candida* infection is the cause of a wide array of somatic and psychological symptoms. There is no scientific support for this theory or its advocated treatments.

## Parasitic Infections

---

### Neurocysticercosis

One of the world's most common parasitic infections—neurocysticercosis—is an infection of the CNS by the larval form (cysticerci) of *Taenia solium*, also known as the pork tapeworm. For neurocysticercosis to occur, a human must ingest the tapeworm's eggs, from contact with infected swine or humans. Once ingested, the eggs hematogenously spread to the CNS and other sites. Cysticercosis is endemic in the developing nations. In the United States, it is usually reported in immigrants from Latin America and recently has been reportedly found in 10% of the patients with seizures presenting to an emergency department in Los Angeles, California, and in 6% in an emergency department in New Mexico (Ong et al. 2002). However, infected food handlers may transmit it to people who have no contact with pork or other contaminated foods (e.g., an Orthodox Jewish community in New York City) (Schantz et al. 1992).

A high percentage of neurocysticercosis infections remain asymptomatic. Cerebral involvement may produce seizures, stroke, or hydrocephalus; neurocysticercosis is the leading cause of seizures in adults in endemic areas. Psychiatric symptoms are frequently reported, including depression, psychosis, and cognitive decline (Forlenza et al. 1997; Shandera et al. 1994).

Between clinical history, neuroimaging, and serology, a presumptive diagnosis of neurocysticercosis usually can be made (Pittella 1997a). Definitive diagnosis of neurocysticercosis is through biopsy, but this is usually impractical. Treatment of neurocysticercosis has involved anticonvulsants, steroids, antihelminthics, and shunting for

hydrocephalus. However, antihelminthic drugs in neurocysticercosis may actually aggravate neuropsychiatric symptoms, and their use in some forms of the disease is controversial (Garcia et al. 2004; Salinas and Prasad 2000).

### Toxoplasmosis

Toxoplasmosis refers to the disease caused by *Toxoplasma gondii*, a parasite ubiquitously affecting all mammals, some birds, and probably some reptiles (Yermakov et al. 1982). Latent infection is common, but in immunosuppressed individuals, particularly those with AIDS, it may preferentially infect the CNS, resulting in a wide range of clinical presentations. Mass lesions mimicking tumor or abscess are most common, but psychosis has been reported as a presenting symptom (Donnet et al. 1991). Effective antibiotic therapy can produce rapid remission of active infection but must be continued throughout life to prevent recurrence (B.A. Cohen 1999).

### Trypanosomiasis

The family of protozoa Trypanosomatidae causes two different syndromes: African trypanosomiasis (sleeping sickness) and American trypanosomiasis (Chagas' disease). African trypanosomiasis, which occurs in several sub-Saharan African countries, is caused by a subspecies of *Trypanosoma brucei* and is transmitted to humans and animals by the bite of the blood-sucking tsetse fly. The illness begins with a lesion at the site of the fly bite, headache, fever, malaise, weight loss, and myalgia and is often misdiagnosed as malaria. Patients with African trypanosomiasis often report excruciating pain after minor injuries (Kerandel's hyperesthesia) (Chimelli and Scaravilli 1997). Meningoencephalitis may develop with prominent somnolence—hence the name *sleeping sickness* (Villanueva 1993). Posterior cervical lymphadenopathy in Africans is considered highly suggestive of CNS infection by *T. brucei* (Chimelli and Scaravilli 1997). Africans living in other countries have received misdiagnoses of primary psychiatric disorder (Bedat-Millet et al. 2000). The drug used to treat late-stage disease is very toxic, with an often-fatal encephalopathy the most feared complication of treatment (Blum et al. 2001); for this reason, early detection—permitting less toxic treatment—is important (Hoeprich et al. 1994).

American trypanosomiasis, or Chagas' disease, is caused by *Trypanosoma cruzi*, which is carried by insects ("kissing bugs" or "assassin bugs") in Latin America. Transmission is so inefficient that years of exposure are required to acquire the infection, and most infections are quiescent.

Following immunosuppression, reactivated disease may present as meningoencephalitis.

On brain imaging, the lesions are indistinguishable from those of toxoplasmosis, and the organism is often not identifiable in blood. Reactivated Chagas' disease should be suspected in immunosuppressed immigrants from endemic areas of Latin America, especially in presumed cases of toxoplasmosis not responsive to chemotherapy (Chimelli and Scaravilli 1997; Villanueva 1993).

## Malaria

Malaria remains a major cause of morbidity in tropical nations, especially in young children and pregnant women. In other parts of the world, cases occur in immigrants and travelers to malarial areas. *Plasmodium* species are transmitted to humans by the bite of mosquitoes. The complete life cycle of the parasite is described elsewhere (Hoeprich et al. 1994).

Relapsing fever typifies malaria, and with temperatures commonly in excess of 41°C (105°F), delirium is common. *Plasmodium falciparum* causes cerebral malaria, the most catastrophic complication of malaria, which begins with disorientation, mild stupor, or even psychosis and rapidly progresses to seizures and coma with decerebrate posturing. The severity of the symptoms is correlated with the amount of sequestered parasitized red blood cells in the CNS (Turner 1997). Despite the severity and high fatality of cerebral malaria, those who recover appear to have little or no persisting cognitive dysfunction (Dugbartey et al. 1998), although one case-control study in U.S. Vietnam veterans three decades after they had had cerebral malaria found subtle affective and cognitive abnormalities (Varney et al. 1997). Anxiety and depression do appear to be common after recovery (Dugbartey et al. 1998), but they are more likely a result of psychological and social stress associated with severe illness (Weiss 1985). More severe neuropsychiatric signs, including psychosis in fully recovered (aparasitemic) cerebral malaria, are most likely attributable to pharmacotherapy (Nguyen et al. 1996). Antimalarial drugs commonly cause psychiatric side effects (see Table 27-3 later in this chapter).

## Schistosomiasis

Schistosomiasis is an infection caused by blood flukes (trematodes) of the genus *Schistosoma*. Infection by the larval stage usually occurs while the individual is swimming in infected fresh water. The infection affects about 200 million people in 74 countries (*Schistosoma japonicum* in the Far East; *Schistosoma mansoni* and *Schistosoma bae-*

*matobium* in Africa). Most infections are asymptomatic. CNS symptoms are uncommon, but once the worms mature and the eggs have been laid, CNS involvement may be observed with any of the clinical forms of schistosomal infection. Eggs in the CNS may induce a granulomatous reaction, leading to symptoms of increased intracranial pressure (e.g., headache, confusion, nausea, and papilledema) (Pittella 1997b). Focal lesions in brain or spinal cord reflect location of the granulomas. However, in most cases, eggs in the CNS are clinically silent. In advanced disease with *S. mansoni* or *S. haematobium*, portal hypertension is a serious complication, with hepatic encephalopathy.

## Trichinosis

Trichinosis is a worldwide disease caused by the ingestion of *Trichinella* larvae encysted in the muscles of infected animals. They are most commonly found in pork in the United States and Europe, but 150 species of mammals from all latitudes may acquire the infection. Trichinosis has become rare in developed nations but still occurs in ethnic groups that prefer raw or undercooked pork or wild animals, such as polar bear or walrus. Typical symptoms of infection include a febrile illness with myalgias and diarrhea, accompanied by marked eosinophilia. CNS involvement occurs in 10%–20% through a variety of mechanisms, including obstruction, toxicity, inflammation, vasculitis, and allergic reactions, such as headache, delirium, insomnia, meningoencephalitis, and seizures (Nikolic et al. 1998; Taratuto and Venturiello 1997). CT scan shows multiple small hypodense lesions with ringlike enhancement with contrast. A muscle biopsy is usually diagnostic. Treatment in severe cases requires corticosteroids for the inflammation and antihelminthic drugs to kill *Trichinella*. Residual cognitive dysfunction may occur (Harms et al. 1993).

## Amebiasis

Several amebas cause human disease, and all are ubiquitous in the environment worldwide. CNS infection with amebas is rare in the United States, but it is increasing. Primary amebic meningoencephalitis is produced by *Naegleria fowleri* in healthy, young individuals engaged in water sports. Its course is acute and fulminant, with headache, nausea, confusion, and stiff neck followed by coma and death within days. Granulomatous amebic encephalitis, caused by *Balamuthia mandrillaris* and some species of *Acanthamoeba*, usually occurs in debilitated, immunosuppressed (especially in cases of AIDS) or malnourished individuals. The course is more chronic, with

personality changes, confusion, and irritability, eventually progressing to seizures and death (Martinez and Visvesvara 1997).

## Other Organisms

### Pfiesteria

*Pfiesteria piscicida* is a dinoflagellate, a microorganism difficult to classify as a plant or an animal, that can release a toxin capable of killing large numbers of fish. It occurs along the eastern coast of the United States from the Gulf of Mexico to Delaware Bay. A similar species has been identified in northern Europe. There have been reports of neurotoxic effects in humans in Maryland and North Carolina, primarily in waterpersons exposed to large-scale fish kills and in researchers who cultured *Pfiesteria*. Prominent symptoms included headache, skin lesions, burning sensation on contact with water, and reversible difficulties with learning and other higher cognitive func-

tions, improving months after cessation of exposure (Grattan et al. 1998). However, a multistate prospective cohort study has not yet detected adverse human effects (Moe et al. 2001).

## Drugs for Infectious Diseases: Adverse Psychiatric Effects and Drug Interactions

That antibiotics can cause delirium and other psychiatric symptoms is not well appreciated. The best-documented psychiatric side effects of drugs for infectious diseases are listed in Table 27–3. Delirium and psychosis have been particularly associated with quinolones (e.g., ciprofloxacin), procaine penicillin, antimalarial and other antiparasitic drugs, and the antituberculous drug cycloserine. The most common adverse effect causing discontinuation of interferon is depression. More detailed review is available elsewhere (Brown and Stoudemire 1998).

**TABLE 27–3. Psychiatric side effects of drugs for infectious diseases (excluding antiretroviral drugs)**

Drug	Side effects
<b>Antibacterial</b>	
Cephalosporins	Euphoria, delusions, depersonalization, illusions
Dapsone	Insomnia, agitation, hallucinations, mania, depression
Procaine penicillin <sup>a</sup>	Agitation, depersonalization, fear of imminent death, hallucinations (probably due to procaine)
Quinolones <sup>a</sup>	Psychosis, paranoia, mania, agitation, Tourette-like syndrome
Trimethoprim–sulfamethoxazole	Delirium, psychosis
Gentamicin	Delirium, psychosis
Clarithromycin	Delirium, mania
<b>Antituberculous</b>	
Cycloserine <sup>a</sup>	Agitation, depression, psychosis, anxiety
Isoniazid	Psychosis, mania
Ethionamide	Depression, hallucinations
<b>Antiviral</b>	
Acyclovir, ganciclovir	Psychosis, delirium, depression, anxiety
Amantadine <sup>a</sup>	Psychosis, delirium
Interferon-alfa <sup>a</sup>	Irritability, depression, agitation, paranoia
Interleukin-2	Psychosis, delirium
<b>Antiparasitic</b>	
Antimalarials <sup>a</sup>	Confusion, psychosis, mania, depression, anxiety, aggression, delirium
Metronidazole	Depression, delirium
Thiabendazole	Psychosis
<b>Antifungal</b>	
Amphotericin	Delirium, psychosis, depression

Note. See also Brown and Stoudemire 1998.

<sup>a</sup>More significant (more frequent and/or better established) effects.

Source. Adapted from Abouesh A, Stone C, Hobbs WR: "Antimicrobial-Induced Mania (Antimania): A Review of Spontaneous Reports." *Journal of Clinical Psychopharmacology* 22:71–81, 2002; "Drugs That May Cause Psychiatric Symptoms." *Medical Letter* 44:59–62, 2002.

Table 27–4 shows selected well-established interactions between antimicrobial and psychotropic drugs. Drug interactions between antibiotics and nonpsychiatric drugs also may present risk in psychiatric practice. Erythromycin (and similar antibiotics like clarithromycin) and ketoconazole (and similar antifungals) may cause QT interval prolongation and ventricular arrhythmias when given to a patient taking other QT-prolonging drugs, including tricyclic antidepressants and many antipsychotics.

**TABLE 27–4. Selected antimicrobial–psychotropic drug interactions**

Antimicrobial	Effect on psychiatric drug
Antimalarials	Increase phenothiazine level
Azoles	Increase alprazolam, midazolam levels Increase buspirone level
Clarithromycin, erythromycin	Increase alprazolam, midazolam levels Increase carbamazepine level Increase buspirone level Increase clozapine level
Quinolones	Increase clozapine level Increase benzodiazepine level Decrease benzodiazepine effect via GABA receptor
Isoniazid	Increase haloperidol level Increase carbamazepine level With disulfiram, causes ataxia

Note. GABA=gamma-aminobutyric acid.

## Fears of Infectious Disease

Infectious diseases historically have been, and remain, frightening. In the recent epidemic of SARS, both affected patients and health care workers experienced fears of the illness and fears of contagion to family and friends. Quarantined patients struggle with loneliness, isolation, and stigmatization, and they fear the effect of their absence on those who depend on them (Maunder et al. 2003). Both individual and group reactions to real or imagined threats of infectious diseases also may include hysterical and phobic behaviors. Anxiety about acquiring a feared disease may lead to conversion symptoms, hypochondriacal preoccupation, and unnecessary avoidance behaviors. Contamination obsessions and washing com-

pulsions are among the most frequent symptoms in OCD. Delusional fears or beliefs that one is infected also occur in psychotic disorders, including schizophrenia, psychotic depression, and delusional disorder, somatic type (e.g., delusions of intestinal parasitosis) (Ford et al. 2001; Podoll et al. 1993); however, it is important to consider that a patient with a delusion of infection may actually be infected (Chigusa et al. 2000). Unrealistic fears of infection are especially likely with venereal diseases (particularly HIV), serious outbreaks (e.g., meningococcal meningitis on campus), and infectious threats given heavy media coverage (e.g., bacterial food contamination, bovine spongiform encephalopathy, SARS, anthrax, smallpox) (Logsdail et al. 1991; McEvedy and Basquille 1997; Vuorio et al. 1990; Weir 2001). Of course, how much vigilance and which precautions are optimal may be uncertain even among experts, but the early years of the AIDS epidemic were a clear example of the potential for widespread, irrational behaviors among the public, health care professionals, and officials.

At times, mass outbreaks of symptoms occur, falsely attributed to a supposed toxic exposure (e.g., bacterial food poisoning or toxic fumes) or infectious disease. There have been hundreds of reports in the literature of such outbreaks of “mass psychogenic” or “mass sociogenic” illness, and they tend to follow trends in societal concerns (e.g., bioterrorism) (Bartholomew and Wessely 2002). They are most likely to occur in groups of young people in close quarters, such as students at schools (Jones et al. 2000) or military recruits (Struewing and Gray 1990). Some aspects of “germ panic” have become socially normative (Tomes 2000)—for example, inappropriate use of antibiotics such as ciprofloxacin during the anthrax scare, and the widespread overuse of antiseptic soaps, mouthwashes, sprays, and cleaning agents. A related phobia of fever in their children remains prevalent among parents (Crocetti et al. 2001).

## Psychiatric Aspects of Immunizations

Mass outbreaks of psychogenic symptoms similar to those described earlier in this chapter have been reported several times following vaccinations (Kharabsheh et al. 2001; Peiro et al. 1996). In developed countries, the public's fears of vaccine-preventable diseases have waned, and awareness of potential adverse effects of the vaccines has increased, which is threatening vaccine acceptance (Wilson and Marcuse 2001). The media and Web sites have disseminated much disinformation about vaccination risks, adding to the tendency toward phobic avoidance of immunization. Rare, serious CNS adverse effects, includ-

ing acute disseminated encephalomyelitis (see section "Viral Infections" earlier in this chapter; see also Nasr et al. 2000), can occur after a variety of vaccinations. However, recent studies have found no basis for the widely publicized fears that measles-mumps-rubella vaccination causes encephalitis, aseptic meningitis, or autism (Chen et al. 2004; Madsen et al. 2002; Makela et al. 2002).

Finally, it should be kept in mind that the chronically mentally ill often do not receive basic preventive medical care (Folsom et al. 2002). Psychiatrists can help ensure that their patients receive important immunizations.

# 28 HIV/AIDS

---

Niccolo D. Della Penna, M.D.

Glenn J. Treisman, M.D., Ph.D.

**SOON AFTER THE** human immunodeficiency virus (HIV) epidemic began in the early 1980s, neurologists described several HIV-related central nervous system (CNS) syndromes. Psychiatrists and other mental health professionals initially focused on grief, loss, and supportive psychotherapy but soon recognized some specific psychiatric conditions, including acquired immunodeficiency syndrome (AIDS) dementia; AIDS mania; increased rates of major depression; and psychiatric consequences of CNS involvement with HIV, opportunistic infections, and neoplasms.

Two decades later, it is apparent that psychiatric issues play a central role in the HIV epidemic. HIV is transmitted almost entirely by specific risk behaviors and in high-risk populations targeted for education and prevention since the mid-1980s. Because of this, HIV, at least in the developed countries, has become a condition predominantly of vulnerable people with certain risk factors. Transfusion recipients and homosexual men who were unaware of the risk of HIV were the early patients, whereas many current individuals are aware of the risks but are at increased risk because of addictions, personality vulnerabilities, mood disorders, impulse-control disorders, cognitive impairment, social isolation and disenfranchisement, or other barriers to behavior change. HIV-infected patients with psychiatric illness may have great difficulty in modifying risk behaviors. Psychiatric disorders also can adversely affect the treatment of HIV infection primarily through undermining adherence, and taking medications as prescribed is critical to successful treatment. Thus, the same psychiatric disorders that prevented patients from reducing their risk prevent them from obtaining benefit from their treatment. Untreated patients with high viral loads are more infectious, leading to an increased potential for spread of the HIV epidemic.

In this chapter, we address those conditions commonly seen in HIV, including those that increase risk for HIV or are barriers to HIV treatment. The introductory part of the chapter is a medical overview of HIV disease. The second part considers neuropsychiatric and medical complications associated with HIV, and the third part includes psychiatric conditions associated with HIV. Additional details regarding psychiatric disorders and treatment issues can be found in the American Psychiatric Association's "Practice Guideline for the Treatment of Patients With HIV/AIDS" (American Psychiatric Association 2000b).

## Overview of HIV Infection and AIDS

---

HIV was originally recognized through a series of cases of young homosexual men with *Pneumocystis carinii* pneumonia in the early 1980s in California. It later became clear that these patients had severe immune system compromise and were vulnerable to infections commonly seen in other immunocompromised individuals. Current global statistics suggest that 750,000 infants are born each year with HIV infection, and some estimate that 16,000 new infections occur each day, with one individual being infected about every 10 seconds (UNAIDS Joint United Nations Programme on HIV/AIDS Update 2000).

In the United States, as of December 31, 2001, 807,075 adults and adolescents had been reported as having AIDS, with current estimates suggested around 1 million. Of these, 462,653 (57%) have died. As of the end of 2002, 42 million people were estimated to be living with HIV/AIDS worldwide, with an estimated 5 million people acquiring the infection in 2002 (Centers for Disease Control and Prevention 2001). An estimated 20 million individuals have died from HIV worldwide.

Some populations within the United States are at increased risk for infection. Homosexual men have reduced their risk substantially but as a group continue to have high seroprevalence. Blood product screening has made transfusion risk negligible. Vertical transmission risk from mother to fetus, which occurs in up to 25%–30% of live births without intervention, is influenced by delivery type, severity of HIV disease, and the availability of preventive antiviral treatment. The frequency of vertical transmission in the developed countries has decreased dramatically in the last decade but remains a significant problem in many other parts of the world and in some subpopulations in the United States and other developed countries. Unfortunately, psychiatric disorders continue to make many vulnerable patients unable to access or benefit from prevention efforts. For example, intravenous drug users and their sexual partners are currently the population with the greatest risk for infection.

Patients who are likely to have poor adherence and therefore fail treatment may be excluded from treatment. The primary reason for excluding them from antiretroviral drug treatment is that inconsistent adherence breeds viral resistance, rendering treatment ineffective and increasing public health risk. Additionally, resources are often scarce in HIV clinics, and patients who are less likely to remain adherent are the least likely to receive effective treatment. These patients include intravenous drug users, mentally ill patients, and other patients at high risk for poor outcomes. Therefore, the ability to provide adequate psychiatric care to HIV-infected patients is critical for effective treatment of HIV. Psychiatric disorders compromise the ability to take medications, adhere to treatment, practice safer sexual behaviors, and stop using intravenous drugs.

## Neuropsychiatric and Medical Complications of HIV Infection

---

Opportunistic infections are covered in Chapter 27, “Infectious Diseases,” but here we review some specifics related to HIV infection.

### Toxoplasmosis

Infection with *Toxoplasma gondii* generally occurs in patients with fewer than 200 CD4 cells/mm<sup>3</sup>. In AIDS patients, toxoplasmosis is the most common reason for intracranial masses, affecting between 2% and 4% of the AIDS population. Symptoms of CNS infection are fever, change in level of alertness, headache, focal neurological

signs (approximately 80% of cases), and partial or generalized seizures (approximately 30% of cases). Computed tomography (CT) and magnetic resonance imaging (MRI) scans usually show multiple ring-enhancing lesions in the basal ganglia or at the gray–white matter junction.

Treatment is usually empirical, based on clinical and imaging findings, and consists of pyrimethamine and leucovorin plus sulfadiazine or clindamycin. Clinical and radiological improvement is seen in more than 85% of the patients by day 7 (Luft et al. 1993). Acute treatment (6 weeks) must be followed by continuous prophylaxis to prevent relapse. The use of trimethoprim–sulfamethoxazole as prophylaxis has reduced the incidence of *Toxoplasma* infection in HIV. Patients with hypersensitivity to sulfa drugs may use pyrimethamine plus dapsone.

### Cytomegalovirus

Cytomegalovirus (CMV) infection is found at autopsy in about 30% of brains from HIV-infected patients. However, the development of clinically evident CMV encephalitis is fairly rare and most often occurs in patients with CD4 cell counts less than 50 cells/mm<sup>3</sup>. CMV infection of another organ, such as retina, blood, adrenal glands, or gastrointestinal tract, is often found at the time of encephalitis diagnosis. CMV encephalitis in AIDS may progress gradually as a dementia with focal deficits (Holland et al. 1994) or rapidly as a fatal delirium (Kalayjian et al. 1993).

Treatment is mostly supportive. Ganciclovir and foscarnet may be prescribed but are of questionable benefit. Trials of a promising new medication, cidofovir, are under way.

### Cryptococcal Meningitis

Although meningitis caused by *Cryptococcus neoformans* is rare in immunocompetent persons, it occurs in approximately 8%–10% of AIDS patients and may be devastating. Patients generally present with fever and delirium. Meningeal signs are not universally seen. Seizures and focal neurological deficits occur in about 10% of patients, and intracranial pressure is elevated in about 50% of patients.

Treatment of cryptococcal meningitis in HIV requires amphotericin B. Patients who survive must receive prophylaxis against recurrence. Prophylaxis can be prescribed as oral fluconazole or intermittent intravenous amphotericin B. Some authors suggest that patients who receive highly active antiretroviral therapy (HAART) for 6 months with a rise in CD4 cell count to greater than 100 cells/mm<sup>3</sup> may terminate secondary prophylaxis (E. Martinez et al. 2000). Primary prophylaxis for *C. neoformans* is not recommended.

## Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of white matter in immunocompromised patients. First described in cancer patients, the causative agent is a polyomavirus, named JC virus after a patient. Its transmission route is unclear but may be respiratory, and there is no clear clinical syndrome of acute infection. The prevalence of PML in AIDS is between 1% and 10%, and AIDS patients account for almost three-quarters of PML cases reported in the United States. Typically, PML affects AIDS patients with fewer than 100 CD4 cells/mm<sup>3</sup>.

The clinical syndrome consists of multiple focal neurological deficits, such as mono- or hemiparetic limb weakness, dysarthria, gait disturbances, sensory deficits, and progressive dementia, with eventual coma and death. Occasionally, seizures or visual losses may occur. Usually, no fever or headache occurs.

The pathology of PML consists of demyelination and death of astrocytes and oligodendroglia. MRI is more useful than CT in diagnosis; multiple areas of attenuated signal are seen on T2 images, primarily in the white matter of brain, although gray matter, brain stem, cerebellar, and spinal cord lesions are possible. Cerebrospinal fluid (CSF) studies are generally unhelpful, except for polymerase chain reaction evaluation for the presence of JC virus, which is sensitive and specific. Brain biopsy provides the definitive diagnosis but is rarely used. Trials of antiviral agents for the treatment of PML are under way but have been largely unsuccessful, probably because the acute infection with JC virus occurs many years before PML develops.

## Central Nervous System Neoplasms

Lymphoma is the most common neoplasm seen in AIDS patients, affecting between 0.6% and 3%. AIDS is the most common condition associated with primary CNS lymphoma. The patient is generally afebrile; may develop a single lesion with focal neurological signs or small, multifocal lesions; and most commonly presents with mental status change. Seizures occur in about 15% of these patients.

CNS lymphoma is at times misdiagnosed as toxoplasmosis, HIV dementia, or other encephalopathy. CT scan of the brain may be normal or show multiple hypodense or patchy, nodular enhancing lesions. MRI generally shows enhanced lesions that may be difficult to differentiate from CNS toxoplasmosis, but thallium single photon emission computed tomography (SPECT) scanning

may help differentiate the two disorders. CSF studies may be normal or show a moderate monocytosis; cytology studies report lymphoma cells in fewer than 5% of patients. Brain biopsy is required for confirmation of the diagnosis of CNS lymphoma. Because this procedure carries some morbidity, clinicians should strongly consider the possibility of lymphoma in afebrile patients with a negative toxoplasma immunoglobulin G (IgG) screening test result, patients with a single lesion, and patients who fail to respond to empirical therapy for toxoplasmosis as indicated by clinical examination and repeat MRI. The differential diagnosis of CNS neoplasm also includes metastatic Kaposi's sarcoma and primary glial tumors.

Lymphoma may respond in part to radiation therapy, thus alleviating high intracranial pressure and its associated symptoms. Chemotherapy is generally adjunctive for lymphoma. CNS lymphoma had a grim prognosis with an average survival of 3–5 months prior to the advent of HAART, but the prognosis is now dependent on the HAART response, with considerable improvement possible in patients who respond.

## Fatigue in HIV

Fatigue is a very common symptom in HIV-infected patients, which is often overlooked, improperly assessed, or inadequately investigated. It is associated with poor quality of life and impaired physical functioning (Breitbart et al. 1998; Darko et al. 1992; Hoover et al. 1993; Longo et al. 1990; Vlahov et al. 1994). Estimates of prevalence of fatigue in patients infected with HIV range from 10% to 30% in early cases to 40% to 50% in AIDS cases (Anderson and Grady 1994; Crocker 1989; Miller et al. 1991; Revicki et al. 1994; Richman et al. 1987). Fatigue may be mild and annoying, or it may be severe enough to impair function. Several scales have been published to assess fatigue symptoms and severity (Portenoy et al. 1992, 1994). Fatigue is a nonspecific symptom and may have a single or multifactorial etiology. In a sample of ambulatory AIDS patients, fatigue significantly correlated with anemia and pain (Breitbart et al. 1998). In addition to disease causes, fatigue may be a side effect of medications, including HAART. Fatigue is one of the most common side effects of protease inhibitors and may be a reason for non-adherence (Duran et al. 2001).

Fatigue also may be the result of substance abuse, depression, or other psychiatric disorders. HIV patients with major depression are much more likely to complain of fatigue than are patients without depression (Ferrando et al. 1998a; Perkins et al. 1995). HIV wasting syndrome, chronic diarrhea, and testosterone deficiency are all associated with fatigue. Low serum testosterone has been

found among symptomatic AIDS patients, especially those with HIV wasting syndrome (Berger et al. 1998; Dobs et al. 1996; Grinspoon et al. 1998; Laudat et al. 1995; Muurahainen and Mulligan 1998). Hypotestosteronism is most likely in advanced AIDS (Kopicko et al. 1999) but also may be due to medications (e.g., fluconazole, ketoconazole, or ganciclovir) (Wagner et al. 1995).

In many HIV patients, the fatigue has no clear etiology, and empirical treatment is reasonable. Testosterone may be a successful treatment for fatigue in HIV-infected men, even when depressive symptoms are present (Wagner et al. 1998). More activating antidepressants may be better tolerated by fatigued depressed patients. Some authors have reported that stimulants may be useful in treating fatigue and depression in HIV, as discussed later in this chapter. Care must be exercised in using stimulants in patients with histories of substance abuse, although risk of abuse loses relevance in terminal AIDS.

## Psychiatric Conditions Associated With HIV

### Delirium

Delirium occurs frequently in patients with advanced HIV infection (Bialer et al. 1991; Fernandez et al. 1989). One study found that 46% of the AIDS patients at a skilled nursing facility had at least one episode of delirium (Uldall and Berghuis 1997). More subtle delirium is common in compromised patients, although assessment can be difficult. In addition, delirium has been shown to be a marker for decreased survival in patients with AIDS (Uldall et al. 2000b). Hospitalized patients with AIDS also were found to have increased mortality if delirium complicated their hospital course (Uldall et al. 2000a).

The clinical presentation of delirium in HIV patients is the same as in non-HIV-infected individuals and is characterized by inattention, disorganized thinking or confusion, and fluctuations in level of consciousness. Emotional changes are common and often unpredictable, and hallucinations and delusions are frequently seen. The syndrome has an acute or a subacute onset and remits fairly rapidly once the underlying etiology is treated. If untreated, patients have a marked increased risk of mortality, with estimates of about 20% in hospitalized patients.

Aside from general risk factors such as older age, multiple medical problems, multiple medications, impaired visual acuity, and previous episodes of delirium, patients with HIV-associated dementia are at increased risk to develop delirium. The differential diagnosis of delirium in-

cludes HIV-associated dementia (especially with AIDS mania), minor cognitive-motor disorder, major depression, bipolar disorder, panic disorder, and schizophrenia. Delirium usually can be differentiated on the basis of its rapid onset, fluctuating level of consciousness, and link to medical etiology.

The cause of delirium should be aggressively sought. The approach to determining cause is similar to that for delirium in general (see Chapter 6, "Delirium"). Particular considerations in HIV patients include hypoxia with *Pneumocystis* pneumonia, malnutrition, CNS infections and neoplasms, systemic infections (e.g., mycobacteria, CMV, bacterial sepsis), HIV nephropathy, substance intoxication and withdrawal, medication toxicity, and polypharmacy. Variations in hydration or electrolyte status also may profoundly affect patients with HIV who already have cerebral compromise. HIV infection itself also may produce an acute encephalopathy similar to that reported with CMV (Bialer et al. 2000).

### Treatment

Management of delirium in HIV is very similar to that for delirium in general (see Chapter 6, "Delirium"), including identification and removal of the underlying cause (when possible), nonpharmacological reorientation and environmental interventions, and pharmacotherapy. Low doses of high-potency antipsychotic agents usually are effective. Newer, atypical antipsychotics are currently being used with some success, but those with more anticholinergic activity may worsen the condition. Benzodiazepines should be used with caution because they may contribute to delirium in some patients but are of particular use in alcohol or benzodiazepine withdrawal delirium. Physical restraint may be necessary if the patient becomes violent but should be used only when alternatives are inadequate, because restraint may worsen delirium.

Treatment with antipsychotic medication requires awareness of the higher susceptibility of patients with HIV to neuroleptic-induced extrapyramidal symptoms (EPS), even with exposure to drugs with low potential for inducing EPS (Edelstein and Knight 1987; Hollander et al. 1985; Hriso et al. 1991). This susceptibility is a result of HIV-induced damage to the basal ganglia (American Psychiatric Association 2000b; Ferrando and Wapenyi 2002). Increased susceptibility to EPS has been particularly notable with use of conventional neuroleptic medications and has limited the dosage that can be used to treat patients (Maj 1990; Sewell et al. 1994b). Patients with AIDS-related psychosis are more sensitive to EPS and respond to lower than standard doses of antipsychotics (M. Harris et al. 1991; Sewell et al. 1994b; A. Singh et al. 1997). Extreme sensitivity to EPS is encountered

in patients with HIV dementia (Fernandez et al. 1989). Marked neuronal degeneration in the basal ganglia of patients with HIV (Itoh et al. 2000), with accompanying dopaminergic neuron destruction and/or alteration, may explain these findings.

To date, only one randomized controlled trial in delirious patients with AIDS has documented efficacy of low-dose haloperidol and chlorpromazine. Lorazepam was ineffective and was associated with significant adverse effects (Breitbart et al. 1996). Lorazepam was reported to be useful in cases of AIDS-associated psychosis with catatonia, however (Scamvougeras and Rosebush 1992). Case reports indicate that molindone is of benefit for HIV-associated psychosis and has minimal EPS (Fernandez and Levy 1993).

If indicated, typical neuroleptic medications should be used at the lowest dosage and for the briefest duration possible. Atypical antipsychotics are generally preferred because of lower risk for EPS. Terminal delirium in HIV, as in other terminal diseases, is much more refractory to treatment.

## Dementia

### *Prevalence*

Early in the AIDS epidemic, some patients presented with rapidly progressing neurocognitive disturbances, which led to an intensive search for etiology. Several CNS opportunistic conditions were identified, including CMV encephalitis, PML, cerebral toxoplasmosis, cryptococcal meningitis, and CNS lymphoma. However, a subset of patients remained for which no identifiable pathogen could be found, and it was deduced that HIV itself was the causative factor behind the dementia. Autopsy studies of AIDS patients with dementia found characteristic white matter changes and demyelination, microglial nodules, multinucleated giant cells, and perivascular infiltrates but a marked absence of HIV within neurons. This has led to the current theories of neuronal loss through the action of macrophages and microglial cells and/or through activation of cytokines and chemokines that trigger abnormal neuronal pruning. It appears that basal ganglia and nigrostriatal structures are affected early in the dementia process, with diffuse neuronal losses following. Typical late findings show an approximate 40% reduction in frontal and temporal neurons. Analyses of CSF (Gallo et al. 1989; Laverda et al. 1994) and autopsy material (Tyor et al. 1992; Wesselingh et al. 1994) also have shown aberrant production of specific cytokines in patients with HIV-associated dementia.

In 1986, HIV-associated dementia was reported in up to two-thirds of AIDS patients (Navia et al. 1986), but it

is less frequent now in patients receiving HAART. It has become one of the leading causes of dementia in persons younger than 60 (McArthur et al. 1993). However, its frequency among patients with otherwise asymptomatic HIV infection or CD4 cell count greater than 500 cells/mm<sup>3</sup> is probably less than 5% in a community sample (Handelsman et al. 1992; Krikorian et al. 1990; Maj et al. 1994; McKegney et al. 1990; Wilkie et al. 1990). For hospitalized HIV-infected patients seen in psychiatric consultation, the rate of HIV-associated dementia has been measured at 7%–25%. In a study in a general hospital, HIV-associated dementia was diagnosed in 17% of the patients with HIV for whom psychiatric consultation was requested (Buhrich and Cooper 1987; Dilley et al. 1985). In the Multicenter AIDS Cohort Study (Sacktor et al. 1999a), the incidence of HIV-associated dementia declined 50% from 1990–1992 to 1996–1998, a period during which effective antiretroviral therapy was used (Sacktor et al. 1999a). HIV-associated dementia is generally seen in late stages of HIV illness, usually in patients who have had a CD4 cell count nadir of less than 200/mm<sup>3</sup>.

Risk factors associated with eventual development of HIV dementia include higher HIV RNA viral load, lower educational level, older age, anemia, illicit drug use, and female sex. High CSF HIV RNA levels may be present in patients with relatively low serum HIV RNA levels and may correlate more directly with severity of neurological deficits (McArthur et al. 1997).

### *Pathophysiology*

Mechanisms of neuronal death in HIV-associated dementia are unclear (McArthur et al. 1989; Wiley et al. 1991). Neurotoxic proteins, such as gp120 and Tat, have been associated with overstimulation of glutamate receptors, which can be blocked by *N*-methyl-D-aspartate (NMDA) and non-NMDA antagonists (Magnuson et al. 1995; Nath et al. 2000). Patients with HIV-associated dementia have been found to have increased CSF levels of glutamate compared with nondemented control subjects (Ferrarese et al. 1997) and patients with other neurological diseases or Alzheimer's dementia (Ferrarese et al. 2001). Atrophy of the caudate nuclei was particularly notable in those patients with HIV-associated dementia, supporting other reports of basal ganglia sensitivity to excitotoxicity (Bernal et al. 2000). Known HIV-associated dementia markers include CSF HIV RNA (Brew et al. 1997; McArthur et al. 1997; Sei et al. 1996), CSF beta<sub>2</sub>-microglobulin, neopterin, quinolinic acid, prostaglandins, and matrix metalloproteinases (Brew 2001). Recent evidence also suggests axonal injury with presence of beta-amyloid precursor protein in brains of patients with HIV-associated dementia (Nebuloni et al. 2001).

### *Assessment*

Clinically, HIV dementia presents with the typical triad of symptoms seen in other subcortical dementias—memory and psychomotor speed impairments, depressive symptoms, and movement disorders. Initially, patients may notice slight problems with reading, comprehension, memory, and mathematical skills, but these symptoms are subtle, so they may be overlooked or discounted as being caused by fatigue and illness. Patients with early dementia usually will show impairments in timed trials, such as a timed oral Trail-Making Test or grooved pegboard. The Modified HIV Dementia Scale is a very useful bedside screen and can be administered serially to document disease progression (Davis et al. 2002). Later, patients develop more global dementia, with marked impairments in naming, language, and praxis.

Motor symptoms are also often subtle in the early stages and include occasional stumbling while walking or running; slowing of fine repetitive movements, such as playing the piano or typing; and slight tremor. On examination, patients will have impaired saccadic eye movements, dysdiadochokinesia, hyperreflexia, and, especially in later stages, frontal release signs. In late stages, motor symptoms may be quite severe, with marked difficulty in smooth limb movements, especially in the lower extremities. Impairments on tests of psychomotor speed in patients at the time of AIDS diagnosis with no memory complaints have been shown to predict development of HIV-associated dementia up to 2 years later (Dunlop et al. 2002). Rate of progression is variable and may cause mild dysfunction over a long period or rapid progression with severe impairment (Price and Brew 1988). Parkinsonian features are common in HIV-associated dementia, and clinical correlates between HIV and parkinsonism have been identified (Koutsilieri et al. 2002; Mirsattari et al. 1998). Parkinsonian features may be provoked by dopamine antagonists (Hriso et al. 1991), opportunistic infections including toxoplasmosis (P. Maggi et al. 2000), or CNS infection with HIV itself (Mirsattari et al. 1998).

Apathy is a common early symptom of HIV-associated dementia, often causing noticeable withdrawal by the patient from social activity. A frank depressive syndrome also commonly develops, typically with irritable mood and anhedonia instead of sadness and crying spells. Sleep disturbances and weight loss are common. Restlessness and anxiety may occur. Psychosis develops in a significant number of patients, typically with paranoid thoughts and hallucinations. In about 5%–8% of patients, a syndrome known as AIDS mania develops (see subsection “Bipolar Disorder in HIV” later in this chapter). Overall, HIV-associated dementia is rapidly progressive, usually ending in death within 2 years. Because of impulsive behavior and emotional

ability, HIV-associated dementia has been suggested as a strong risk factor for suicide (Alfonso and Cohen 1994).

### *Diagnosis*

Typical findings on MRI of patients with advanced HIV-associated dementia include significant white matter lesions, as well as cortical and subcortical atrophy (Dal Pan et al. 1992; Jarvik et al. 1988; Stout et al. 1998). These abnormalities may appear as discreet foci, as patchy regions of confluent involvement, or as diffuse parenchymal involvement (Broderick et al. 1993; M.P. Grassi et al. 1997; Hawkins et al. 1993; Olsen et al. 1988). Partial improvement of MRI signal abnormalities (Olsen et al. 1988) and worsening of atrophy and white matter lesions (Post et al. 1992) have been reported in small reviews of patients taking zidovudine. MRI also has been suggested to be of utility in monitoring HIV-associated dementia treatment with HAART (Thurnher et al. 2000).

Various functional neuroimaging techniques, including positron-emission tomography (PET) (Rottenberg et al. 1996), SPECT (G.J. Harris et al. 1994; Rosci et al. 1996), and magnetic resonance spectroscopy (MRS) (Barker et al. 1995; Chang et al. 1999; Lopez-Villegas et al. 1997), have shown alterations in cerebral blood flow and metabolic patterns in the brains of individuals infected with HIV. Most of these studies were done in patients with dementia or other cognitive impairment, but other MRS investigations showed abnormalities in patients with no cognitive deficit (Chang et al. 1999; Meyerhoff et al. 1999; Suwanwela et al. 2000). Increased brain activation on functional MRI during working memory was found in patients with early HIV cognitive disturbance (Chang et al. 2001). Further studies showed increased activation on functional MRI in HIV-positive patients that predated clinical signs or deficits on cognitive tests (Ernst et al. 2002).

Recent evidence suggests that HIV-associated dementia may develop in the presence of milder immunosuppression (Dore et al. 1999). The rates of HIV-associated dementia have declined but not to the same extent that other AIDS-defining illnesses have declined, suggesting that CNS eradication of HIV is becoming more challenging with current antiretroviral regimens. It has been proposed that increasing resistance to HAART regimens may be linked to this possible evolution. In the Multicenter AIDS Cohort Study (1990–1998; Sacktor et al. 2001), the proportion of cases of HIV-associated dementia in patients with CD4 cell counts between 201 and 350 cells/mm<sup>3</sup> was higher in 1996–1998 compared with the early 1990s. This suggests that screening for HIV-associated dementia should be extended to patients with CD4 cell counts less than 350 cells/mm<sup>3</sup> (Sacktor et al. 1999b, 2001).

The extended survival that antiretroviral regimens have offered patients also may increase their vulnerability to developing dementia rather than dying secondary to other fulminant complications (Lopez et al. 1999).

### *Treatment*

Controlled trials for HIV-associated dementia through 2000 have been reviewed elsewhere (Clifford 2000). The addition of protease inhibitors to antiviral regimens improves cognitive outcomes in comparison with regimens with less intensive antiretroviral therapy (Ferrando et al. 1998b). Intensification of antiretroviral therapy and associated control of viral load are associated with significantly lower risk for progression to HIV-associated dementia (Childs et al. 1999). Initial open-label studies of zidovudine showed promising results, with patients improving on neuropsychological tests (Fischl et al. 1987). The AIDS Clinical Trial Groups trial compared high doses of zidovudine with placebo but was stopped prematurely after preliminary data showed dramatic cognitive improvement in those receiving zidovudine (Siddis et al. 1993). A sharp decline in the incidence of HIV-associated dementia was observed following widespread use of zidovudine (Chiesi et al. 1990, 1996; Portegies et al. 1989), and HIV-associated dementia became rare in patients receiving continued zidovudine treatment (Portegies et al. 1989). Zidovudine might produce improvement in patients already affected by dementia (Tozzi et al. 1993; Vion-Dury et al. 1995). More recent studies have shown efficacy of HAART in improving cognitive impairment in patients with HIV-associated dementia (Ferrando et al. 1998b; Giesen et al. 2000; Halman and Rourke 2000; Letendre et al. 2000; Price et al. 1999; Tozzi et al. 1999, 2001).

Controversy exists regarding the duration of treatment and outcome of dementia. Some studies suggest a dose-response relationship between duration of exposure to zidovudine and dementia-related morbidity (Cornelisse et al. 2000; Portegies 1994; Vago et al. 1993). Other evidence shows a temporary relation between zidovudine and stability of improvement of cognitive function (Vago et al. 1993). The long-term effect of HAART on the course of HIV-associated dementia remains undetermined, with some evidence of ongoing HIV-related cognitive damage despite more than 3 years of potent antiretroviral treatment (Tozzi et al. 2001). The only other controlled trial of antiretroviral drugs compared effective antiviral therapy with and without added high-dose abacavir (Brew et al. 1998), but the study did not detect further cognitive improvement.

At first, it was believed that only antiretroviral agents with good penetration into the CNS would be useful in

treating HIV-associated dementia with associated reduction of CSF HIV RNA levels (Halman and Rourke 2000), but later efforts indicated that HAART in many different combinations, including those with poor CNS levels, could provide some relief. Drugs that cross well into CSF include nucleoside reverse transcriptase inhibitors (zidovudine, stavudine, and abacavir) and the nonnucleoside nevirapine. Despite these theoretical considerations, little evidence suggests an improved outcome for any particular antiretroviral regimen (Clifford 2000). However, the observation of increased proportions of patients with HIV-associated dementia compared with other AIDS-defining illnesses (Dore et al. 1999; Masliah et al. 2000) suggests that HAART may not be as effective for treating HIV-associated dementia.

Various clinical trials have evaluated neuroprotective medications for HIV-associated dementia. Nimodipine was found to be tolerable but not efficacious (Navia et al. 1998). Other trials assessing tolerability have been performed with antioxidants (The Dana Consortium on the Therapy of HIV Dementia and Related Cognitive Disorders 1998, 1999), a platelet-activating factor antagonist (Schifitto et al. 1999), and peptide T (Heseltine et al. 1998). Memantine, an NMDA antagonist, is currently being studied (Clifford 2000) for use in AIDS dementia but has been approved for use in other dementia syndromes.

Use of dopamine receptor agonists in pediatric patients with HIV and parkinsonian features has led to improvement in motor function (Mintz et al. 1996), yet results of similar medications in adults have been less fruitful (Kieburz et al. 1991a). Psychostimulants have been shown to improve cognitive performance in patients with HIV (Brown 1995; Hinkin et al. 2001), but others have noted apparent acceleration of HIV-associated dementia following psychostimulant use (Czub et al. 2001; Nath et al. 2001).

Risperidone and clozapine have been described in case reports of HIV-associated dementia with psychosis, with significant improvement in psychotic symptoms and few EPS (Dettling et al. 1998; Zilakis et al. 1998).

Quality care for patients with HIV-associated dementia is to ensure an optimal HAART regimen and to treat associated symptoms aggressively. Depression can be treated with standard antidepressants, and, in some cases, methylphenidate or other stimulants may be useful in treatment of apathy.

### Minor Cognitive-Motor Disorder

HIV-associated dementia is a late-stage disorder, whereas minor cognitive-motor disorder (or mild neurocognitive

disorder) is a less severe syndrome seen in earlier HIV infection. The symptoms of minor cognitive-motor disorder are often overlooked because they may be very subtle, but they are essentially mild manifestations of the same symptoms seen in HIV-associated dementia (cognitive and motor slowing). Patients with this disorder may present with a singular minor complaint, such as taking longer to read a novel, dysfunction when performing fine motor tasks such as playing the piano, an increased tendency to stumble or trip, or making more mistakes when balancing the checkbook. Minor cognitive-motor disorder is now regarded as part of the spectrum of HIV-associated dementia, and its description in the literature has fallen out of use.

Prevalence data for minor cognitive-motor disorder are variable, often suggesting up to 60% prevalence by late-stage AIDS. Prevalence in earlier stages is not well defined. Whether minor cognitive-motor disorder inevitably leads to HIV-associated dementia is uncertain. It appears that some patients may continue to have minor problems, whereas others will progress to frank dementia. This question is now confounded by the effects of HAART; data from earlier in the epidemic cannot be reasonably compared with current data.

### **Treatment**

No controlled treatment data are available specifically for minor cognitive-motor disorder.

## Major Depression

Depression is a significant problem among persons with HIV and AIDS. The question of whether the incidence or prevalence of major depression is increased in HIV-infected patients has been a controversial topic (Ciesla and Roberts 2001). Several factors complicate this issue. First, identification of major depressive disorder rather than depressive symptoms is a methodological barrier to cross-sample comparison. Additionally, populations at risk for HIV infection, including homosexual men and patients with substance use disorders, have elevated rates of major depression. A recent meta-analysis of 10 studies comparing HIV-positive and at-risk HIV-negative patients found a twofold increase in the prevalence of major depression in patients infected with HIV (Ciesla and Roberts 2001). Studies have shown that depression has a negative effect on patient adherence (Dimatteo et al. 2000), quality of life (Lenz and Demal 2000; Meltzer-Brody and Davidson 2000), and treatment outcome (J. Holmes and House 2000).

Lyketsos and Treisman reported an association between depression and HIV infection as early as 1993 and

speculated that major depression was a risk factor for developing HIV (Lyketsos et al. 1993a). Studies have shown prevalence rates of major depression among individuals with HIV of 15%–40%, depending on the setting and risk group studied (American Psychiatric Association 2000b; Atkinson et al. 1988; Perkins et al. 1994; Treisman et al. 1998). However, the prevalence exceeds 50% in persons with HIV seeking psychiatric treatment (American Psychiatric Association 2000b). Major depression is a risk factor for HIV infection (McDermott et al. 1994) by virtue of its effect on behavior, intensification of substance abuse, exacerbation of self-destructive behaviors, and promotion of poor partner choice in relationships. HIV-negative persons with higher scores on screening instruments for general psychological distress were found to have increased risk behaviors for HIV acquisition (Hartgers et al. 1992). Distress symptoms in AIDS patients have been found to correlate with poor performance, decreased global quality of life, and presence of HIV-related medical conditions but not with CD4 cell count (Vogl et al. 1999). A sevenfold increase was found in the lifetime prevalence of mood disorders among patients without substance use disorders presenting for HIV screening (Perry et al. 1990).

Major depression also is a risk factor for various behavioral disturbances that may increase exposure to HIV infection (Regier et al. 1990). In this way, depression can be seen as a vector of HIV transmission (Angelino and Treisman 2001; Treisman et al. 1998). Depression not only serves as a risk for perpetuation of the HIV epidemic (Morrill et al. 1996; Nyamathi 1992; Orr et al. 1994) but also is a complication preventing effective treatment. It has been clearly shown to hinder effective treatment of HIV infection (van Servellen et al. 2002). Patients with major depression are at increased risk for disease progression and mortality (Ickovics et al. 2001).

HIV increases the risk of developing major depression through a variety of mechanisms, including direct injury to subcortical areas of brain, chronic stress, worsening social isolation, and intense demoralization. Direct evidence for a relation between worsening HIV disease and the development of major depression is limited, but several studies support this link, particularly the Multicenter AIDS Cohort Study. This study showed that rates of depression increased 2.5-fold as CD4 cells declined to fewer than 200/mm<sup>3</sup> just before patients developed AIDS (Lyketsos et al. 1996a), suggesting that lower CD4 cell counts predict increased rates of depression.

Patients with AIDS have been recognized as a group with a high risk for psychological distress (Lyketsos et al. 1996b). High prevalence rates of suicide have been reported among HIV-infected patients (Cournos et al. 1991;

L. Grassi 1996; Pugh et al. 1993; Sacks et al. 1992; Weingardt and Carey 1995). Factors associated with HIV and suicide include depression, hopelessness, alcohol abuse, poor social support, low self-esteem, and history of psychiatric disorder (Fawcett 1992; Murphy 1977). Recent diagnosis of HIV or presence of pain also is associated with increased suicidal thoughts (Louhivuori and Hakama 1979; Steer et al. 1994). The course of HIV has been purported to affect the prevalence of suicidal thoughts and behavior (Rabkin et al. 1993), and stage of HIV infection also may alter the potential for suicidal behavior and other psychiatric symptoms (Lyketsos et al. 1994) (see also Chapter 10, "Suicidality").

Taken together, these lines of evidence indicate that HIV is a risk factor for depression and that depression is a risk factor for HIV and its morbidity, underlining the importance of recognition and treatment of depression in HIV-infected patients.

### *Differential Diagnosis*

The diagnosis of major depression in the HIV clinic is complicated by the high frequency of depressive symptoms that are associated with these other problems. Despite this, studies of HIV-positive patients with major depression have shown that its response to treatment is similar to that expected in other populations.

The differential diagnosis of depression in HIV includes nonpathological states of grief and mourning (sometimes made quite severe by the vulnerabilities of the person) and a variety of psychological and physiological disturbances. Patients with complaints of depressive syndromes can have dysthymia, dementia, delirium, demoralization, intoxication, withdrawal, CNS injury or infection, malnutrition, wasting syndromes, medication side effects, and a variety of other conditions. HIV-associated dementia and other HIV-related CNS conditions can produce a flat, apathetic state that is often misdiagnosed as depression. Cocaine withdrawal produces a depressive syndrome, and hypoactive delirium can be mistaken for depression. CNS syphilis, a condition that had become quite rare prior to the HIV epidemic, has been reappearing and remains "the great imitator," as it was originally described.

HIV-infected patients with major depression frequently present to internists and family practitioners with multiple somatic symptoms. These include, but are not limited to, headache, gastrointestinal disturbances, inexplicable musculoskeletal or visceral pain, cardiac symptoms, dizziness, tinnitus, weakness, and anesthesia. Neurovegetative symptoms are especially common. Patients report slowed thought processes, with impairments in concentration and short-term memory and occasionally

generalized confusion. Given the burdens of HIV, the medical problems associated with the disease, and the side effects of medications, depression may be very low on the list of considered causes of the patient's complaints. Even patients complaining of depressive symptoms may have their depression overlooked or discounted because of the presence of a plethora of other diagnoses. Nonspecific somatic symptoms are often the result of depression rather than HIV infection in patients whose infection is early and asymptomatic. Depression is most likely to be missed when symptoms are attributed to HIV-associated dementia, fatigue, demoralization and disenfranchisement, wasting syndrome, or substance abuse. Care should be taken in distinguishing between major depression and demoralization (i.e., adjustment disorder) in patients with HIV. Approximately one-half of the patients presenting to an urban HIV clinic with depressive complaints were found to have demoralization alone (Lyketsos et al. 1994). The ability to report feeling fairly normal when distracted from thinking about the precipitating event or circumstance causing distress is a hallmark of demoralization.

As an example, fatigue has been found to be more associated with depression than with HIV disease progression. Worsening of fatigue and insomnia at 6-month follow-up was highly correlated with worsening depression but not with CD4 cell count, change in CD4 cell count, or disease progression by Centers for Disease Control and Prevention category (Perkins et al. 1995). These findings support the notion that somatic symptoms generally suggestive of depression should trigger a full psychiatric evaluation. In later-stage HIV infection, various illnesses are common, often moving depression down on the differential diagnosis list. Somatic symptoms always should be evaluated carefully and considered in context (i.e., either with other indicators of progression of HIV disease or with other indicators of depression).

Certain HIV-related medical conditions and medications can cause depressive symptoms. These include CNS infections, such as toxoplasmosis, cryptococcal meningitis, lymphoma, and syphilis. Some investigators have found significant rates of depressive symptoms, including low mood, poor appetite with loss of weight, decreased libido, and fatigue, among male HIV-positive patients with low testosterone levels (Rabkin et al. 1999b). Several drugs used in patients with HIV, including efavirenz, interferon, metoclopramide, clonidine, propranolol, sulfonamides, anabolic steroids, and corticosteroids, have been reported to produce depression. These depressive symptoms often respond to withdrawal of the offending drug; when they do not respond to withdrawal of the drug or when the drug must be continued, the symptoms should be treated

as major depression with appropriate antidepressant medication.

Routine screening for psychiatric disease in HIV clinic patients can effectively preempt urgent referrals for rapidly progressing disorders. In one study that specifically examined HIV-infected patients, the combination of two brief self-administered questionnaires, the Beck Depression Inventory and the General Health Questionnaire, prospectively predicted a psychiatric disorder (depression in most cases) other than substance abuse with a sensitivity of 81%, a specificity of 61%, and a positive predictive value of 71% (Lyketsos et al. 1994).

### **Treatment**

Treatment with HAART was associated with significant improvement in symptoms of depression but did not necessarily have a causal relationship (Brechtel et al. 2001). Several studies reported efficacy of various antidepressants in HIV-infected patients, but no single antidepressant has been found superior in treating HIV-infected patients as a group. As with all depressed patients, nonadherence is the most common reason for ineffective drug treatment, and adverse effects are the most common reason for nonadherence. Because HIV-infected patients are likely to be more sensitive to side effects, antidepressants should be started at subtherapeutic dosage and raised slowly.

For a detailed review of the pharmacological treatment of major depression in HIV, see the article by Ferrando and Wapenyi (2002). There are methodological limitations in interpreting these clinical trial outcomes, including variable stage of infection, wide-ranging durations of treatment, overrepresentation of gay and bisexual males, and underrepresentation of intravenous drug users and women. Inclusion and outcome criteria also have been variable, and high placebo response rates have been seen (up to 50%).

One early double-blind study reported a favorable response to imipramine; 74% of the patients responded, compared with 30% taking placebo (Rabkin et al. 1994a). Another study found a favorable response to imipramine but showed a slightly higher placebo response (Manning et al. 1990). Attrition from the imipramine group was significant; 30% discontinued it by 6 months, most often because of side effects. Open-label trials of fluoxetine, sertraline, and paroxetine in various stages of HIV illness reported response rates (including affective and somatic depressive symptoms) between 70% and 90%, and all the medications were well tolerated (Ferrando et al. 1997; Rabkin et al. 1994a, 1994b). One double-blind, placebo-controlled study of fluoxetine found significant response (Rabkin et al. 1999a). Another similarly designed trial in

HIV-infected users of intravenous cocaine and opioids showed significant reduction in depressive symptoms with fluoxetine compared with placebo (Batki et al. 1993).

Supportive group psychotherapy and fluoxetine were found to be superior to placebo plus group therapy for a population of homosexual or bisexual men with HIV, and patients with more severe symptoms tended to achieve greater benefits from medication (Zisook et al. 1998). In a comparison of paroxetine and imipramine, both drugs were superior to placebo in patients with HIV and major depression (Elliott et al. 1998). Small open-label trials of venlafaxine, mirtazapine, and nefazodone in patients with major depression and HIV found that response rates were higher than 70% and there were few side effects (Elliott and Roy-Byrne 2000; Elliott et al. 1999; Fernandez and Levy 1997).

Few specific studies of the treatment of major depression in HIV-positive women have been done. In a comparison between fluoxetine and desipramine in women with AIDS, rates of response were 53% and 75%, respectively (Schwartz and McDaniel 1999). A separate trial comparing women taking fluoxetine and sertraline showed response rates of 78% and 75%, respectively (Ferrando et al. 1999).

Major depression in HIV-positive men with testosterone deficiency has been effectively treated with intramuscular testosterone in an open trial (with 79% response in mood symptoms) (Rabkin et al. 1999b) and was replicated in a double-blind, controlled trial (Rabkin et al. 2000b). Dehydroepiandrosterone, a precursor to testosterone, improved mood symptoms during an open-label phase but not during a placebo-controlled discontinuation phase (Rabkin et al. 2000a).

Psychostimulants also have been evaluated for treatment of fatigue, cognitive impairment, and depression in patients with HIV. Open-label trials report an 85% mood response rate in patients with HIV-associated dementia taking methylphenidate (V.F. Holmes et al. 1989) and a 95% mood response rate in men with AIDS taking dextroamphetamine (Wagner et al. 1997). A double-blind trial showed a significant response to dextroamphetamine compared with placebo in patients with AIDS and major depression, subthreshold major depression, or dysthymia (Wagner and Rabkin 2000). Double-blind comparison of methylphenidate, pemoline, and placebo in patients with HIV (most with AIDS) found improvement in both depressive symptoms and fatigue (Breitbart et al. 2001). Others have reported similar outcomes in treating fatigue and depression in HIV (Fernandez et al. 1995; Masand and Tesar 1996; White et al. 1992). No known reports document abuse of prescription stimulants in patients with HIV (Ferrando and Wapenyi 2002).

St. John's wort is often used by patients as alternative antidepressant treatment, but it may lower serum levels of protease inhibitors ("St. John's Wort and HAART" 2000) (see also Chapter 37, "Psychopharmacology"), and patients receiving any HIV treatment should be advised not to take it. *S*-Adenosylmethionine also has been studied in patients with HIV and major depression, with preliminary suggestion of antidepressant efficacy (Cerngul et al. 2001).

The side effects of certain antidepressants can render them advantageous or disadvantageous in particular patients with HIV. For example, selective serotonin reuptake inhibitors are best avoided in patients with chronic diarrhea. Sedating antidepressants should be avoided in patients with weakness, lethargy, orthostasis, or other risk for falls. Tricyclic antidepressants should be avoided with oral candidiasis because of the aggravating effect of dry mouth on thrush. In cases of anorexia or cachexia, antidepressants with appetite-stimulating effects are best selected.

An important issue is the interaction of antidepressants and HAART medications. Potential interactions are designated in Table 37-2 in Chapter 37, "Psychopharmacology." Two points deserve emphasis. First, particularly because depression is associated with reductions in adherence to HAART, the risks of untreated depression must be measured against those of potential medication interactions. Second, clinical significance of these drug-drug interactions has not yet been clearly established (i.e., dose adjustments are probably not required). This is likely because both antidepressants and HAART, unlike drugs such as warfarin or digoxin, have wide therapeutic indices. Finally, no evidence indicates that antidepressants cause fluctuations in CD4 cell counts (Wagner et al. 1996).

**Psychotherapy.** The literature on the use of psychotherapy for treatment of depression in HIV-infected patients is extensive, but clinical trial data are sparse. One study showed that interpersonal psychotherapy and supportive psychotherapy with adjunctive use of imipramine were superior to cognitive-behavioral therapy (CBT) or supportive psychotherapy without antidepressants in treating symptoms of depression and improving Karnofsky performance scores (Markowitz et al. 1998). Group CBT used alone or in combination with medication also has shown efficacy for HIV-infected patients. Improvements have been reported as well for HIV-positive patients receiving group CBT either as a single treatment modality or combined with medication (Antoni et al. 1991; Chesney et al. 1996; Kelly 1998; Lutgendorf et al. 1997a). Quality of life in women with AIDS also improved after group-based cognitive-behavioral interventions (Lechner et al. 2003).

A wide range of intrapsychic or interpersonal issues may be the focus of psychotherapy. Supportive psychotherapy can help patients with major depression who interpret their suffering to be a sign of weakness in the face of adversity. These patients often believe that they should pull themselves out of depression and get frustrated when they fail. Education about the disease and nature of their depression, encouragement, and therapeutic optimism all may be helpful. Other issues that arise in psychotherapy include guilt over acquiring HIV; guilt over infecting others; and anger at the source of disease, at oneself, or at God. The diagnosis of HIV infection may lead to precipitous revelation of hidden sexual or drug abuse behavior, eliciting shame and self-loathing. The stigma of HIV may lead to rejection or abandonment by loved ones, and shunning by wider society, making patients feel like lepers. Despite the development of HAART, some patients become hopeless and nihilistic and forgo HIV treatment.

## Bipolar Disorder

Patients with preexisting bipolar disorder may experience exacerbations because of the stresses of HIV illness. Perhaps the additional presence of CNS inflammation or degeneration secondary to HIV may also worsen underlying bipolar disorder, and new-onset mania could be a result of the organic insult itself. The first report of mania associated with HIV was in 1984; a 31-year-old man with Kaposi's sarcoma and recent diagnosis of *P. carinii* pneumonia developed an acute brain syndrome during antibiotic treatment. After a seizure, symptoms of mania with psychotic features were noted, along with confusion, and treatment with haloperidol effected resolution (Hoffman 1984). Numerous case reports and case series since then have described mania in HIV-infected patients (Boccellari et al. 1988; Halman et al. 1993; Kiebertz et al. 1991b; Lyketsos et al. 1993b, 1997).

The prevalence of mania has been found to be increased in patients with AIDS when compared with the general population (Halman et al. 1993; Kiebertz et al. 1991b). One report indicated a 17-month prevalence of 1.4% in those with HIV and 8.0% in patients with AIDS, which was 10 times the expected 6-month prevalence in the general population (Lyketsos et al. 1993b). In this group, late-onset patients were less likely to have a personal or family history of mood disorder. Another study among inpatients reported a 29-month prevalence of secondary mania of 1.2% in patients with HIV and 4.3% in those with AIDS (Ellen et al. 1999).

Some have suggested that mania should be subdivided into primary and secondary types, with patients who have the secondary type showing close temporal proximity to

an organic insult, no history of illness, essentially negative family history, and late age at onset (Krauthammer and Klerman 1978). Secondary mania includes those cases due to HIV brain disease itself (Gabel et al. 1986; Kermani et al. 1985; Perry and Jacobsen 1986; Schmidt and Miller 1988), those due to antiretroviral drugs (Brouillette et al. 1994; Maxwell et al. 1988; O'Dowd and McKegney 1988; Wright et al. 1989), and those due to other HIV-related conditions (e.g., cryptococcal meningitis) or medications (Fichtner and Braun 1992; V.F. Holmes and Ficchione 1989; Johannessen and Wilson 1988; Nightingale et al. 1995; Pickles and Spelman 1996). Concurrent or subsequent cognitive impairment has been reported among cases of HIV-related mania (Kermani et al. 1985; Lyketsos et al. 1997; Perry and Jacobsen 1986; Schmidt and Miller 1988); however, cases without such deficits also have been reported (Buhrich et al. 1988; Ellen et al. 1999; Schmidt and Miller 1988). An increased risk of HIV-associated dementia and cognitive slowing was found in one group of patients with secondary HIV mania, with cognitive decline prior to onset of mania (Lyketsos et al. 1997). In addition, the secondary mania associated with HIV was found to be associated with low CD4 cell count (Ellen et al. 1999; Lyketsos et al. 1993b), often lower than 100 cells/mm<sup>3</sup>. The incidence of secondary mania, like that of HIV-associated dementia, appears to have declined since the widespread use of HAART (Ferrando and Wapenyi 2002).

AIDS mania seems to have a clinical profile somewhat different from that of primary mania (Ellen et al. 1999; Lyketsos et al. 1993b, 1997). Irritable mood is often a prominent feature, but elevated mood can be observed. Sometimes prominent psychomotor slowing accompanying the cognitive slowing of AIDS dementia will replace the expected hyperactivity of mania, which complicates the differential diagnosis. AIDS mania is usually quite severe in its presentation and malignant in its course. In one series, late-onset patients (presumed to have AIDS mania) had a greater total number of manic symptoms than did early-onset patients. Late-onset patients also were more commonly irritable and less commonly hyperverbal. AIDS mania seems to be more chronic than episodic, with infrequent spontaneous remissions, and usually relapses with cessation of treatment. Because of their cognitive deficits, patients have little functional reserve to begin with and are less able to pursue treatment independently or consistently.

One presentation of mania, either early or late, is the delusional belief that one has discovered a cure for HIV or has been cured. Although this belief may serve to cheer otherwise demoralized patients, it also may result in the resumption of high-risk behavior and lead to the spread of

HIV and exposure to other infections. When euphoria is a prominent symptom in otherwise debilitated late-stage patients, caregivers may question whether to deprive patients of the illusion of happiness. It is the often-devastating effects of the other symptoms of mania that tip the balance toward treatment.

Neuroradiological correlates of secondary HIV mania have been attempted, but the results have been conflicting. Some studies indicate that findings on neuroimaging are not of any clinical significance (Ellen et al. 1999). Abnormal MRI scans have been reported, however (Kiebertz et al. 1991b).

### **Treatment**

Treatment of secondary HIV or AIDS mania has not been systematically studied to date, and the optimal treatment remains unclear. Reports often have indicated a particular resistance of manic symptoms to treatment. Others have noted few differences in response in the treatment of secondary HIV mania compared with bipolar disorder (Ellen et al. 1999). The treatment of mania in early-stage HIV infection is not substantially different from the standard treatment of bipolar disorder with mood stabilizers and antipsychotics. As HIV infection advances, with lower CD4 cell counts, more medical complications, more CNS involvement, and greater overall physiological vulnerability, changes in treatment may be required. Treatment with traditional antimanic agents can be very difficult in patients with advanced disease. AIDS mania patients may respond to monotherapy with antipsychotic agents, as was shown in case reports (Ellen et al. 1999). Late-stage patients are sensitive to side effects of antipsychotics, especially EPS, as noted earlier in this chapter (see "Treatment" subsection of "Delirium" section). As such, the dose of antipsychotic required may be much lower than that customarily used for mania. The more advanced these patients' HIV and/or dementia, the more sensitive they are to small dosage changes. These patients are also very sensitive to anticholinergic side effects, including delirium.

There has been considerable experience with traditional mood-stabilizing agents in selected AIDS mania patients, but with relatively little published literature. One case report of lithium use in secondary HIV mania showed control of symptoms at a dose of 1,200 mg/day (Tanquary 1993). Lithium use has been problematic for several reasons, including side effects of cognitive slowing, nausea, diarrhea, and polyuria resulting in dehydration, all of which may already plague HIV-infected patients. The major problem with lithium in AIDS patients has been rapid fluctuations in blood level, especially in the hospital despite previously stable doses. Anecdotal reports describe problems with administering lithium and

valproic acid because of subsequent delirium (Angelino and Treisman 2001).

Valproic acid has been used with success, titrated to the usual therapeutic serum levels of 50–100 µg/L. Enteric-coated valproic acid is better tolerated in many patients. A study of valproic acid in the treatment of HIV-associated mania reported that it was well tolerated and led to significant improvement in manic symptoms, with doses up to 1,750 mg/day and serum levels greater than 50 µg/L (Halman et al. 1993). Another report documented reduction in symptoms with levels of 93 and 110 µg/L (RachBeisel and Weintraub 1997). Concern has been raised over hepatotoxicity in patients with HIV taking valproic acid (Cozza et al. 2000). In cases of severe hepatic insufficiency (e.g., *Mycobacterium avium* complex [MAC] infiltration with portal hypertension), valproic acid probably should be avoided, but this has not been studied. Valproic acid also can affect hematopoietic function, so white blood cell and platelet counts must be monitored. In addition, sodium valproate has been reported to increase HIV replication in vitro (Jennings and Romanelli 1999; Moog et al. 1996; Simon et al. 1994; Witvrouw et al. 1997), as well as increase CMV replication (Jennings and Romanelli 1999). However, retrospective case series reports of divalproex sodium in patients with secondary HIV mania found no increase in HIV-1 viral load in the presence of antiretroviral medications (J.D. Maggi and Halman 2001). Prospective studies of in vivo increases in HIV viral load have not been reported (Ferrando and Wapenyi 2002), but trials are under way.

Carbamazepine also may be effective, but concerns exist regarding the potential for synergistic bone marrow suppression in combination with antiviral medications and HIV itself. It also may lower serum levels of protease inhibitors (Ferrando and Wapenyi 2002). No reports are available for newer anticonvulsants such as gabapentin and lamotrigine in HIV mania. Potential drug interactions between anticonvulsant mood stabilizers and HAART are shown in Chapter 37, “Psychopharmacology.”

The treatment of psychosis in HIV-related mania with risperidone has shown significant improvement (A. Singh et al. 1997). No evidence of notable drug interactions, drug-induced leukopenia, or extrapyramidal signs was found. Olanzapine has been anecdotally reported to be effective in HIV-associated mania (Ferrando and Wapenyi 2002). Remoxipride was found to be effective in HIV-related mania but was subsequently withdrawn because of reports of aplastic anemia (Scurlock et al. 1995). Atypical antipsychotics have the advantage of lower risk of tardive dyskinesia, but this is not an important issue for patients with end-stage AIDS. Reduction of the risk of EPS is a noteworthy consideration in selecting an antipsychotic, in ad-

dition to other factors including affordability. The common side effect of significant weight gain with some atypical antipsychotics is less problematic for patients with HIV who are cachectic.

One case report showed rapid clinical improvement of HIV-associated manic symptoms with clonazepam, allowing reduction of antipsychotic dosage (Budman and Vandersall 1990). No unacceptable side effects were reported, but treatment with benzodiazepines is less useful in maintenance treatment because of tolerance, abuse liability, and cognitive impairment.

## Schizophrenia

The literature on patients with severe and chronic mental illnesses, primarily schizophrenia and bipolar disorder, reports HIV prevalence rates of between 2% and 20% in both inpatient and outpatient samples (Ayuso-Mateos et al. 1997; Blank et al. 2002; Empfield et al. 1993; Meyer et al. 1993; Naber et al. 1994; Silberstein et al. 1994; Volavka et al. 1991; Walkup et al. 1999). Investigators have noted that clinicians working with patients with schizophrenia were often unaware of their increased risk for acquiring HIV and made little effort to screen for seropositivity (Cournos et al. 1991). Perhaps this is because schizophrenic patients have been traditionally seen as markedly hyposexual because of the illness itself (Akhtar and Thomson 1980; Gray et al. 2002) and antipsychotic drugs (Gray 1999). However, many schizophrenic patients are sexually active (Cournos et al. 1994), often with higher risk partners (Kalichman et al. 1994); seldom use condoms (Cournos et al. 1994); and do not otherwise practice safe sex. Substance abuse is very common in schizophrenic patients, including during sexual activity (Cournos et al. 1994). Patients with schizophrenia have significantly less knowledge about HIV infection and transmission than do persons without schizophrenia (Kalichman et al. 1994; Kelly et al. 1992). Even increased knowledge about HIV in schizophrenic patients may not lead to decreased risk behaviors (McKinnon et al. 1996). Cumulatively, these factors help explain the increased risk of HIV infection in schizophrenic patients (Cournos et al. 1991). Suicidality is increased in patients with both schizophrenia and HIV infection. For all these reasons, clinicians should evaluate schizophrenic patients for risk behaviors and for their knowledge about HIV. A validated screening tool—the Risk Behaviors Questionnaire—is available (Volavka et al. 1992).

### Treatment

Treatment of schizophrenia in HIV-infected patients follows the same basic principles as for other patients with

schizophrenia—namely, control of symptoms with medications and psychosocial support and rehabilitation. Close collaboration with HIV providers is strongly suggested, so that HIV treatment can be coordinated and monitored. Schizophrenic patients are very likely to have difficulties accessing care, affording medication, and adhering to complex HAART regimens. Educational interventions have promoted safer sexual practices (Baer et al. 1988; Jacobs and Bobek 1991) and may decrease risk behaviors (Carmen and Brady 1990; Kalichman et al. 1995).

Haloperidol was found to be effective in treating psychotic symptoms of schizophrenia in patients with HIV (Mauri et al. 1997; Sewell et al. 1994a, 1994b). Patients with HIV may be highly sensitive to the EPS of antipsychotic medications, as already noted. Treatment with thioridazine was reported to be efficacious without EPS (Sewell et al. 1994b). Molindone was reported to be of benefit for psychosis and agitation with few EPS in patients with HIV (Fernandez and Levy 1993). Clozapine also has shown efficacy in treating HIV-associated psychosis in patients with drug-induced parkinsonism (Lera and Zirulnik 1999). Risperidone also has been reported to be effective (A. Singh et al. 1997). Drug interactions between antipsychotics and HAART are discussed in Chapter 37, “Psychopharmacology.”

## Substance Abuse and Addiction

Substance abuse is a primary vector for the spread of HIV for those who use intravenous drugs and their sexual partners and those who are disinhibited by intoxication or driven by addiction to unsafe sexual practices. Patients with substance use disorders may not seek health care or may be excluded from or discriminated against in health care. In addition, intoxication and the behaviors necessary to obtain drugs interfere with access to, and effectiveness of, health care.

*Triple diagnosis* refers to a patient with a dual diagnosis (substance abuse and psychiatric disorder) who also has HIV, and such patients are overrepresented in HIV treatment. One study found that as many as 44% of the new entrants to the HIV medical clinic at the Johns Hopkins Hospital had an active substance use disorder. Of these patients, 24% had both a current substance use disorder and another nonsubstance-related Axis I diagnosis (Lyketos et al. 1994).

In the United States at the end of 2001, the proportion of injection drug users with AIDS was 24% (Centers for Disease Control and Prevention 2001). Even among non-injection drug users, substance abuse plays a major, albeit more subtle, role in HIV transmission. Addiction and high-risk sexual behavior have been linked across a

wide range of settings. For example, crack cocaine abusers are more likely to engage in prostitution to obtain money for drugs (Astemborski et al. 1994; Edlin et al. 1994). Men who use crack cocaine are more likely to engage in unprotected anal sex with casual male contacts (de Souza et al. 2002). Alcohol intoxication also can lead to risky sexual behaviors by way of cognitive impairment and disinhibition (Rees et al. 2001; Stein et al. 2000).

Neuropsychological testing of drug abusers with and without HIV indicates that substance use can contribute to the cognitive decline of HIV-associated dementia (Pakesch et al. 1992). Substance use may augment HIV replication in the CNS and increase HIV encephalopathy in early AIDS (Kibayashi et al. 1996). For example, cocaine abuse augments HIV replication in vitro (Peterson et al. 1991) and also increases permeability of the blood-brain barrier to HIV (Nottet et al. 1996; Zhang et al. 1998).

Substance abuse can be successfully treated in those at risk for HIV. One of the most extensively studied interventions in risk reduction is methadone maintenance, which resulted in sustained reductions in HIV risk and lower incidence of HIV infection (Metzger et al. 1991, 1998).

### *Substance Use Disorders and Interaction With HIV Treatment*

The medical sequelae of chronic substance abuse accelerate the process of immunocompromise and amplify the burdens of HIV infection. Injection drug users are at higher risk for developing bacterial infections such as pneumonia, sepsis, and endocarditis. Tuberculosis, sexually transmitted diseases (STDs), viral hepatitis, coinfection with human CD4 cell lymphotropic virus, and lymphomas also occur more commonly in injection drug users with HIV than in other patients with HIV. HIV-infected injection drug users are at higher risk for fungal or bacterial infections of the CNS. Alcohol abuse is immunosuppressive and increases risk for bacterial infections, tuberculosis, and dementia. Heroin may worsen HIV-associated nephropathy.

Important drug interactions occur between abused substances and antiretroviral and antibiotic drugs. Rifampin increases the elimination of methadone and may result in withdrawal symptoms. Decreased plasma levels of methadone also occur with concurrent administration of ritonavir, nelfinavir, efavirenz, and nevirapine (Gourevitch and Friedland 2000). Patients in a methadone program will be unlikely to take medications that have caused withdrawal.

## Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) and its symptoms occur at greatly increased rates in HIV-infected patients

(A. Martinez et al. 2002). Of the HIV-infected women attending county medical clinics, 42% met diagnostic criteria for PTSD (Cottler et al. 2001). Minority women (Basuk et al. 1998) and women prisoners (Hutton et al. 2001) are particularly at risk for both PTSD and HIV. Male veterans with a diagnosis of PTSD are at increased risk for HIV infection, especially if they are substance abusers (Hoff et al. 1997). PTSD symptoms are associated with high-risk behaviors, including prostitution, choosing other high-risk sexual partners, injection drug use, and unsafe sexual practices (Stiffman et al. 1992). Among the HIV-infected female partners of male drug users, those who had a history of rape or being assaulted were more likely to engage in high-risk HIV behaviors (He et al. 1998). These studies are cross-sectional and cannot determine causality. PTSD from early life trauma may predispose an individual to engage in high-risk sexual or drug behavior. On the other hand, risk behaviors such as prostitution and drug abuse increase exposure to trauma and thus the likelihood of developing PTSD. Finally, HIV infection itself may be the cause of PTSD. Rates of PTSD in response to HIV infection are higher than those in response to other debilitating illnesses (Fauerbach et al. 1997; Perez-Jimenez et al. 1994; van Driel and Op den Velde 1995), including cancer (Alter et al. 1996; Cordova et al. 1995). In one study, about 30% of persons recently diagnosed with HIV subsequently developed PTSD, with half of the cases appearing within 1 month of HIV diagnosis (Kelly et al. 1998). Prior PTSD increased the risk for PTSD in response to HIV diagnosis. Even asymptomatic HIV-infected individuals have high levels of PTSD symptoms (Botha 1996).

PTSD in at-risk or HIV-infected individuals is significant for several reasons. PTSD has high rates of psychiatric comorbidity (up to 80%), most often depression (Kelly et al. 1998) and cocaine and opioid abuse (Kessler et al. 1995), which are also risks for HIV (Lyketsos and Federman 1995). HIV-infected persons with PTSD have higher levels of pain (Smith et al. 2002). PTSD symptoms in HIV-positive patients in one study predicted lower CD4 cell counts (Lutgendorf et al. 1997b) and in another study, lower CD4 to CD8 T-cell ratios (Kimerling et al. 1999). This may represent faster HIV disease progression, generally associated with stressful life events (Evans et al. 1997; Leserman et al. 2000; Moss et al. 1988).

Persons at risk for HIV and HIV-infected individuals should be routinely screened for PTSD and psychiatric comorbidities, with treatment targeted accordingly. Failure to do so in this very high-risk population has serious consequences, both for this population's welfare and for public health.

## Issues of Personality in Patients Infected With HIV

---

A disturbing trend in the HIV epidemic has been the persistence of modifiable risk factors among persons who are HIV infected. Such individuals, who report high rates of sexual and/or drug risk behaviors, include HIV-infected drug users (Avants et al. 2000; Novotna et al. 1999), patients presenting at HIV primary care clinics for medical treatment (Erbelding et al. 2000), and HIV-infected men who have sex with other men (Kohl et al. 1999). The fact that knowledge of HIV and its transmission is insufficient to deter these individuals from engaging in HIV risk behaviors suggests that certain personality characteristics may enhance a person's tendency to engage in such behaviors.

Traditional approaches in risk reduction counseling emphasize the avoidance of negative consequences in the future, such as condom use during sexual intercourse to prevent STDs. Such educational approaches have proved ineffective for individuals with certain personality characteristics (Kalichman et al. 1996; Trobst et al. 2000). Effective prevention and treatment programs for HIV-infected individuals must consider specific personality factors. In this section, we outline the role of personality characteristics and personality disorders in the risk of acquiring HIV and highlight specific interventions to reduce the risk of HIV that are formulated for individuals whose personality characteristics place them at increased risk.

### Implications for HIV Risk Behavior

Our clinical experience suggests that unstable extroverts are the most prone to engage in practices that place them at risk for HIV. We estimate that in the psychiatry service of the Johns Hopkins AIDS clinic (a referral-biased sample), about 60% of our patients present with this blend of extroversion and emotional instability. These individuals are preoccupied by, and act on, their feelings, which are labile, leading to unpredictable and inconsistent behavior. Most striking is the inconsistency between thought and action. Regardless of intellectual ability or knowledge of HIV, unstable extroverts can engage in extremely risky behavior. Past experience and future consequences have little importance in decision making for the individual who is ruled by feeling; the present is paramount. Their primary goal is to achieve immediate pleasure or removal of pain, regardless of circumstances. As part of their emotional instability, they experience intense fluctuations in mood. It is difficult for them to tolerate painful affects; they want to escape or avoid feelings as quickly as pos-

sible. They are motivated to pursue pleasurable experiences, however risky, to eliminate negative moods.

Unstable extroverts are more likely to engage in behavior that places them at risk for HIV infection and are more likely to pursue sex promiscuously. They are less likely to plan and carry condoms and more likely to have unprotected vaginal or anal sex. They are more fixed on the reward of sex and remarkably inattentive to the STD they may acquire if they do not use a condom. Unstable extroverts are also less likely to accept the diminution of pleasure associated with the use of condoms or, once aroused, to interrupt the “heat of the moment” to use condoms. Similarly, unstable extroverts are more vulnerable to alcohol and drug abuse. They are drawn to alcohol and drugs as a quick route to pleasure. They are more likely to experiment with different kinds of drugs and to use greater quantities. Unstable extroverts are also more likely to become injection drug users.

The second most common personality type that we have observed, which may represent about 25% of our patients, is that of the stable extrovert. Stable extroverts are also present oriented and pleasure seeking; however, their emotions are not as intense, as easily provoked, or as mercurial. Hence, they are not as strongly driven to achieve pleasure. Stable extroverts may be at risk because they are too optimistic or sanguine to believe that they will become infected with HIV.

Introverted personalities appear to be less common among our psychiatric patients. Their focus on the future, avoidance of negative consequences, and preference for cognition over feeling render them more likely to engage in protective and preventive behaviors. HIV risk for introverts is determined by the dimension of emotional instability–stability. About 14% of our patients present with a blend of introversion and instability. Unstable introverts are anxious, moody, and pessimistic. Typically, these patients seek drugs and/or sex not for pleasure, but for relief or distraction from pain. They are concerned about the future and adverse outcomes but believe that they have little control over their fates. Stable introverts constitute the remaining 1% of patients. These patients, with their controlled, even-tempered personalities, are least likely to engage in risky or hedonistic behaviors. Typically, these individuals are HIV positive as a result of a blood transfusion or an occupational needle stick. These percentages of personality styles are illustrative of one center’s experience and may not be generalizable.

### Personality Disorder in HIV

Prevalence rates of personality disorders among HIV-infected patients (19%–36%) and individuals at risk for

HIV (15%–20%) (Jacobsberg et al. 1995; J. G. Johnson et al. 1995; Perkins et al. 1993) are high and significantly exceed rates found in the general population (10%) (J. G. Johnson et al. 1995). The most common personality disorders among HIV-infected patients are antisocial and borderline types (Golding and Perkins 1996). Antisocial personality disorder is the most common (Perkins et al. 1993) and is a risk factor for HIV infection (Weissman 1993). Individuals with personality disorder, particularly antisocial personality disorder, have high rates of substance abuse and are more likely to inject drugs and share needles compared with those without an Axis II diagnosis (Brooner et al. 1993; Dinwiddie et al. 1996; Golding and Perkins 1996). Approximately half of drug abusers may meet criteria for a diagnosis of antisocial personality disorder. Individuals with antisocial personality disorder are also more likely to have higher numbers of lifetime sexual partners, engage in unprotected anal sex, and contract STDs compared with individuals without antisocial personality disorder (Brooner et al. 1993; Hudgins et al. 1995; Kleinman et al. 1994).

In our AIDS clinic, patients are characterized along the dimensions of extraversion–introversion and emotional stability–instability rather than in the discrete categories provided by DSM’s Axis II for several reasons. First, it is easier for staff to determine where a patient falls along two dimensions than to evaluate the many criteria for personality disorders. Second, it is simpler to design intervention strategies for two dimensions. Third, a diagnosis of antisocial or borderline personality disorder can be stigmatizing, particularly in a general medical clinic. Finally, a classification system based on a continuum approach may be a better predictor of HIV risk behavior than are DSM-IV-TR (American Psychiatric Association 2000a) Axis II categories (Tourian et al. 1997).

### Implications for Medication Adherence

Identifying factors that influence adherence in HIV disease is important in improving overall health outcomes (Eldred et al. 1998). Adherence is especially challenging in HIV, which carries all of the components of low adherence—long duration of treatment, preventive rather than curative treatment, asymptomatic periods, and frequent and complex medication dosing (Blackwell 1996; Haynes 1979; Kruse et al. 1991). In patients with HIV, estimates of zidovudine adherence vary widely from 26% to 94% (Wagner et al. 1996).

Our clinical experience suggests that nonadherence is more common among our extraverted or unstable patients. The same personality characteristics that place them at risk for HIV also reduce their ability to adhere to

demanding drug regimens. Specifically, their present-time orientation, combined with reward-seeking behavior, makes it more difficult to tolerate side effects from drugs whose benefits may not be immediately apparent. It is also difficult for feeling-driven individuals to maintain consistent, well-ordered routines, so following frequent, rigid dosing schedules is problematic. Our unstable, extroverted patients usually intend to follow the schedule, but their chaotic and mercurial emotions interfere and disrupt daily routines. For example, a patient may report that he felt very upset and nihilistic after a fight with a family member and missed several doses of his antiretroviral medicines. Missing doses of HAART can increase the chance of HIV resistance developing.

### Treatment Implications

We have found that a cognitive-behavioral approach is most effective in treating patients who present with extroverted and/or emotionally unstable personalities. Five principles guide our care:

1. *Focus on thoughts, not feelings.* Individuals with unstable, extroverted personalities often do not recognize the extent to which their actions are driven by feelings of the moment.
2. *Use a behavioral contract for all patients to build consistency.* The contract outlines goals for treatment and responsibilities and expectations of both the patient and the providers.
3. *Emphasize constructive rewards.* Positive outcomes, not adverse consequences, are salient to extroverts. Most of the patients have already experienced negative consequences from their behavior. Exhortations to use condoms to avoid STDs are unpersuasive. More success has been achieved with extroverts by eroticizing the use of condoms (Tanner and Pollack 1988) or by incorporating novel techniques into sexual repertoires (Abramson and Pinkerton 1995). Similarly, the rewards of abstaining from drugs or alcohol are emphasized, such as having money to buy clothing, having a stable home, or maintaining positive relationships with children. In building adherence to antiretroviral therapies, the focus is on the rewards of an increased CD4 cell count and reduced viral load rather than on avoidance of illness. Use of the viral load as a strategy to build adherence can increase acceptance in all patients but is especially effective in reward-driven extroverts.
4. *Use relapse prevention techniques.* The relapse prevention model, originally developed for treatment of substance abuse behavior, is an effective method for changing habitual ways of behaving.
5. *Develop a coordinated treatment plan.* The mental health professional coordinates with the medical care provider, supplying information about a patient's personality and how it influences behavior. Both professionals work in tandem to develop behavioral contracts to reduce HIV risk behaviors and build medication adherence.

## Psychosocial Interventions to Prevent HIV Transmission

---

In intervention studies of men who have sex with other men (still the largest subgroup in terms of new HIV infections in the United States), many psychosocial interventions have shown a decrease in either risk behaviors or infection (Dilley et al. 2002; W.D. Johnson et al. 2002). A meta-analysis examining the effect of HIV prevention strategies found that psychosocial interventions can lead to sexual risk reduction among drug users (Semaan et al. 2002), as did a separate large study of cocaine-dependent patients (Woody et al. 2003). Studied interventions have included stress management and relaxation techniques, group counseling, education, cognitive training, negotiation skills training, psychotherapy directed at emotional distress reduction, relapse prevention models of high-risk behavior reduction, education directed at eroticizing safer sex, assertiveness training, and peer education in bars. All of these interventions showed a modest effect on either risk behavior or HIV infection. Although most studies focused on men who have sex with other men, the results have been similar in heterosexually transmitted HIV, women, and injection drug users. It is unclear from the data what the best intervention is and how to stratify the interventions.

### Adherence Counseling

The single most important factor regarding outcome of HIV treatment is the patient's ability to adhere to a prescribed regimen. A recent study of HIV-infected prisoners reported that under directly observed therapy in a prison setting, 85% of the individuals developed undetectable viral loads with prisoners taking approximately 93% of doses (Kirkland et al. 2002). In contrast, British community studies found that only 42% of treatment-naive patients taking antiretroviral medications attained undetectable viral loads (Lee and Monteiro 2003). Antiretroviral adherence rates between 54% and 76% have been reported in other general clinic or community samples (Liu et al. 2001; McNabb et al. 2001; Paterson et al. 2000; Wagner and Ghosh-Dastidar 2002), including a

group of patients with serious mental illness (Wagner et al. 2003).

The literature on adherence indicates that four groups of factors affect adherence: environmental factors, treatment factors, illness factors, and patient factors. Environmental factors include medication cost, work schedules, transportation, housing issues, and lack of supportive relationships. Missed appointments are a strong predictor of treatment failure, suggesting that any factor that interferes with patients coming for treatment will interfere with adherence (Lucas et al. 1999). Patient survey data indicate that the patient-provider relationship has a strong effect on adherence (Altice et al. 2001; Stone et al. 1998). These factors should be assessed when discussing a patient's readiness to start treatment, and identified barriers must be targeted.

Treatment factors include the type of medication and amount of pill burden. Once-a-day medications are easier to remember to take regularly than twice-a-day medications, but both are markedly better for adherence than three- or four-times-a-day medications (Kleeberger et al. 2001). However, some studies have not found any effect of pill burden on adherence (Gifford et al. 2000). Perceived side effects also correlate with poor adherence and can prevent patients from taking all required doses in an attempt to prevent adverse consequences. Patients are less likely to adhere to regimens if they believe that they are ineffective. These barriers should be assessed before treatment and at every follow-up visit, and treatment must be tailored accordingly.

Illness chronicity, symptoms, and curability also affect adherence. Lifelong illnesses have the highest degree of nonadherence, as do illnesses that are asymptomatic, because the patient is unable to feel any benefit or effect from taking a medication. Similarly, illnesses that cause symptoms that are unrelieved by treatment are often associated with poor adherence. Diseases with no potential cure may make patients nihilistic about treatment and unable to perceive the potential benefits. Providers who practice therapeutic optimism and are willing to explore patients' feelings about these issues, remain supportive, and emphasize positive aspects of treatment will find improved adherence in their patients.

Patient factors associated with nonadherence, including dementia, depression, psychosis, personality factors, and substance use, are detailed elsewhere in this chapter. Many studies have shown decreased adherence to HAART attributable to depression (Catz et al. 2000; Chesney et al. 2000; N. Singh et al. 1996). Depressed patients feel hopeless and may see no purpose in taking further medications. Psychotic patients may refuse medications, deny their illness, or be too disorganized to manage adherence.

Patients with dementia may forget doses and appointments. Personality vulnerabilities also have strong effects on adherence. Constant and consistent coaching of patients at each visit is imperative, including clarifying goals of treatment (both short-term and long-term) and anticipating misunderstandings. It is also useful over time to show rewards of adherence to treatment, no matter how small.

More subtle factors affecting adherence include psychosocial support networks, individual coping skills, life structure, access to resources, and behavioral control. Interventions such as cognitive-behavioral psychotherapy, structured psychoeducational psychotherapy, supportive psychotherapy, and group interventions all have been used to improve patient adherence to medication regimens. The current literature on HIV medication adherence focuses on technical interventions, such as pillbox and timer reminders, less complex pharmacological interventions, decreased pill burdens, and increased access to care. A growing literature examines psychosocial interventions, relationship with care providers, case management, and psychiatric disorders as barriers to adherence. In this arena, mental health care can have an enormous effect on outcome.

## **Mental Health Care for Patients With HIV Infection**

---

Patients with HIV infection are underserved with regard to mental health. This is critical because psychiatric disorders increase the risk for HIV and have a negative effect on HIV treatment. Although model clinics exist, in which treatment for HIV, substance abuse, and psychiatric illness is integrated, these clinics are exceptional. Psychiatric disorders are underrecognized and undertreated in patients with many chronic medical conditions, but HIV-infected patients are especially likely to be impoverished, disenfranchised, vulnerable, and members of underserved minorities, all of which further decrease the likelihood that they will receive adequate treatment. Integrated expert care by psychiatrists and other mental health professionals should be a high priority both to promote effective treatment of HIV infection and to stem the tide of an epidemic that spreads through modifiable behaviors.

## **Conclusion**

---

The interrelationships between HIV/AIDS and psychiatry are myriad and complex. In a sense, psychiatric disorder

ders can be seen as vectors of HIV transmission, through associated high-risk behaviors. They also complicate the treatment of HIV infection. HIV causes a number of psychiatric conditions and exacerbates many others. Comorbid psychopathology—including major depression, schizophrenia, addictions, personality vulnerabilities such as unstable extraversion, and the effects of traumatic life experiences—is highly prevalent in patients with HIV/AIDS. Each of these problems has the potential to sabotage treatment for HIV infection and its many complications. Yet there is a profound shortage of funding and availability of psychiatric care in HIV clinics. Our experience in caring for HIV patients is that by developing a comprehensive diagnostic formulation on which to base treatment, even many of the most difficult patients can be successfully treated.

With the advent of HAART, we have seen terminal patients who have undergone nearly miraculous recoveries only to find themselves unprepared to meet the challenges of facing life again—of pressing on in the face of the daily burdens of ongoing treatment, side effects, stigma, and continuing injury. To assist them with this monumental task is a great challenge, but we have the lessons from the field of psychiatry that have helped patients shoulder similar burdens from chronic mental illness. At the heart of our work we try to impart hope for the future, therapeutic optimism, advocacy, sanctuary, and rehabilitation.

# 29 Dermatology

---

Lesley M. Arnold, M.D.

**PSYCHOCUTANEOUS DISORDERS** include dermatological diseases that are affected by psychological factors and psychiatric illnesses in which the skin is the target of disordered thinking, behavior, or perception. Emerging evidence of the role of the nervous system in skin pathophysiology provides clues into possible links between stress and dermatological diseases. In this chapter, I review the pathophysiology of these dermatological diseases, emphasizing the involvement of the central nervous system (CNS), and examine recent developments in the management of psychocutaneous disorders.

## Classification

---

Table 29–1 shows the classification of psychocutaneous disorders in DSM-IV-TR (American Psychiatric Association 2000) categories. Psychological factors affecting medical condition includes dermatological diseases that are commonly affected by psychiatric factors. Somatoform disorders include disorders of the skin that are not fully explained by a known dermatological disease. Delusional disorder, somatic type, is the most common diagnosis in patients with delusional parasitosis, but the differential diagnosis of delusions of parasitosis includes major depressive disorder, bipolar disorder, schizophrenia, psychotic disorder due to a general medical condition, and substance-induced psychotic disorder. A preoccupation with a defect in appearance (body dysmorphic disorder) has a delusional variant, classified as a delusional disorder, somatic type. Trichotillomania is classified under the impulse-control disorders. Psychogenic excoriation and onychophagia are not currently included in DSM-IV-TR but could probably be classified under the category of impulse-control disorder not otherwise specified. Trichotillomania, psychogenic excoriation, and onychophagia frequently have symptoms that overlap with

obsessive-compulsive disorder. Factitious disorders include factitious dermatitis (also called dermatitis artefacta) and psychogenic purpura.

## Psychological Factors Affecting Medical Condition

---

### Atopic Dermatitis

Atopic dermatitis, a chronic skin disorder characterized by pruritus and inflammation (eczema), often begins as an erythematous, pruritic, maculopapular eruption (Ehlers et al. 1995; Gil et al. 1987; Lammintausta et al. 1991). Lichenification, excoriations, and infections frequently occur in response to excessive scratching (Gil et al. 1987). Atopic dermatitis typically begins in early infancy, childhood, or adolescence and is frequently associated with a personal or family history of atopic dermatitis, allergic rhinitis, or asthma (Ginsburg et al. 1993). Atopic dermatitis is a common disorder, with a female-to-male ratio of 1.2:1.0 (M.L. Johnson 1977; Rajka 1989). The prevalence of atopic dermatitis has increased to greater than 10% in the past decade, possibly as a result of greater exposure to provocative factors such as outdoor pollution, reagents in highly insulated buildings, house mites, food additives, and increased parental and physician awareness of atopic dermatitis (Leung et al. 1999; Rothe and Grant-Kels 1996; Williams 1992, 1995).

Mild cases of atopic dermatitis may spontaneously resolve, but most patients experience persistent or relapsing symptoms. In one study of 47 patients diagnosed with atopic dermatitis by age 2 years and followed up for 20 years, 72% continued to have signs of atopic dermatitis (Kissling and Wuthrich 1994). In another study, symptoms persisted or recurred in 77%–91% of the adult patients who had moderate or severe symptoms as teenagers

**TABLE 29–1. Classification of psychocutaneous disorders by DSM-IV-TR categories**

I. Psychological factors affecting medical condition
Atopic dermatitis
Psoriasis
Alopecia areata
Urticaria and angioedema
Acne vulgaris
II. Somatoform disorders
Chronic idiopathic pruritus
Idiopathic pruritus ani, vulvae, and scroti
Body dysmorphic disorder
III. Delusional disorder, somatic type
Delusional parasitosis
Delusions of a defect in appearance
Delusions of a foul body odor
IV. Impulse-control disorders
Psychogenic excoriation
Trichotillomania
Onychophagia
V. Factitious disorders
Factitious dermatitis (dermatitis artefacta)
Psychogenic purpura

(Lammintausta et al. 1991). In general, comorbid asthma or allergic rhinitis, early age at onset, severe dermatitis, female sex, and a family history of Alzheimer's disease positively correlate with disease chronicity (Leung et al. 1999).

Although genetic factors are probably involved in the pathophysiology of atopic dermatitis (Schultz Larson 1993; Uehara and Kimura 1993), environmental factors frequently trigger or exacerbate the disease (Ehlers et al. 1995). Environmental triggers include food allergy or intolerance, contact irritants and allergens, aeroallergens (house dust mite, pollen, molds, human and animal dander), microbial organisms, hormones, climate, sweating, and stress (Morren et al. 1994). Affected patients seem to have a lower response threshold and more prolonged reaction than control subjects to pruritic stimuli (Morren et al. 1994). A vicious cycle of itching, scratching, and lesion aggravation frequently develops and contributes to symptom chronicity (Gil et al. 1987; Gupta and Gupta 1996; Morren et al. 1994).

Stressful life events often precede the onset or exacerbation of atopic dermatitis (Kodama et al. 1999; Morren et al. 1994; Picardi and Abeni 2001). Stress may have an effect on atopic dermatitis through an interaction between the CNS and the immune system. The CNS appears to regulate immune function through the neuroendocrine system and through direct efferent autonomic

nervous system connections. Stress-related fluctuations in the neuroendocrine system or autonomic nervous system might contribute to the development of altered immunological reactivity and subsequent increased vulnerability to allergic inflammation (Buske-Kirshbaum et al. 2001).

Controlled studies have found that adult patients with atopic dermatitis are more anxious and depressed compared with clinical and disease-free control groups (Ehlers et al. 1995; Hashiro and Okumura 1997). Anxiety or depression might exacerbate atopic dermatitis by eliciting the scratching behavior. In another study of pruritus associated with atopic dermatitis and other dermatological conditions, depressive symptoms appeared to amplify the itch perception (Gupta et al. 1994). Furthermore, emotional distress aggravates pruritus in many patients with Alzheimer's disease (Heyer et al. 1995). Distress appears to perturb the epidermal permeability barrier homeostasis, resulting in inflammation and pruritus. The stress-induced deterioration of the barrier function may be mediated by glucocorticoids or by neuropeptides released within the epidermis (Garg et al. 2001).

In a study of children with atopic dermatitis, about a third of the children with severe atopic dermatitis symptoms had significantly higher morbidity levels on behavioral screening questionnaires. The emotional state in children with atopic dermatitis was closely related to the severity of the illness (Daud et al. 1993). In another study, children with moderate to severe atopic dermatitis were significantly more likely to be distressed than a control group with minor skin problems (Absolon et al. 1997). Certain dimensions of family environment, such as independence and organization, correlated with less severe symptoms of atopic dermatitis, whereas parental responses of attention or physical contact reinforced scratching (Gil and Sampson 1989).

Because increased distress, anxiety, and depression occur in many patients with atopic dermatitis, a psychiatric evaluation should be included in the overall management of patients with atopic dermatitis, especially in those with moderate to severe symptoms. Psychiatric treatment also might help to improve health-related quality of life, which is adversely affected by atopic dermatitis, particularly in social functioning and psychological well-being (Kiebert et al. 2002).

Treatment of atopic dermatitis strives to interrupt the vicious cycle of itching and scratching. Psychiatric treatment modalities include psychological or behavioral therapies and psychotropic medications. In controlled studies, relaxation training, habit reversal training, cognitive-behavioral techniques, and stress management training resulted in significant and stable adjunctive treatment re-

sponses to standard medical care and reduction in anxiety and depression (Ehlers et al. 1995). Topical 5% doxepin cream, which has potent histamine antagonism, was effective in reducing pruritus in patients with atopic dermatitis in controlled trials (Drake et al. 1994, 1995). Another antidepressant with histamine receptor antagonism, trimipramine (50 mg/day), decreased the fragmentation of sleep and reduced the time spent in stage I sleep, which reduced the amount of scratching during the night in atopic dermatitis patients (Savin et al. 1979).

## Psoriasis

Psoriasis is a chronic, relapsing disease of the skin with characteristic lesions that involve both the vasculature and the epidermis and have clear-cut borders and noncoherent silvery scales over a glossy, homogeneous erythema. The lesions vary from pinpoint plaques to extensive (erythrodermic) skin involvement, nail dystrophy, and arthritis (Christophers and Mrowietz 1999). Psoriasis affects about 2% of the United States general population and is equally common in women and men. Most develop initial lesions in the third decade of life (Christophers and Mrowietz 1999). Early onset (before age 15 years), commonly associated with a family history of psoriasis, predicts greater disease severity, with a higher percentage of body surface involvement and a worse treatment response (Christophers and Mrowietz 1999). Although spontaneous remissions have been reported and have lasted between 1 and 54 years (Farber and Nall 1974), most patients with psoriasis experience unpredictable exacerbations throughout life.

The pathogenesis of psoriasis appears to involve skin repair systems, inflammatory defense mechanisms, and immunity. Both genetic (Christophers and Mrowietz 1999) and environmental factors probably contribute to the liability to psoriasis. Common triggers of psoriasis include cold weather, physical trauma, acute bacterial and viral infections, corticosteroid withdrawal, beta-adrenergic blockers, and lithium (Christophers and Mrowietz 1999). Lithium-induced psoriasis typically occurs within the first few years of treatment, is resistant to treatment, and resolves after discontinuation of lithium (Krahn and Goldberg 1994). In patients with comorbid psoriasis and bipolar disorder, alternatives to lithium that are less likely to exacerbate psoriasis include valproate and carbamazepine (Gerner and Stanton 1992).

Psoriasis is associated with substantial impairment of health-related quality of life, with a negative effect on psychological, vocational, social, and physical function (McKenna and Stern 1997; Rapp et al. 1999). In a survey of psoriatic patients, 46% reported daily problems sec-

ondary to psoriasis (Gupta et al. 1990b). More than any other medical or health status variable, the best predictor of disability in patients with psoriasis in one study was the amount of stress that resulted from the anticipation of others' reaction to their psoriasis lesions (Fortune et al. 1997b). Other studies also have found that psychological factors, including perceived health, perceptions of stigmatization, and depression, are stronger determinants of disability in patients with psoriasis than are disease severity, location, and duration (Rapp et al. 1997; Richards et al. 2001).

Stress has been reported to trigger psoriasis (Al'Abadie et al. 1994; Farber and Nall 1993; Gaston et al. 1987). Most patients who report episodes of psoriasis triggered by stress describe disease-related stress, resulting from the cosmetic disfigurement and social stigma of psoriasis, rather than stressful major life events or general levels of distress (Ginsburg 1995; Gupta et al. 1989, 1990b; Richards et al. 2001). Psoriasis-related stress appears to result from psychosocial difficulties inherent in the interpersonal relationships of patients with psoriasis rather than the severity or chronicity of psoriasis activity (Fortune et al. 1997a). The mechanism of stress-induced exacerbations may involve the nervous, endocrine, and immune systems. For example, descending autonomic information from the CNS might be transmitted to sensory nerves in the skin, resulting in release of neuropeptides such as substance P, which could initiate and maintain the inflammatory response in psoriatic lesions (Farber 1995; Harvina et al. 1993; Raychaudhuri et al. 1995).

In controlled studies, patients with psoriasis had high levels of anxiety and depression and significant comorbidity with several personality disorders, including schizoid, avoidant, passive-aggressive, and compulsive personality disorders (Devrimci-Ozguven et al. 2000; Fried et al. 1995; Gupta and Gupta 1998; Richards et al. 2001; Rubino et al. 1995). A direct correlation was found between patients' self-report of psoriasis severity and depression and suicidal ideation. Furthermore, comorbid depression reduced the threshold for pruritus in psoriatic patients (Gupta et al. 1993b, 1994). Heavy alcohol drinking (>80 g/day of ethanol) in male psoriatic patients predicts a poor treatment outcome (Gupta et al. 1993a).

Evidence of psychological morbidity associated with psoriasis has led to the development of psychosocial interventions as part of its treatment. Meditation, hypnosis, relaxation training, cognitive-behavioral stress management, and symptom control imagery training were effective in reducing psoriasis activity in controlled studies (Fortune et al. 2002; Gaston et al. 1991; Kabat-Zinn et al. 1998; Zachariae et al. 1996). Controlled trials of psychopharmacological treatment of psoriasis are needed to de-

termine whether treatment of depressive or anxiety symptoms has an effect on psoriasis activity (Griffiths and Richards 2001).

## Alopecia Areata

Alopecia areata is characterized by nonscarring hair loss in patches of typically well-demarcated smooth skin. Breakage of the hair shaft results in characteristic “exclamation-mark hairs.” Hair loss often occurs on the scalp but also can affect the eyebrows, eyelashes, beard, and body hair and varies from a single patch to multiple patches or total hair loss (Koblenzer 1987). Alopecia areata accounts for about 2% of new dermatological outpatient visits in the United States. An estimated 1% of the U.S. population will have at least one episode by age 50 years (V. Price 1991). The incidence is equal in men and women and peaks during the third to fifth decades (Olsen 1999). Of the patients with alopecia areata, 30% completely recover, but 20%–30% never recover from the first episode (Koblenzer 1987). Factors associated with poor prognosis include rapid evolution, prepubertal onset, ophiasis (loss of hair along the scalp margins), multiple episodes, associated atopy, severe nail changes, and loss of eyebrows and eyelashes (Olsen 1999). The pathogenesis of alopecia areata probably involves immunological and genetic factors (Olsen 1999).

Debate continues about the role of psychiatric factors in the development of alopecia areata (Picardi and Abeni 2001). Controlled studies have yielded contradictory findings regarding the rates of psychopathology and the role of psychosocial events or stress in the onset of alopecia areata. In one controlled study, patients with alopecia areata reported significantly more life events with a substantial effect, including exits from social fields (e.g., death, divorce), uncontrolled events, and socially desirable and undesirable events in the 6 months preceding the onset of symptoms than did control subjects (Perini et al. 1984). In uncontrolled studies of lifetime comorbid psychiatric disorders in adults with alopecia areata, many patients reported lifetime psychiatric diagnoses, particularly major depression, generalized anxiety disorder, and paranoid disorder (Colón et al. 1991; Koo et al. 1994). Patients with highly stress-reactive alopecia areata reported more depressive symptoms than did patients without stress-reactive alopecia areata (Gupta et al. 1997). Finally, children with alopecia areata reported more symptoms of depression and anxiety than did control subjects (Liakopoulou et al. 1997).

Recent studies suggest ways in which stress might precipitate alopecia areata. Substance P, a neuropeptide that induces neurogenic inflammation, has been found to be endogenously released by dermal nerve fibers around hair

follicles and may be involved in the pathogenesis of alopecia areata (Toyoda et al. 2001). Locally released corticotropin-releasing hormone in the skin from dorsal root ganglia or immune cells in response to stress also might contribute to the intense local inflammation around hair follicles and symptoms of alopecia areata (Katsarou-Katsari et al. 2001).

Few studies of the psychiatric treatment of patients with alopecia areata have been done. In a double-blind, placebo-controlled trial, patients taking imipramine (75 mg/day) had significantly more hair regrowth than did control subjects, an effect that was independent of a reduction in anxiety or depression (Perini et al. 1994). Patients with alopecia areata and comorbid depressive and anxiety disorders who received selective serotonin reuptake inhibitors (SSRIs) in open trials and a small controlled study also experienced improvement in the symptoms of alopecia areata (Cipriani et al. 2001; Ruiz-Doblado et al. 1999). Uncontrolled studies of psychotherapy and relaxation training have been promising in the treatment of alopecia areata, but more study is needed (Garcia-Hernandez et al. 1999).

## Urticaria and Angioedema

Urticaria (hives) is characterized by circumscribed, raised, erythematous, usually pruritic areas of edema that involve the superficial dermis. Angioedema occurs when the edema extends into the deep dermis, subcutaneous, or submucosal layers (Soter 1999). About 15%–20% of the general population develops urticaria, with a peak incidence between ages 20 and 40 (Koblenzer 1987). The male-to-female ratio is equal in children, but more women than men develop urticaria in adulthood (Koblenzer 1987). Most patients with acute urticaria (duration of less than 6 weeks) readily respond to treatment of the underlying cause, usually infection or intolerance to specific drugs or food. However, the cause of chronic urticaria or angioedema (duration of greater than 6 weeks) in about 70% of patients is unknown. Chronic idiopathic urticaria often responds poorly to usual dermatological treatment. The prognosis is better in patients with mild severity, relatively short duration of the episode, and positive response to antihistamines (Champion et al. 1969). About 20% of the patients with chronic idiopathic urticaria have persistent symptoms after 10 years (Champion et al. 1969). Chronic idiopathic urticaria adversely affects quality of life to an extent comparable to that of patients with chronic heart disease (O'Donnell et al. 1997).

The manifestations of urticaria are a result of the release of vasoactive mediators in the skin, primarily histamine from mast cells or basophils (Soter 1999). The etiology of chronic idiopathic urticaria is unknown, but

studies have found an association with autoantibodies against the high-affinity immunoglobulin E receptor on mast cells, suggesting an autoimmune pathogenesis in some patients (Demera et al. 2001). One form of angioedema is caused by a hereditary deficiency of C1-esterase inhibitor function (Goring et al. 1998).

Psychiatric factors are involved in the development of adrenergic urticaria. The typical "halo-hives" (papules surrounded by a white halo) that develop after acute emotional stress are associated with increased levels of plasma noradrenaline and adrenaline, are reproduced with intradermal injection of noradrenaline, and resolve after treatment with the beta-adrenoreceptor blocker propranolol (Haustein 1990; Shelley and Shelley 1985).

The relation between chronic idiopathic urticaria or angioedema and psychiatric factors is less clear. Controlled studies have found that patients, particularly females, with chronic idiopathic urticaria are frequently depressed and anxious (Badoux and Levy 1994; Hashiro and Okumura 1994; Sheehan-Dare et al. 1990; Sperber et al. 1989). Controlled studies also demonstrated an association between stressful life events and the onset of urticaria (Fava et al. 1980; Lyketsos et al. 1985). Clinically, stress so often seemed a precipitant to angioedema that for many years it was referred to as *angioneurotic edema*. The connection between stress and urticaria and angioedema might have a physiological basis. For example, stress may lead to the secretion of neuropeptides, such as vasoactive intestinal peptide and substance P, that can cause vasodilation and contribute to the development of urticarial wheals (see Koblenzer 1987).

In a controlled study of psychological treatment of chronic idiopathic urticaria, hypnosis with relaxation reduced pruritus but not the number of hives (Shertzer and Lookingbill 1987). Controlled trials indicated that antidepressant medications were effective in the management of chronic idiopathic urticaria. Doxepin (10 mg three times a day) was more effective than diphenhydramine (25 mg three times a day) for the control of chronic idiopathic urticaria (Greene et al. 1985), and nortriptyline (25 mg three times a day) was significantly better than placebo in the treatment of pruritus and wheals (Morley 1969). In two case reports, both comorbid panic disorder and urticaria responded to treatment with the SSRI fluoxetine (40 mg/day) or sertraline (100 mg/day), suggesting a possible role for serotonergic mechanisms (Gupta and Gupta 1995).

## Acne Vulgaris

Acne vulgaris, a common sebaceous gland disease, is characterized by a variety of lesions, including comedones,

papules, pustules, and nodules. Possible complications from the lesions include development of pitted or hypertrophic scars. Most cases of acne vulgaris develop between the middle and late teenage years. The course of acne vulgaris is usually self-limited, with spontaneous remission after several years, but it may persist through the third decade and later. Although women are more likely than men to have persistent acne, it tends to be more severe in men (Strauss and Thiboutot 1999).

Although the cause of acne vulgaris is unknown, many factors are probably involved in its pathogenesis, including stress. Stress-induced aggravation of acne might be caused by the release of adrenal steroids, which affect the sebaceous glands (Koo and Smith 1991; Strauss and Thiboutot 1999).

Severe acne is associated with increased anxiety and poor self-image (Koo and Smith 1991). Acne can substantially interfere with social and occupational functioning. Patients with even mild to moderate acne may experience significant psychological distress and body image concerns (Gupta et al. 1990a). Successful treatment of acne with isotretinoin led to a reduction in both anxiety and depressive symptoms and a significant improvement in self-image (Kellet and Gawkrödger 1999; Rubinow et al. 1987). Also, case reports have shown improvement in acne after treatment of depression with paroxetine (Moussavian 2001). In another study, biofeedback-assisted relaxation and cognitive imagery added to usual dermatological treatment resulted in significant reduction in acne severity compared with medical control groups (Hughes et al. 1983).

The use of isotretinoin for treatment of acne vulgaris has been associated with depression, suicidal ideation, suicide attempts, and suicide in anecdotal reports that received extensive media attention (Jick et al. 2000). The U.S. Food and Drug Administration (FDA) MedWatch system reports of psychiatric disorders linked to use of isotretinoin led to additional label warnings in 1998. Recently, the FDA and isotretinoin's manufacturer added the possible development of aggressive and/or violent behavior to the psychiatric disorder warning section of the package insert (Enders and Enders 2003). However, a large population-based cohort study comparing the prevalence of psychiatric disorders, suicide, and attempted suicide in isotretinoin and antibiotic users found no evidence for an increased risk of depression, suicide, or other psychiatric disorders with the use of isotretinoin (Jick et al. 2000). Other studies also found no causal connection between isotretinoin and depression or suicide (Hersom et al. 2003; Jacobs et al. 2001). Design limitations of these studies preclude firm conclusions about a possible causal relation between isotretinoin and psychiatric disorders

(Enders and Enders 2003). Furthermore, many patients with acne vulgaris present with psychiatric comorbidity. Therefore, it is important to educate patients about the risk of major depressive disorder, suicide, and other psychiatric disorders and to monitor each patient carefully (Gupta and Gupta 2001).

## Somatoform Disorders

---

### Chronic Idiopathic Pruritus

Pruritus, or itchiness, is a common symptom of dermatological diseases and of several systemic diseases, including chronic renal disease, hepatic disease, hematopoietic disorders, endocrine disorders, malignant neoplasms, drug toxicity, neurological syndromes (e.g., multiple sclerosis), infections with parasites, and viremia. Advanced age is also associated with pruritus (Gilchrest 1982). The pathophysiology of pruritus is not completely understood (Greaves and Wall 1996). Chronic idiopathic pruritus and idiopathic pruritus ani (itching in the anal area), vulvae (itching in the vaginal area), and scroti (itching in the scrotum) may be the result of central nervous mechanisms.

In a study of histamine-induced pruritus, psychic trauma lowered itch threshold, aggravated itch intensity, and prolonged itch duration. Furthermore, the duration of the pruritus was more pronounced in subjects reporting "moodiness" during stressor exposure (Fjellner and Arnetz 1985; Fjellner et al. 1985). Recent stressful life events also have been correlated with an increased ability to detect itch. A study of pruritus in psoriasis, atopic dermatitis, and chronic idiopathic urticaria found a direct correlation between pruritus severity and the degree of depressive symptoms, possibly a result of a reduced itch threshold (Gupta et al. 1994).

Antidepressant medications, particularly the tricyclic antidepressants, can relieve chronic idiopathic pruritus. Behavioral treatment, such as habit reversal training and cognitive-behavior therapy (Rosenbaum and Ayllon 1981; Welkowitz et al. 1989), aimed at interrupting the itch-scratch cycle may help to prevent complications of long-term scratching, such as lichen simplex chronicus, a condition of prominent skin markings and thickening of the tissue.

### Body Dysmorphic Disorder

Body dysmorphic disorder is a preoccupation with an imagined defect in appearance (Phillips et al. 1993). Body dysmorphic disorder is common in dermatology practice. Approximately 12% of the patients seeking dermatologi-

cal treatment for concerns about the skin or hair had positive screening test results for body dysmorphic disorder, and it was equally common in men and women (Phillips et al. 2000). Patients with body dysmorphic disorder in cosmetic dermatology practice may have more severe symptoms than those in general dermatology practice (Phillips et al. 2000). Some patients with body dysmorphic disorder pick their skin in an attempt to improve their appearance, as discussed later in this chapter in the "Psychogenic Excoriation" subsection (Phillips and Taub 1995). Although body dysmorphic disorder is classified as a somatoform disorder, it has phenomenological similarities to obsessive-compulsive disorder (Phillips et al. 1995). Dermatological treatment alone is not effective for body dysmorphic disorder, which often responds to treatment with SSRIs and cognitive-behavioral therapy (Phillips et al. 2002).

## Delusional Disorder, Somatic Type

---

### Delusional Parasitosis

Delusional parasitosis is characterized by a fixed, false conviction that one is infested with living organisms (G.C. Johnson and Anton 1985). Patients with delusional parasitosis seek treatment from dermatologists because the delusions often involve a cutaneous invasion. There are also cases of delusional oral, ocular, and intestinal parasitosis (Ford et al. 2001; Maeda et al. 1998; Sherman et al. 1998). Delusional parasitosis typically occurs as a single somatic delusion with no other impairment of thought or thought process. It was previously called *monosymptomatic hypochondriacal psychosis* (Munro 1978) and is classified under delusional disorder, somatic type, in DSM-IV-TR. Occasionally, patients describe tactile sensations of crawling, biting, or stinging and other perceptual abnormalities such as buzzing or other sounds. Delusional parasitosis appears to be uncommon, with an equal sex distribution in patients younger than 50 years and a female-to-male ratio of 3:1 in patients ages 50 years and older (Lyell 1983).

The differential diagnosis of delusions of parasitosis includes numerous medical disorders, such as tuberculosis, syphilis, chronic lymphocytic leukemia, polycythemia vera, malignant lymphoma, congestive heart failure, arteriosclerosis, diabetes mellitus, vitamin B<sub>12</sub> deficiency, pellagra, renal failure, hypothyroidism, hepatic disease, and the dermatological disorders stasis dermatitis and vitiligo (G.C. Johnson and Anton 1985; Wykoff 1987). Neurological conditions associated with delusions of parasitosis include dementia, multiple sclerosis, Parkinson's disease, Huntington's disease, cerebral infarction, and CNS tu-

mors (G.C. Johnson and Anton 1985; Morris 1991). Patients with other psychiatric disorders, including major depressive disorder, bipolar disorder, and schizophrenia, also may have delusions of parasitosis (Freinhar 1984; G.C. Johnson and Anton 1985). Finally, delusions of parasitosis are associated with long-term use of amphetamines, methylphenidate, cocaine, alcohol, phenelzine, pargyline, or corticosteroids. The delusions usually resolve with discontinuation of the drug (G.C. Johnson and Anton 1985; Morris 1991; Wykoff 1987).

Characteristic features of delusional parasitosis include a specific precipitant, a history of potential or actual exposure to contagious organisms or actual infestation, and a history of multiple consultations with physicians and other professionals such as entomologists and exterminators (Lyell 1983). Many patients are reluctant to accept psychiatric evaluation for fear of being told the infestation is not real (Morris 1991). Patients make multiple attempts at treatment, including repetitive washing, checking, and cleaning; excoriation of the skin with needles, knives, or fingernails; discarding or destroying possessions; and excessive use of insect repellents and insecticides (Lyell 1983; Wykoff 1987). Other individuals may share the delusion (*folie à deux*), and the fear of contaminating others is often present (Lyell 1983; Morris 1991). Also, cases of delusional parasitosis by proxy involve children or pets (Nel et al. 2001). Patients may bring in specimens of inanimate material, nonharmful insects, or bits of hair and skin for examination by the physician in an attempt to provide evidence of infestation (Lyell 1983). Descriptions of the offending parasite vary from the imprecise "things" or "bugs" to detailed explanations of the organism's (usually insects, spiders, or worms) appearance, behavior, and life cycle (Lyell 1983; Morris 1991; Wykoff 1987). The mistaken worries about infestation span a spectrum from nondelusional to delusional thinking (Wykoff 1987). Sometimes the preoccupation with infestation resembles obsessions in that it is distressing, anxiety-provoking, persistent, recurrent, and difficult to resist or control. The repetitive behaviors accompanying the preoccupation are often compulsive in nature. Patients frequently report social isolation and loss of employment as a result of the delusions (Wykoff 1987), and rarely patients have been reported to commit suicide (Monk and Rao 1994).

Patients with delusional parasitosis respond to treatment with the potent neuroleptic pimozide. Only one controlled study of the treatment of delusional parasitosis with pimozide has been done, in which 10 of 11 patients improved after 6 weeks of 1–5 mg/day (Hamann and Avnstorop 1982). A follow-up study indicated that many patients taking pimozide could discontinue the medication

after a mean treatment duration of 5 months without recurrence of the delusions (Lindskov and Baadsgaard 1985). In other anecdotal reports, pimozide doses of up to 12 mg/day have been used in delusional parasitosis (G.C. Johnson and Anton 1985). Full remission of delusional parasitosis has been reported in 50% of the patients receiving pimozide (Trabert 1995). There are uncontrolled reports of efficacy with other antipsychotic medications, including chlorpromazine, trifluoperazine, haloperidol, risperidone, and fluphenazine decanoate (DeLeon et al. 1997; Freinhar 1984; Gallucci and Beard 1995; Kitamura 1997; Morris 1991; Songer and Roman 1996). Although pimozide is most commonly advocated for the treatment of delusional parasitosis, no conclusive evidence indicates that pimozide is superior to other antipsychotics. However, pimozide is the only neuroleptic used in the treatment of delusional parasitosis that is a potent opiate antagonist (Creese et al. 1976). Pimozide may be antipruritic as a result of its opiate antagonism, and the relief of pruritus or paresthesias could contribute to improvement in delusional parasitosis (G.C. Johnson and Anton 1983). The cardiovascular side effect of QT prolongation associated with pimozide precludes its use in patients with cardiac dysrhythmias and prolonged congenital QT syndrome because of the risk of life-threatening arrhythmias. Patients without a significant cardiac history whose treatment with pimozide is initiated at low doses and increased slowly are at minimal risk for cardiac complications (Opler and Feinberg 1991).

Case reports show successful treatment of delusional parasitosis with tricyclic antidepressants, SSRIs, and electroconvulsive therapy (Bhatia et al. 2000; Morris 1991; Pylko and Sicznan 1985; Slaughter et al. 1998). Because of the obsessive-compulsive symptoms in many patients with delusional parasitosis, controlled studies with the SSRIs are needed.

Psychotherapy has minimal efficacy in the treatment of delusional parasitosis (Freinhar 1984). Dermatologists have advocated an approach to patients with delusional parasitosis that allows for the development of a therapeutic relationship. This is accomplished by listening to patients' stories, asking how the condition affects their lives, being alert to any area in which patients will accept help, and trying to reduce the patients' sense of isolation (Gould and Gragg 1976).

## Other Delusional Disorders, Somatic Type

In the delusional variant of body dysmorphic disorder, the preoccupations with a defect in appearance are of delusional intensity, although the distinction between an obsessive concern and delusions is not always clear (see

McElroy et al. 1993; Phillips et al. 1994). Delusional body dysmorphic disorder may respond preferentially to SSRIs, and if a patient's symptoms do not completely respond to an SSRI, the addition of an antipsychotic, such as pimozide, may be helpful (Phillips 1996; Phillips et al. 2002).

The delusion of a foul body odor is another encapsulated somatic delusion that a dermatologist may encounter in patients. Treatment data are limited, but pimozide and other antipsychotic medications may be effective (Manschreck 1996).

## Impulse-Control Disorders

---

### Psychogenic Excoriation

Psychogenic excoriation (neurotic excoriation, acne excoriée, pathological or compulsive skin picking, or dermatotillomania) is a disorder characterized by self-induced skin lesions from excoriating the skin in response to skin sensations or an urge to remove an irregularity on the skin (Gupta et al. 1987). Lesions are found in areas that the patient can easily reach, such as the face, upper back, and upper and lower extremities. Typical lesions are a few millimeters in diameter and weeping, crusted, or scarred with occasional postinflammatory hypo- or hyperpigmentation (Koblenzer 1987). Psychogenic excoriation occurs in about 2% of dermatology outpatients and is more common in women (Gupta et al. 1986). Most studies report a mean age at onset between 30 and 45 years, although the disorder can begin in adolescence. The mean duration of symptoms is 5 years, with a better prognosis for patients who have had the symptoms for less than 1 year (Gupta et al. 1986).

The behavior associated with psychogenic excoriation is heterogeneous. Some patients exhibit behavior that resembles obsessive-compulsive disorder in that it is repetitive, ritualistic, and tension reducing, and patients attempt, often unsuccessfully, to resist excoriating, a behavior they find ego-dystonic (Stein and Hollander 1992a). Patients sometimes describe obsessions about an irregularity on the skin or preoccupations with having smooth skin and may excoriate in response to such thoughts. The preoccupation with appearance can be severe enough to meet criteria for body dysmorphic disorder, a disorder possibly related to obsessive-compulsive disorder (Phillips and Taub 1995). Patients also may describe symptoms of impulse-control disorders, such as an increase in tension before the behavior and transient pleasure or relief immediately afterward (Arnold et al. 1998). As in other impulse-control disorders, patients with psychogenic ex-

coriation often find themselves acting automatically. Thus, behaviors can span a "compulsivity-impulsivity" continuum from purely obsessive-compulsive to purely impulsive, with mixed symptoms between these poles (McElroy et al. 1994). Preliminary operational criteria that take into account the heterogeneity of the behaviors and allow for subtyping along a "compulsivity-impulsivity" spectrum have been proposed for the diagnosis of psychogenic excoriation (Arnold et al. 2001) (Table 29–2).

Depressive and anxiety disorders are common in patients with psychogenic excoriation (Arnold et al. 1998; Gupta et al. 1987; Simeon et al. 1997). In one study, patients with impulsive excoriative behavior had a high rate of comorbid bipolar disorder, particularly bipolar II disorder, consistent with studies of other impulse-control disorders in which bipolar disorder is frequently comorbid (Arnold et al. 1998).

Case reports and open trials suggest that psychogenic excoriation responds to treatment with oral doxepin (Harris et al. 1987) and the serotonin reuptake inhibitors fluoxetine (Gupta and Gupta 1993; Phillips and Taub 1995; Stein et al. 1993; Stout 1990; Vittorio and Phillips 1997), sertraline (Kalivas et al. 1996), clomipramine (Gupta et al. 1986), paroxetine (Biondi et al. 2000; Ravindran et al. 1999), and fluvoxamine (Arnold et al. 1999). There are also case reports of successful treatment of psychogenic excoriation with olanzapine (Garnis-Jones et al. 2000; Gupta and Gupta 2000), pimozide (Duke 1983), and naltrexone (Lienemann and Walker 1989). A 10-week double-blind, placebo-controlled trial found that fluoxetine, at a mean dose of 55 mg/day, was significantly better than placebo in reducing psychogenic excoriation (Simeon et al. 1997). A study of open-label fluoxetine, at a mean dose of 41 mg/day for 6 weeks followed by a 6-week double-blind, placebo-controlled phase, also reported that fluoxetine significantly reduced skin excoriation (Block et al. 2000). Studies of the behavioral treatment of psychogenic excoriation are limited to case reports, which showed promising results (Deckersbach et al. 2002; Kent and Drummond 1988; Welkowitz et al. 1989).

### Trichotillomania

Trichotillomania is a disorder of chronic pulling out of one's hair. Trichotillomania is classified as an impulse-control disorder in DSM-IV-TR but, like psychogenic excoriation, has both impulsive and compulsive features (Stein et al. 1995a, 1995b). Trichotillomania causes substantial distress and impairment in functioning and leads to alopecia, most commonly involving the scalp hair but also eyelashes, eyebrows, pubic hair, and other body hair

**TABLE 29–2. Proposed diagnostic criteria for psychogenic excoriation**

- A. Maladaptive skin excoriation (e.g., scratching, picking, gouging, lancing, digging, rubbing, or squeezing skin) or maladaptive preoccupation with skin excoriation as indicated by at least one of the following:
1. Preoccupation with skin excoriation and/or recurrent impulses to excoriate the skin that is/are experienced as irresistible, intrusive, and/or senseless.
  2. Recurrent excoriation of the skin resulting in noticeable skin damage.
- B. The preoccupation, impulses, or behaviors associated with skin excoriation cause marked distress, are time-consuming, significantly interfere with social or occupational activities, or result in medical problems (e.g., infections).
- C. The disturbance is not better accounted for by another mental disorder and is not due to a general medical condition.

**Subtypes:***Compulsive type:*

1. Skin excoriation is performed to avoid increased anxiety or to prevent a dreaded event or situation and/or is elicited by an obsession (e.g., obsession about contamination of the skin).
2. It is performed in full awareness.
3. It is associated with some resistance to performing the behavior.
4. There is some insight into its senselessness or harmfulness.

*Impulsive type:*

1. Skin excoriation is associated with arousal, pleasure, or reduction of tension.
2. It is performed at times with minimal awareness (e.g., automatically).
3. It is associated with little resistance to performing the behavior.
4. There is little insight into its senselessness or harmfulness.

*Mixed type:*

Skin excoriation has both compulsive and impulsive features.

*Source.* Reprinted from Arnold LM, Auchenbach MB, McElroy SL: "Psychogenic Excoriation: Clinical Features, Proposed Diagnostic Criteria, Epidemiology, and Approaches to Treatment." *CNS Drugs* 15:351–359, 2001. Used with permission. Adis International Ltd., Auckland, New Zealand.

(Christenson et al. 1991a). The extracted hair is sometimes chewed or swallowed, resulting in the development of trichobezoars (Christenson and Crow 1996). Patients may develop infections at the site of hair pulling, change in texture or color of the hair, or carpal tunnel syndrome from pulling (Christenson and Crow 1996).

In a survey of college freshmen, the lifetime prevalence of trichotillomania (by strict criteria) was 0.6% for both men and women but rose to 3.4% for women and 1.5% for men if all hair pulling with noticeable hair loss was included (Christenson et al. 1991b). The condition typically persists for years, with a mean age at onset of 13 years (Christenson et al. 1991a). The prognosis appears to be better with hair pulling of 6 months' duration or less. Most patients do not seek treatment (Christenson and Crow 1996).

There are two types of hair pulling (Christenson and Crow 1996). In the "focused style," patients focus solely on the pulling without attention to other thoughts and activities. Symptoms resemble obsessive-compulsive disorder in that the patient resists the pulling and feels relief with pulling. However, most patients engage in an "automatic style" of pulling that occurs during situations described as sedentary or contemplative, such as reading or watching television, which is consistent with impulse-

control disorders. Many patients have a combination of these two styles (Christenson et al. 1993).

Comorbid psychiatric disorders in patients with trichotillomania include anxiety, mood, substance abuse or dependence, and eating disorders (Christenson et al. 1991a; Cohen et al. 1995; Schlosser et al. 1994; Swedo and Leonard 1992). The most frequent comorbid personality disorders include Cluster B (histrionic, borderline) and Cluster C (obsessive-compulsive, avoidant, dependent) disorders (Schlosser et al. 1994; Swedo and Leonard 1992). One particular personality disorder is not characteristic of patients with trichotillomania (Christenson et al. 1992). Patients with trichotillomania frequently have first-degree relatives with obsessive-compulsive disorder and trichotillomania (Swedo and Leonard 1992) and family histories of mood disorders, substance use disorders, anxiety disorders, and schizophrenia (Cohen et al. 1995).

In a double-blind crossover study, trichotillomania responded preferentially to the antiobsessional agent clomipramine, at a mean dose of 180 mg/day, over desipramine, at a mean dose of 173 mg/day (Swedo et al. 1989). In another report, response to clomipramine negatively correlated with anterior cingulate and orbital frontal metabolism on positron emission tomography (PET) examination, a finding also characteristic of obsessive-compulsive

disorder (Swedo et al. 1991). Open studies of the SSRI fluoxetine reported positive short- and long-term results (Koran et al. 1992; Winchel et al. 1992); however, controlled studies have yielded mixed findings. Two placebo-controlled studies found that fluoxetine was not superior to placebo in the treatment of trichotillomania (Christenson et al. 1991c; Streichenwein and Thornby 1995), but in a double-blind crossover study of clomipramine and fluoxetine, both medications had positive treatment effects on trichotillomania (Pigott et al. 1992). Case reports and open trials reported positive responses to treatment with other drugs, including fluvoxamine (Christenson et al. 1998; Stanley et al. 1997), paroxetine (Reid 1994), sertraline (Bradford and Gratzler 1995; Rahman and Gregory 1995), citalopram (Stein et al. 1997), venlafaxine (Ninan et al. 1998), other antidepressants (Christenson and Crow 1996), lithium (Christenson et al. 1991d), and buspirone (Reid 1992). Pimozide augmentation of clomipramine or fluoxetine also has proved useful in a small case series (Stein and Hollander 1992b). A case series of olanzapine augmentation of citalopram was effective in three of four patients (Ashton 2001). Finally, there are case reports of successful treatment of resistant trichotillomania with a combination of risperidone and fluvoxamine (Gabriel 2001) and with risperidone alone (Sentürk and Tanrıverdi 2002).

The behavioral treatment of habit reversal has been reported to be effective in trichotillomania and involves increasing awareness of situations or stressors associated with hair pulling, relaxation training, and competing response training (Azrin et al. 1980). A small 9-week controlled study examining the efficacy of cognitive-behavior therapy and clomipramine compared with placebo found that cognitive-behavior therapy substantially reduced the symptoms of trichotillomania and was significantly more effective than clomipramine or placebo. Clomipramine treatment resulted in symptom reduction greater than that of placebo, but the difference was not statistically significant (Ninan et al. 2000). A 12-week controlled study compared fluoxetine with behavioral treatment that consisted of six individual 45-minute sessions aimed at self-control, which relied on self-report and self-monitoring. The behavioral treatment resulted in significantly greater reduction in trichotillomania symptoms compared with the fluoxetine or a waiting-list control condition (van Minnen et al. 2003). Hypnosis and other behavioral treatments also have been useful according to case reports (Peterson et al. 1994).

For many patients with trichotillomania, the initial response to treatment is followed by a plateau in improvement and, for up to one-third, a loss of beneficial medication effect (Keuthen et al. 2001). Preliminary evidence

suggests that concurrent use of behavioral therapies and medication treatment for trichotillomania may be more effective than either treatment alone, but more study is needed (Keuthen et al. 1998).

## Onychophagia

Onychophagia, or repetitive nail biting, is a common behavior that can begin as early as age 4 years, with a peak between ages 10 and 18 years, and that appears to be familial (Leonard et al. 1991). Severe onychophagia can lead to significant medical and dental problems, such as hand infection (Zook 1986) and craniomandibular disorders (Westling 1988). Onychotillomania, the picking or tearing of the nail, may be a variant of the behavior. Like trichotillomania and psychogenic excoriation, onychophagia has the phenomenological features of repetition, resistance, and relief (Leonard et al. 1991).

A double-blind crossover study reported that onychophagia responded preferentially to clomipramine, at a mean dosage of 120 mg/day, over desipramine, at a mean dosage of 135 mg/day (Leonard et al. 1991). Many forms of behavior therapy, including habit reversal, have been efficacious (Peterson et al. 1994). In a recent controlled study of chronic nail biting, habit reversal training (a total of 2 hours spread over three sessions) was compared with a placebo treatment in which patients simply discussed their nail biting. The habit reversal intervention produced a greater increase in nail length compared with the placebo (Twohig et al. 2003).

## Factitious Disorders

---

### Factitious Dermatitis

Factitious dermatitis (dermatitis artefacta) is a disorder in which patients intentionally produce skin lesions in order to assume the sick role. Patients typically deny the self-inflicted nature of the disorder (Gupta et al. 1987).

Factitious dermatitis can present with a wide variety of lesions depending on the methods used by the patient. Patients may either simulate actual medical dermatoses or aggravate a preexisting dermatological condition (Koblenzer 1987). Lesions include excoriations, blisters, purpura, ulcers, erythema, edema, sinuses, and nodules (Gupta et al. 1987). Methods used by patients include rubbing; scratching; picking; cutting; puncturing; sucking; biting; applying suction cups; occluding; applying dye, heat, or caustic substances onto the skin; or injecting caustics, infected material, blood, feces, or other substances into the skin (Gupta et al. 1987; Koblenzer 1987; Lyell 1979; Spraker 1983).

Skin damage can be extensive, with full-thickness skin loss and severe scarring requiring plastic surgery or even amputation (Hollender and Abram 1973). Affected sites tend to be easily accessible to the patient and are more prominent on one side of the body, depending on the handedness of the patient (Hollender and Abram 1973). Excoriated lesions frequently have sharp, geometric borders with normal surrounding skin or lines at the margin if a caustic was used and some liquid dripped out of the site (Hollender and Abram 1973; Spraker 1983). The natural progression of the lesions through the different stages of development is not evident (Spraker 1983). The history is often vague and “hollow” (Lyell 1979), and patients are often very suggestible as to the site of the next lesion (Hollender and Abram 1973). The use of an occlusive dressing such as an Unna’s paste boot (a dressing that hardens to form a protective covering) can help make the diagnosis because the lesions heal when the patients are unable to reach them (Hollender and Abram 1973; Koblenzer 1987).

Factitious dermatitis occurs in about 0.3% of dermatology patients (Gupta et al. 1987), with a female-to-male ratio between 3:1 and 8:1 and the greatest frequency in adolescents and young adults (Koblenzer 1987). It reportedly begins after severe psychosocial stress, usually involving loss, threatened loss, or isolation (Stein and Hollander 1992a). As in other factitious disorders, the patient often has experience in medicine as a result of either prior exposure to illness or employment in a health care field. The prognosis varies; some cases resolve after a brief episode, whereas others become lifelong problems (Lyell 1979). In a classic long-term study, 30% of the patients continued to produce lesions more than 12 years after the onset of their symptoms (Sneddon and Sneddon 1975).

The differential diagnosis of factitious dermatitis includes other forms of self-inflicted dermatoses described in the earlier sections. Although borderline personality disorder is commonly comorbid with factitious dermatitis, some patients with borderline personality disorder readily acknowledge that they damage their skin in an impulsive act that resembles obsessive-compulsive spectrum disorders. Self-mutilation in impulsive patients may be a result of low serotonergic function and may respond to the SSRI fluoxetine (Stein and Hollander 1992a). Other self-mutilating patients with psychosis or mental retardation do not have the other characteristics of a factitious disorder (Hollender and Abram 1973).

No controlled trials of the treatment of factitious dermatitis have been published, and treatment recommendations are based on anecdotal experience. An empathic, therapeutic relationship between the dermatologist and the patient is essential in the management of these patients. Because the patients deny the self-inflicted nature

of the lesions, they usually do not immediately accept a referral to a psychiatrist, and direct confrontation may disrupt the doctor–patient relationship. However, once a therapeutic relationship has been established, some patients will accept a psychotherapeutic approach (Koblenzer 1987; Spraker 1983) (see also Chapter 14, “Deception Syndromes: Factitious Disorders and Malingering”).

## Psychogenic Purpura

The spontaneous appearance of recurrent bruising (purpura) is a rare dermatological disorder that often follows an injury or a surgical procedure and typically is initiated by pain, burning, or stinging, followed by warmth, erythema, swelling, and sometimes pruritus and, after hours or days, by ecchymosis (Gardner and Diamond 1955). Blood coagulation and hemostatic tests, however, have normal results (Koblenzer 1987; Stocker et al. 1977). The incidence is unknown, but it affects women more frequently than men, with a female-to-male ratio of 20:1. The age at onset varies from 9 to 53 years, with most cases occurring between ages 14 and 40 (Koblenzer 1987). Three different proposed mechanisms currently exist: autoerythrocyte sensitization, conversion reaction, and factitious disorder.

Autoerythrocyte sensitization (Gardner-Diamond syndrome) is thought to result from sensitization to the stroma of extravasated erythrocytes after trauma (Gardner and Diamond 1955). Some, but not all, patients’ bruises have been reproduced by intracutaneous injection of washed red blood cells or erythrocyte stroma. However, there is no evidence for circulating antibodies to red blood cell components or abnormalities in immunological function. Attempts to use immunosuppressive treatment and desensitization with autologous blood products also have been unsuccessful (Koblenzer 1987). Therefore, the evidence for autoerythrocyte sensitization is very limited.

In support of a psychogenic cause of the purpura, studies have found that it often begins after significant psychosocial stressors. Most patients present with several other unexplained somatic symptoms and have significant comorbid psychiatric symptoms, including depression, anxiety, and personality disorders, particularly borderline and histrionic personality disorders (Ratnoff 1989). The differentiation between conversion and factitious purpura is unclear because patients thought to have conversion symptoms and those found to have factitious disorder share many common features (Stocker et al. 1977). In addition, physicians can identify no mechanism for a conversion reaction or convincingly disprove factitious causation in many cases (Stocker et al. 1977). Although more study is needed, it appears that factitious disorder is the most likely cause of psychogenic purpura.

## Cutaneous Side Effects of Psychiatric Medications

Selected cutaneous side effects of psychiatric medications are summarized in Table 29–3.

**TABLE 29–3. Selected cutaneous side effects of psychotropic medications**

Agent	Cutaneous side effects
<b>Anticonvulsants</b>	Allergic rashes, alopecia, Stevens-Johnson syndrome and toxic epidermal necrolysis (especially lamotrigine), lupuslike syndrome
<b>Antidepressants</b>	Allergic rashes, photosensitivity (tricyclic antidepressants), hyperhidrosis
<b>Antipsychotics</b>	Skin pigmentation (especially thioridazine and chlorpromazine), photosensitivity (especially phenothiazines), lupuslike syndrome (phenothiazines), contact dermatitis, depot injection site reactions
<b>Lithium</b>	Urticaria; rash; alopecia; folliculitis; exacerbation of acne, warts, psoriasis

## Conclusion

Patients with psychocutaneous disorders are a diverse group who frequently present to dermatologists for evaluation and treatment. Included in this group are patients who have dermatological diseases (e.g., psoriasis), in which the course may be affected by psychological factors, such as stress or comorbid mood and anxiety disorders. Patients who have primary psychiatric disorders with skin-related symptoms (e.g., delusional parasitosis) are also included under the broad category of psychocutaneous disorders. Psychocutaneous disorders can be particularly challenging for dermatologists because patients with these disorders are often reluctant to seek psychiatric treatment. Furthermore, the understanding of the pathophysiology of these disorders is limited, and relatively few treatment studies are available to guide the management of these disorders.

Patients may be more willing to accept a psychiatric evaluation if a psychiatrist is working within the dermatology clinic. In a study of a dermatology-liaison clinic, most of the psychiatric workload involved the treatment of comorbid depressive and anxiety disorders. Furthermore, most of the patients who were seen in the liaison

clinic responded well to psychiatric treatment (Woodruff et al. 1997). However, many communities do not have psychiatrists available to perform a liaison function within dermatology settings. As an alternative, psychiatrists with an interest in psychocutaneous disorders could develop working relationships with dermatologists to improve the access to psychiatric evaluation and treatment. Collaboration between the psychiatrist and dermatologist is likely to positively affect the treatment outcome of patients with psychocutaneous disorders.

# 30 Surgery

---

Pauline S. Powers, M.D.

Carlos A. Santana, M.D.

**SURGICAL PATIENTS OFTEN** have preexisting psychiatric disorders, and a range of psychosocial problems may become evident after surgery. Estimates of the prevalence of psychiatric problems in surgical patients range from 15% to 50% (Kain et al. 2002; Strain 1982). Although surgeons report lower-than-actual frequencies of various psychiatric disorders in their patients than do other non-psychiatric physicians, the difference between the medical and the surgical specialties is low (Chadda 2001). Surgeons are also less likely to refer patients to psychiatrists than are other physicians, who themselves generally underestimate the prevalence of psychiatric disorders among their patients. Thus, a large proportion of psychopathology in surgical patients is either undiagnosed or misdiagnosed.

In the hospital, psychiatrists provide consultations for patients on general surgical floors, but they are more likely to provide liaison services to specialized surgical units such as burn units or organ transplant programs. Consultations for general surgical patients often involve preoperative issues such as consent for surgery, fear of anesthesia or surgery, or management of preexisting psychiatric disorders during hospitalization. Postoperative hospital consultations are often initiated for assessment and treatment of delirium or behavior problems. On specialized surgical units, the psychiatrist is likely to provide classic liaison services, including teaching other members of an interdisciplinary team to recognize and manage various psychiatric and psychological problems unique to the unit.

## General Issues

---

### Open, Closed, and Random Systems

The general surgical unit and specialized units often have significant differences in operational style. Systems the-

ory can be helpful in understanding these differences (Luhmann and Knodt 1995). An *open system* has regular members who belong to the system and flexible rules about entering and leaving the system. In the *closed system*, only certain individuals can come into and go out of the system, and “outsiders” are excluded from the system. In *random systems*, individuals move into and out of the system at random, with few rules about how entry and exit occur.

Most general surgical units are open systems, and some poorly functioning ones are random systems. Specialized units, such as burn units, are often closed systems with very rigid rules about entering or leaving the system. Because hospital consultations are usually one to three sessions, it is important that the consultant be able to move easily into and out of the system. This is possible in the open systems typically present on general surgical floors. However, communication with the consultee may require significant effort on the part of the consultant, who may have to track down the consulting surgeon (who may be in the operating room all day); this problem is accentuated on a ward that tends toward randomness. In contrast, the psychiatrist who provides liaison to a closed specialized unit will need to be well known to the team and be a regular attendee at team meetings. Communication within the closed system may be easier because all members are likely to accept recommendations from another member of the team.

### Outpatient Consultation-Liaison Services

In the outpatient department, the psychiatrist may be an integral part of a specialized team. For example, bariatric surgery teams typically rely on a presurgical psychiatric assessment of patients to determine whether the patient is

an appropriate candidate for surgery; the psychiatrist also may participate in the long-term follow-up of the patient after bariatric surgery. This type of psychiatry requires detailed knowledge of the unique risks and benefits of the proposed surgery.

Other consultations from surgery in the outpatient department are often related to complex problems in which the patient has multiple comorbid psychiatric, surgical, and medical problems. Outpatient consultations sometimes relate to transference or countertransference problems between the surgeon and the patient.

## Transference and Countertransference

*Transference* is defined as the set of emotional reactions that a patient has toward the surgeon: these reactions are shaped by previous relationships with important people in the life of the patient and may facilitate or inhibit the relationship with the surgeon. Relationships with parents and others in authority typically influence current reactions to the surgeon. For example, a surgical candidate who has had a trusting relationship with parents and positive experiences with physicians is likely to approach surgery calmly and to be able to discuss options openly with the surgeon. However, a patient who grew up with harsh, controlling, and demanding parents, and who also has had negative interactions with physicians, is more likely to be suspicious of the surgeon and fearful of the surgery. Recognition of the likely source of the patient's reactions to the surgeon is the key to managing these reactions. For example, if a new patient is suspicious and unduly fearful of a usually safe surgical procedure, it may be helpful to give the patient time to discuss the procedure with a trusted partner or friend and then offer to explain the procedure to this person while the patient is present.

Surgeons, like other physicians, may have countertransference reactions to their patients. Clues to negative countertransference reactions to the patient include feelings of anger, irritability, sadness, or boredom. In these situations, it is often helpful for the surgeon to ask him- or herself: "Why am I (angry, sad, or bored or overly involved with this patient)?" The answer may be that the patient has elicited feelings related to another situation in the surgeon's life. Recognition of this fact usually allows the surgeon to refocus on the patient. An example might be an overly solicitous response to a woman shot by an abusive husband; it might be that in this situation, the surgeon was reminded of his own abusive father. Another example is the surgeon who is angry because a patient fails to improve after multiple back surgeries. This reaction may relate to the surgeon's un-

recognized and unrealistic grandiose belief that she can conquer any problem.

## Staff Coping Mechanisms

Certain surgical situations, such as traumas and burns, particularly among children, elicit powerful emotional responses from the surgeons and nurses working with these patients and their families (Wetzel and Burns 2002). A. Jones (2001) poignantly described the reaction of a patient and her husband to life-threatening surgery and commented that the "impact of physical illness is such that there is potential for the seriously ill to saturate health workers in anxiety and raw feelings" (p. 459). To protect themselves emotionally, the surgeon or nurse may ignore the emotional needs of the patient (and family) and focus solely on the physical aspects of care.

To be able to function effectively, the surgeon must be able to maintain defense mechanisms, including, when appropriate, isolation of affect, denial, humor, and suppression. Treatment team members, including psychiatrists, psychologists, and chaplains, may be able to cope more effectively with the feelings emanating from the patient because they do not have to perform surgery. Although surgeons are often blamed for not attending to the emotional needs of their patients, it may be that it is not usually possible both to fully empathize with the feelings of the patient and to maintain the objectivity needed to perform surgery. Thus, the emotional needs of both the surgeon and the patient must be respected.

## Role of the Family

The effect of the family on the patient's experience with surgery and on long-term recovery is known to be very important.

Qualitative research methods including narratives have been evaluated to understand the experience of the perioperative phase of treatment (Angus 2001; Wyness et al. 2002). A consistent theme from these reports is that for the patient and the family, knowing is better than not knowing. Another consistent theme is that specific information about various surgical strategies and their possible outcomes is important but should be delivered in a way that recognizes the time needed for assimilation (Bunch 2000). Patients and their families are now able to access information in a variety of ways, notably the Internet, and many know details of various surgical critical care pathways. If the patient does not improve as expected on the critical pathway, the family may experience significant stress. Family support groups may be helpful in such situations (Micik and Borbasi 2002).

## General Conceptual Model

---

To conceptualize the problems requiring psychiatric intervention, the perioperative period can be divided into preoperative, intraoperative, and postoperative periods. Although these periods are considered separately because special strategies and different personnel may be required in each, the connection between preoperatively identified psychiatric problems and outcome of surgery has been a topic widely studied. For example, in a study of patients with severe low back pain who underwent surgery, low presurgical neuroticism scores were associated with better postoperative functional improvement (Hagg et al. 2003). In another study of patients with gastroesophageal reflux disorder undergoing laparoscopic antireflux surgery (Kamolz et al. 2003), all the patients had normalized physiological findings after surgery, but the patients with comorbid major depression had significantly more symptoms of postoperative dysphagia and had less improvement in quality of life than did the patients without depression.

Psychiatry is often consulted in the preoperative period around the issues of consent for treatment or refusal of surgery and may be consulted at any time when the patient threatens to sign out against medical advice (AMA). Preexisting psychiatric disorders and their management often are also the reason for psychiatric consultation. Fear of surgery, anesthesia, needles, or machines may result in preoperative panic and necessitate urgent psychiatric intervention.

With the emergence of outpatient surgery and use of drugs that induce a lighter stage of anesthesia, some patients may recall events from the intraoperative period. Psychiatric consultation may be needed to assist the patient in coping with these memories.

In the postoperative period, delirium (including withdrawal from various substances) is a very common cause for consultation. Agitation and management problems are also common. Patients who were admitted because of trauma (including burns) may begin to develop symptoms of posttraumatic stress disorder (PTSD). Other issues in this period include ventilator weaning and the “intensive care unit (ICU) syndrome.”

## General Preoperative Issues

---

### Capacity and Consent

The ethical practice of surgery requires a patient’s voluntary informed consent. In some instances, however, direct

consent is impossible, and surgeons seek permission from surrogates or guidance from written advance directives. Informed consent and decision making are at the core of the preoperative period. The communication of factual information understandable to the patient is the responsibility of the surgeon. It should include diagnosis, reasons that the operation is thought to be the treatment of choice, and expected risks and benefits and their probabilities. Alternatives and their consequences, as well as financial costs, also should be discussed. Competent patients have a right to decide whether to accept or reject proposed surgery. A psychiatric consultant cannot legally declare a patient incompetent, but he or she can evaluate the medical-legal elements of the decision-making capacity of the patient. Examiners must be aware of the legal standards governing determination of competence in their jurisdiction.

The assessment also includes a determination of the cause of the patient’s limitation (i.e., the nature of the mental disorder) and the recommendations for treatment, if treatment is possible. The general principles regarding legal and ethical aspects of capacity and consent are discussed in Chapter 3, “Legal Issues,” and Chapter 4, “Ethical Issues.”

### Preoperative Psychiatric Evaluation

The preoperative period is the time to obtain a psychiatric history. Patients with a history of anxiety disorder, depression, bipolar disorder, or psychosis are at risk for experiencing symptoms of these disorders during the postoperative period. Knowing what medications have been effective or not tolerated in the past is obviously valuable. Certain personality disorders and traits are known to predispose to behavior problems during the postoperative period.

When a surgeon requests a psychiatric consultation, the consultant should establish the urgency. Surgical patients seldom initiate or request a psychiatric consultation and may even assume an adversarial attitude toward the consultant.

However, one of the most common reasons for the underreferral of surgical inpatients is lack of recognition (or dismissal) of psychological distress by the surgical team. In some cases, surgical inpatients have felt the need to refer themselves for psychiatric evaluation of anxiety, although the surgical staff did not consider their anxiety sufficient to warrant a consultation (Fulop and Strain 1985). On the other hand, inappropriate or premature psychiatric consultation sometimes occurs when a patient expresses normal feelings (e.g., starts to cry) that the surgeon finds uncomfortable. One of the psychiatrist’s major

tasks is establishing a relationship with the referring surgeon, who may or may not be knowledgeable about psychiatric issues.

## Psychiatric Disorders in the Perioperative Period

### *Depression*

The proportion of patients taking antidepressants who undergo surgery is reported to be 35% (Scher and Anwar 1999). In the past, when monoamine oxidase inhibitors (MAOIs) were more frequently prescribed, it was common to discontinue antidepressants prior to general anesthesia. This is no longer the case. In their study of 80 depressed patients who were scheduled to undergo orthopedic surgery under general anesthesia, Kudoh and colleagues (2002) determined that antidepressants administered to depressed patients should be continued. Their group concluded that discontinuation of antidepressants did not increase the incidence of hypotension or arrhythmias during anesthesia, but discontinuation increased the symptoms of depression and delirium.

### *Schizophrenia*

The management of schizophrenic patients requiring surgery can be difficult. Bizarre behavior and expression by schizophrenic patients can confuse and upset surgeons, nurses, and other patients, eliciting fear, anger, and nontherapeutic responses. Patients with paranoid delusions may refuse surgery because of psychotic misperception of the surgeon's intentions. Schizophrenic patients also often have deficits in the processing of cognitive or sensory information and concrete reasoning. These deficits may complicate the consent process and the patient's ability to cooperate with treatment, requiring the staff to make changes in management (Adler and Griffith 1991).

### *Bipolar Disorder*

The stress of surgery may psychologically and physiologically destabilize bipolar disorder, and acute relapse into mania in the postoperative period can be extremely disruptive to care, even life-threatening. Periods without oral intake in the perioperative period preclude the use of lithium, anticonvulsants, antidepressants, and most antipsychotics, during which parenteral haloperidol serves as the primary substitute for mood stabilization. Abrupt discontinuation of anticonvulsant mood stabilizers risks causing seizures. Lithium is difficult to use safely during periods of rapid fluid shifts (e.g., after cardiac surgery and acute burns).

## Preoperative Fears

An emerging literature has begun to systematically assess the nature and etiology of common fears, including fears of surgery, anesthesia, needles, and medical machines. The treatments that are likely to be effective are being studied, but current recommendations are based primarily on case reports or consensus rather than clinical trials (see also Chapter 12, "Anxiety Disorders").

### *Fear of Surgery and Anesthesia*

Nearly 20 years ago, Regal and colleagues (1985) systematically assessed 150 patients before surgery and found that 54% were anxious or very anxious. Many patients were anxious about the anesthesia: patients often feared that the anesthetic would prematurely wear off or that they would not wake up from the anesthesia. Nearly one-third of patients are afraid of anesthesia, as distinct from the operation itself (vanWijk and Smalhout 1990).

It has been consistently shown that appropriate provision of information in an empathic relationship can reduce preoperative anxiety, postoperative pain, and length of hospital stay (Klafta and Roizen 1996; Koivula et al. 2002; Nelson 1996). Timing the delivery of information is important and may vary depending on the surgery. For example, among patients undergoing elective coronary artery bypass grafting, fear is highest during the waiting period prior to hospital admission. Providing support and information during this period produces the greatest benefit. Nurses have been in the forefront of devising methods for delivering these services, and the results of their investigations also can inform psychiatric practice.

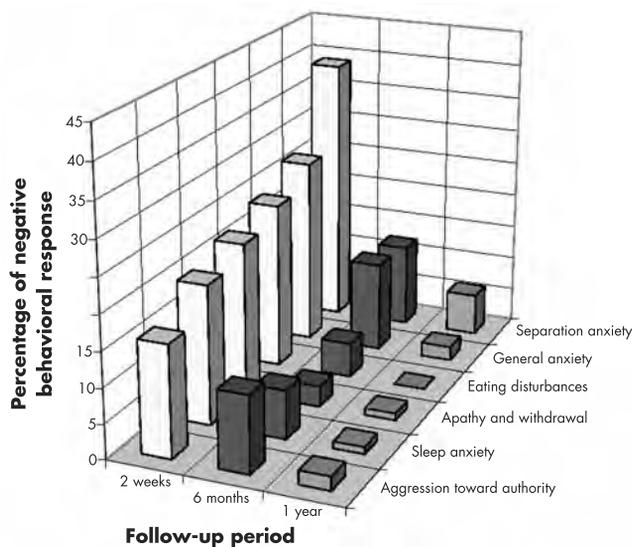

### *Treatment of Preoperative Anxiety*

Preoperative anxiety has been treated with anti-anxiety medications, particularly benzodiazepines. Although the Cochrane Database reviewers concluded that the use of benzodiazepines does not delay discharge after adult outpatient surgery, less is known about the actual clinical benefit of these medications for preoperative anxiety (Smith and Pittaway 2003). For example, in an outpatient surgery program, preoperative benzodiazepines were shown to decrease levels of stress hormones, but the actual effect on clinical anxiety was equivocal (Duggan et al. 2002). However, pediatric dental and oral surgery patients have been the most thoroughly studied, and most of these patients seem to benefit from use of benzodiazepines (see Erlandsson et al. 2001; Marshall et al. 1999). The difference in these findings may relate to differences in the subject populations (age, type of surgery), as well as the relatively greater sophistication of dental anxiety evaluation methods.

Although providing information and social support may be more time-consuming than prescribing an anti-anxiety agent, it may be more effective than medication in reducing preoperative anxiety and is likely to have postoperative benefits as well.

### Children and Preoperative Anxiety

It is estimated that as many as 3 million children undergo anesthesia and surgery annually in the United States. Many children (40%–60%) experience significant anxiety before surgery. It has been postulated that postoperative outcome may be influenced by preoperative anxiety. Kain and colleagues (1996, 2002) emphasized the importance of educating parents about the possible negative behavioral responses that children may have after surgery. Figure 30–1 illustrates changes in the number of negative behavioral responses after surgery as a function of time. At 2 weeks postoperatively, most children had one to three negative behavioral responses, but only 7.6% had seven or more negative responses. By 1 year, only 7.3% of children had one to three negative responses, and no subjects had more than four negative responses. These authors describe preoperative preparation programs for parents and children but note that research is needed to validate their effectiveness in improving postoperative outcomes.

**FIGURE 30–1.** Decreases in postoperative negative behavioral symptoms in children shown as a function of time.

### Fear of Needles, Blood, and Medical Equipment

Fear of needles is common and may first arise in the preoperative period. Estimates of the prevalence of needle phobia have ranged from 10% to 21% (Hamilton 1995; Nir et al. 2003), but probably about 8%–10% of adults have unreasonable fears of needles that interfere with treatment. Needle phobia appears to be partly inherited (especially the vasovagal response that may result in fainting) and partly learned from conditioned responses, including past fainting spells when injected or after watching others be vaccinated (Hamilton 1995; Neale et al. 1994; Nir et al. 2003). Individuals who experience disgust in response to needles may be more likely to faint (Page 2002). Treatments for needle phobia have been primarily described in case reports and include behavioral strategies (exposure techniques and participant modeling), empathy from treating professionals, and anesthesia.

Fear of blood is closely related to fear of needles. There may be a genetic component to these fears as well. In a study of 541 monozygotic twins and 388 dizygotic twins in the Virginia Twin Registry, unreasonable fears of blood, needles, hospitals, and illness were correlated and showed family aggregation (Neale et al. 1994). Some patients are fearful of contracting HIV or hepatitis virus from blood transfusions (now a very rare occurrence) or from needles contaminated with blood (although this should never occur, except in very poor countries); correcting misconceptions and providing accurate information can be reassuring.

Blood refusal is common and is usually related to religious beliefs or fear of bloodborne infections. Because Jehovah's Witnesses and others have refused blood transfusions, there has been a rigorous pursuit of alternatives. Many surgeries previously thought to require transfusions are now routinely done without them. A recent study (Carson et al. 2002) of more than 2,000 postsurgical patients who refused blood found that the risk of death was low when the hemoglobin level was between 7.1 and 8.0 g/dL, but if postoperative levels fell below this range, the risk of death increased dramatically.

If the patient refuses blood, a careful psychiatric assessment may be needed to determine why the patient is refusing and whether the patient is competent to refuse treatment. For anxious patients, cognitive-behavioral interventions and benzodiazepines are helpful. If the patient is a child and the parents refuse transfusion on the basis of the parents' beliefs, legal and ethical consultation should be obtained, but the decision is usually to transfuse the child.

Fear of medical equipment is also common. Claustrophobia in a closed magnetic resonance imaging (MRI) de-

vice is the best described and may result in inability to obtain a scan. Use of an open MRI was shown to result in successful scans in 94% of 50 patients with claustrophobia who had been unable to tolerate the closed MRI (Spouse and Gedroyc 2000). Various coping strategies for the claustrophobia, including patient education and various relaxation techniques, are often helpful but have not been systematically investigated.

## **Intraoperative Issues— Anesthesia and Intraoperative Recall**

---

The prospect of anesthesia can be frightening for many reasons, and some people envision anesthesia as a “death-like” state. Although patients expect to be amnesic for surgery, at the same time, they may fear the loss of control involved, or they may be afraid that they will not wake up from the anesthesia. Some fear that the anesthesia will wear off while the surgery is still under way. Patients also may fear that they will reveal secrets during anesthesia (Blacker 1987), even though this has not been shown during general anesthesia.

In 1992, Ghoneim and Block stated: “It is a sobering commentary that after 145 years it is not always possible to determine with certainty whether an anesthetized patient is conscious during surgery” (p. 296). This is still true more than a decade later despite multiple efforts to determine whether the patient is conscious. During the last decade, several studies have concluded that a small percentage of patients (perhaps 0.5%–2.5%) can explicitly recall events that occurred during surgery (Ranta et al. 2002). Although this is a small percentage, it has been estimated that 40,000 incidents occur per year (Maye and Smith 2001). Several factors are known to influence the likelihood of intraoperative recall, including type of anesthesia, type of preanesthetic, and depth of anesthesia.

Although relatively uncommon, intraoperative recall can be associated with marked psychiatric disability, including PTSD symptoms, especially flashbacks, nightmares, and preoccupation with the surgery. One traumatic component is the experience of total paralysis while aware. In a small series of 18 consecutive, prospectively identified cases of intraoperative awareness with recall, 9 patients were located 2 years later; 4 of the 9 were still severely psychiatrically disabled, and 2 had milder symptoms (Lennmarken et al. 2002). Furthermore, in a study of the American Society of Anesthesiologists Closed Claims Project (Domino et al. 1999), intraoperative awareness claims accounted for 1.9% of the 4,183 claims. Among

these, 18 claims were for the inadvertent paralysis of an aware patient, and the remaining 61 claims were for recall during general anesthesia.

It may not be possible to prevent all cases of intraoperative awareness because outpatient surgery is common and drugs that induce a lighter stage of anesthesia are often indicated. It is always prudent for the surgical team to avoid inappropriate comments that may be remembered by the patient. In addition, preparation of the patient for the unlikely possibility of intraoperative awareness may be helpful.

## **General Postoperative Issues**

---

### **Alcohol Dependence**

Chronic alcohol misuse is more common in surgical patients than in psychiatric or neurological patients. More than 50% of the patients with carcinoma of the gastrointestinal tract have alcohol dependence (Seitz and Simanowski 1986). Almost half of all trauma beds are occupied by patients who were injured while under the influence of alcohol (Gentilello et al. 1995; Spies et al. 1996). In addition to the life-threatening complications of the alcohol withdrawal syndrome, the rate of morbidity and mortality resulting from infections, cardiopulmonary insufficiency, and bleeding disorders is two to four times greater in patients with chronic alcoholism (Spies et al. 1997). The development of an alcohol withdrawal syndrome can change a normal postoperative course into a life-threatening situation in which the patient requires ICU treatment.

An alcohol-related history is frequently unobtainable in trauma patients because of their injuries (which may include closed head injury) and subsequent endotracheal intubation. Laboratory tests with sufficient sensitivity and specificity may assist in the diagnosis and possible prevention of complications (Sillanaukee 1996). If an ordinary alcohol history is not obtainable, the biological marker known as carbohydrate-deficient transferrin is a useful alternative. The carbohydrate-deficient transferrin correlates with alcohol consumption in surgical patients (Tønnesen et al. 1999).

Chronic alcohol intake may produce either enhanced or reduced sensitivity to anesthetics. The net effect varies with the amount of alcohol used, the relative affinity of alcohol and other drugs for the microsomal enzymes, and the severity of any underlying liver injury (Lieber 1995).

Alcohol dependence is often complicated by disorders such as cirrhosis, seizures, pancreatitis, polyneuropathy, or cardiomyopathy. It seems obvious that surgical inter-

ventions in an alcoholic patient with one or more of these disorders may be associated with increased morbidity and mortality. Increased risk of complications is seen after both minor and major surgery, as well as after elective and emergency procedures. In general, the risk of postoperative infections is related to decreased immune function and enhanced stress response to surgical trauma. This enhanced stress response is characterized by a greater release of stress hormones and catecholamines in patients with alcoholism compared with control subjects (Moesgaard and Lykkegaard-Nielsen 1989; Tønnesen et al. 1992). Alcoholic patients are at risk for excessive surgical blood loss secondary to coagulopathy from liver disease and platelet dysfunction. Many alcoholic patients are chronically malnourished, which retards wound healing.

## Opioid Dependence

No evidence indicates that provision of appropriate doses of opiates for postoperative pain in the hospital creates addiction, yet some patients who fear becoming dependent decline or underuse postoperative opiates. If a surgical patient is receiving methadone maintenance, the dose used for maintenance should be continued throughout the surgical hospitalization. If the opioid-dependent patient does not have an established maintenance regimen, control of withdrawal can, in most cases, be achieved with methadone dosages of 10–30 mg/day. Once-daily dosing is usually sufficient to prevent withdrawal, but the total daily dose can be split into two or three doses to prevent breakthrough symptoms. If anesthesia is necessary, the anesthesiologist obviously should be provided with the history of the patient's opioid dependence. Pentazocine or other mixed agonist–antagonists such as buprenorphine are contraindicated for analgesia, because they might cause or worsen withdrawal because they compete with other opiates and block their effect.

Postoperative opiate-dependent patients require higher doses of opiates to control surgical pain because of tolerance. When such patients are given only “normal” doses, they complain of not receiving enough and often are considered to be inappropriately “drug-seeking” when in fact they are being undermedicated.

## Postoperative Delirium

Postoperative delirium is very common, particularly in elderly patients undergoing certain types of surgery such as emergency repair of hip fractures, major gastrointestinal surgery, coronary bypass graft surgery, or lung transplant. Elderly orthopedic surgery patients have been the best studied, with rates of delirium higher than 40% documented

(Galanakis et al. 2001). Estimates of prevalence among postcardiac surgery patients range from 2% to more than 30%, depending on several factors, including age, type of surgery, and whether the patient was on heart-lung bypass (Bayindir et al. 2000; Segatore et al. 1998). Delirium may be even more common and severe after certain procedures such as lung transplant (Craven 1990).

### *Risk Factors and Diagnosis*

Multiple preoperative risk factors for postoperative delirium have been identified and include older age, alcohol use, cognitive impairment (especially the dementias), chronic comorbid illnesses and medications used to treat these illnesses, the severity of the acute illness, and the type of surgery (Flacker and Marcantonio 1998; Williams-Russo et al. 1992). Postoperative changes in the sleep–wake cycle (Kaneko et al. 1997), inadequately treated pain, and use of medications such as benzodiazepines increase the likelihood of delirium.

The diagnosis of delirium is discussed in detail in Chapter 6, “Delirium,” and includes acute onset of changes in mental status, a fluctuating course, the presence of inattention, and an altered level of consciousness or disorganized thinking precipitated by a medical cause. Postoperative delirium usually is identified 2–5 days after surgery and typically, although certainly not always, resolves in about a week. Despite reliable methods for detecting delirium, it is often not diagnosed, or is misdiagnosed, particularly in the postoperative period.

### *Treatment*

Psychiatrists are often consulted on an emergency basis for patients with postoperative delirium. Management is the same as that for other deliria, starting with an attempt to identify a remediable course. Although there is a general consensus on drug treatment of postoperative and other deliria, few controlled clinical trials have been done (see Chapter 6, “Delirium”).

Recent controlled trials have examined interventions that might prevent postoperative delirium. In a Japanese study (Aizawa et al. 2002), half the patients were given diazepam for 3 days immediately following surgery to try to prevent disruption of their sleep–wake cycle; only 5% of the treated patients developed delirium compared with 35% of the nontreated group. This study contradicts the usual wisdom that benzodiazepines are contraindicated in delirium, but the diazepam was given at a particular time with the specific goal of maintaining a normal sleep–wake pattern after surgery. Tokita et al. (2001) found that better pain control through patient-controlled analgesia (compared with a fixed continuous regimen) reduced the inci-

dence of delirium following hepatectomy. Spanish investigators studied the procholinergic drug citicoline for prevention of delirium after hip fracture but found no benefits (Diaz et al. 2001).

Controlled trials of nonpharmacological interventions also have been done. Geriatric consults, compared with usual care, for elderly patients admitted for hip fracture surgery were associated with less postoperative delirium (32% vs. 50%) and even greater improvement in cases of severe delirium (12% vs. 29%) (Marcantonio et al. 2001). A Dutch study found that a nurse-led interdisciplinary psychosocial intervention program for delirium in elderly patients with hip fractures reduced the length and severity, but not the incidence, of postoperative delirium, compared with usual care (Milisen et al. 2001).

### Intensive Care Unit Psychosis

The concept of ICU psychosis emerged after Kornfeld and colleagues (1965) described a delirium that occurred in 38% of the patients in the recovery room after open-heart surgery. Their report noted several organic factors that they thought contributed to the delirium. Patients also were interviewed soon after they left the recovery room. Patients complained of lack of sleep and “the frightening environment, unusual sounds and sense of being chained” (p. 287). This article was very influential and resulted in many positive changes in the ICU environment, including adding windows (so that patients could determine whether it was day or night) and clocks within sight of the patients. It also became standard practice for the ICU staff to reorient patients and help them to understand ongoing procedures.

Despite the fact that the original authors emphasized that this was an acute organic psychosis influenced by environmental factors, the term *ICU psychosis* has come to imply that environmental factors are capable of inducing psychosis. It seems likely that environmental factors can worsen delirium caused by any of a variety of physiological factors, but psychosis resulting from solely a frightening environment occurs rarely, if ever. The danger of invoking the term *ICU psychosis* is that the underlying physiological cause of the postoperative delirium will be unrecognized and untreated. Thus, the psychiatric consultant to surgery may need to educate other medical personnel to diagnose and treat the underlying physiological cause of the delirium.

### Discontinuation of Ventilator Support

A common problem in the surgical ICU is associated with discontinuation of ventilator support (ventilator weaning).

McCartney and Boland (1994) commented, “to be in respiratory distress is to be anxious. To be mechanically ventilated is to be grossly uncomfortable at best. To undergo weaning in the presence of possible severe respiratory compromise, again, inevitably is anxiety provoking” (p. 679). The objective clinical parameters for determining physiological readiness for ventilator weaning are well known (MacIntyre et al. 2001), but much less is known about psychological readiness for ventilator weaning.

Commonsense guidelines for determining psychological readiness for weaning from mechanical ventilation have been proposed (Blackwood 2000). These parameters include ensuring that the patient is oriented to person, place, date, and circumstances; is at mental ease; and has a positive mental attitude. An experienced ICU nurse who knows the patient may be able to determine when ventilator weaning is likely to progress successfully, and the nurse also may be able to recognize early signs of anxiety that will interfere with weaning. Multiple treatments have been proposed, including relaxation techniques, biofeedback, patient education, positive reinforcement, improvement of sleep-wake cycle, and incorporation of the family into the treatment team. A promising single case report described the successful use of several of these techniques (Jacavone and Young 1998), but only one randomized clinical trial has been completed (Holliday and Hyers 1990). In that trial, a control group receiving daily visits consisting of reassurance and attention was compared with the intervention group receiving daily relaxation biofeedback. The intervention group had statistically significantly fewer days from the start of ventilator weaning to completion than did the control group (17 vs. 20 days,  $P=0.01$ ).

The effects of two drugs—midazolam (a short-acting benzodiazepine) and propofol (a sedative-hypnotic agent)—on ventilator weaning time have been widely studied. A recent meta-analysis found that among postoperative patients who had required sedation for less than 36 hours, ventilator weaning was faster with propofol (Walder et al. 2001). However, propofol was associated with an increased likelihood of hypotension and hypertriglyceridemia. An open-label study found that intravenous haloperidol might facilitate ventilator weaning, but several complications were associated with its use (Riker et al. 1994). In an open-label study of patients with DSM-IV-diagnosed depression (American Psychiatric Association 1994), methylphenidate (up to 15 mg/day) improved mood, and ventilator weaning was successful in five of seven patients treated (Rothenhausler et al. 2000). Methylphenidate was chosen because it has much faster onset of action and a shorter half-life compared with traditional antidepressants.

## Posttraumatic Stress Disorder in the Postoperative Period

In the surgical arena, PTSD has been best studied in trauma patients (especially burn patients) and motor vehicle accident victims (Klein et al. 2003), but several recent studies have shown that a significant percentage of patients also develop PTSD following cardiac surgery or neurosurgery (Powell et al. 2002; Stoll et al. 2000). Although full syndromal PTSD develops in 18%–40% of adult patients after trauma, many more develop some of the symptoms of PTSD. Children who experience traumatic disfiguring injuries seem to be at particular risk, with up to 82% having some symptoms of PTSD 1 month after the trauma (Rusch et al. 2002). Quality of life is significantly impaired in patients who develop PTSD posttrauma or postsurgery compared with patients who do not develop PTSD (Zatzick et al. 2002).

Several studies have tried to identify factors that predict the emergence of PTSD (for review, see Tedstone and Tarrrier 2003). As expected, better prior emotional adjustment and social support are relatively protective. However, contrary to expectation, the severity of the injury, or the severity of the illness requiring surgery, is not clearly correlated with the emergence of PTSD. Also, alcohol intoxication or concussion at the time of the trauma seems to decrease the likelihood of PTSD (perhaps because memory for the event is impaired). Furthermore, some patients with no apparent predisposing factors develop PTSD. The course of PTSD is not completely clear, but symptoms usually appear within the first week after a trauma and increase in intensity over the next 3 months. Perhaps the best predictor of PTSD at 1 year is the presence of symptoms during the acute hospitalization after a trauma (Zatzick et al. 2002). Although most studies show that symptoms decrease by 1 year, many patients continue to meet full criteria, and many more still have symptoms.

Diagnosis of acute stress disorder, PTSD's predecessor, can be difficult in surgical trauma or postoperative patients who manifest symptoms of delirium. For the diagnosis of PTSD, the duration criterion is often not met in hospitalized patients because of relatively brief hospital stays. Almost all patients who meet full criteria will have nightmares, but among patients with only some symptoms, the cluster of symptoms likely to be affected varies. For example, female burn victims with facial burns have been reported to have predominantly avoidance and emotional numbness symptoms (Fukunishi 1999), whereas re-experiencing and startle symptoms are more likely in other burn patients (Ehde et al. 1999).

Treatment of PTSD in medical settings is covered in Chapter 12, "Anxiety Disorders." Few studies of treatment

of PTSD have been done specifically in surgical patients, but general principles appear applicable. Cognitive-behavioral therapy (CBT) has been shown to be more effective than a waiting-list control condition or supportive psychotherapy for PTSD among motor vehicle accident survivors (Blanchard et al. 2003). There is general agreement (although not much evidence) that psychotherapy should be the primary treatment of trauma-related PTSD in children and that the selective serotonin reuptake inhibitors should be adjunctive (Putnam and Hulsmann 2002).

## Postoperative Pain

Unrelieved postoperative pain is still reported to be a common clinical problem, which may be related to inadequate routines for pain assessment (Sjostrom et al. 1997). Postoperative pain management remains suboptimal on surgical wards in many countries despite the availability of effective analgesics. New technologies for drug administration and clinical practice guidelines for pain management are now available (Stomberg et al. 2003). The appropriate and optimal use of analgesics is essential for the adequate management of postoperative pain. Greer and colleagues (2001) concluded that fear of addiction is not prevalent among postoperative patients, yet clinician education can further decrease the proportion of surgical patients who fear addiction to pain medication.

During the 1990s, the Joint Commission on Accreditation of Health Care Organizations (JCAHO) studied patterns of pain assessment and management and found that pain often was not recognized and was inadequately treated when it was diagnosed. Multiple reasons for this were identified, including an inappropriate fear of addiction. It was repeatedly documented that many doctors and nurses based clinical practice on myths and misconceptions about pain medications rather than on evidence-based research. Education was attempted to ensure that pain medication was used appropriately, but prescribing patterns did not change (see Summers 2001 for review of the development of these guidelines); consequently, the 1999–2000 JCAHO standards of pain management practice were modified (Curtiss 2001) (see also Chapter 36, "Pain").

## Body Image and Surgery

Body image is the inner mental experience of one's body, with a neurological substrate, also influenced by prior life events and interactions with important people. All of the senses contribute to body image, but touch and kinesthesia are probably the most important. Whereas body image

develops throughout life, the changes that occur during childhood, and particularly during adolescence, are relatively enduring. Nonetheless, there can be wide fluctuations in the experiencing of one's body, even over a few minutes. Adaptations to the new realities of the body (including aging, trauma, and surgical alteration) can occur, but a host of factors influence how readily these changes are incorporated. In three important surgical areas, body image is key to patient outcome: 1) amputation and the phenomenon of phantom limb pain; 2) change in body image that may occur after trauma or surgery, including cosmetic surgery; and 3) body image concerns in bariatric surgery patients.

Phantom limb is the experience of feeling as if an amputated part is still present. It was first described by Ambrose Paré (1649), a seventeenth-century surgeon. In the United States, more than 200,000 surgical amputations occur each year. Up to 70% of these patients experience phantom limb pain immediately after the amputation, and 50% still experience it 5 years later (Bloomquist 2001). The general agreement is that avoiding as much pain as possible prior to amputation decreases the likelihood of phantom limb pain, but other factors contribute as well. For example, phantom limb pain in burned children is more common after electrical injuries than after thermal injuries (Thomas et al. 2003). The exact etiology of both phantom limb and the pain that often accompanies it is complex and poorly understood. The body is schematically represented in the sensory motor cortex of the brain as a homunculus in which the hands and feet (among the most common body parts amputated) have more neural connections than do other body parts. Although investigations are studying the relation between phantom limb pain and various neural pathways, much remains to be understood. The occurrence of phantom limb pain has been shown to be associated with poorer health-related quality of life (van der Schans et al. 2002).

Body image can change after trauma or surgery. Trauma, as in the case of burn injuries, may cause dramatic changes in the body that require significant adaptation and integration of the changes into a new body image. However, the ease with which this integration occurs is influenced more by premorbid adjustment and stage of development than by the actual total body surface area burned. Among changes that occur following surgery, recent work has shown that the type of surgery may influence body image outcome. For example, total abdominal hysterectomy is associated with greater body image dissatisfaction than is vaginal hysterectomy because of the abdominal scar (Gutl et al. 2002).

The literature on body image in obesity is extensive. Stunkard and Burt (1967) studied body image in obese in-

dividuals who had lost significant weight. They found that these patients often misperceived themselves as still large and frequently had negative attitudes toward this misperception. The definition of body image in patients with eating disorders has evolved to divide body image into perceptual and attitudinal aspects. Most current studies of body image following bariatric surgery focus on one part of the attitudinal aspect of body image called *body satisfaction*.

## General Determinants of Functional Outcome

---

Functional outcome includes the ability to carry out the activities of daily living, the ability to function in one's usual role, and satisfaction with life. These areas are currently being explored under the category of quality of life. Perhaps the most interesting finding is that the actual severity of the underlying trauma or surgery does not necessarily determine quality of life. For example, the total body surface area burned does not directly correlate with the likelihood of PTSD nor does the size of a scar necessarily correlate with posttrauma adjustment. It has been repeatedly reported that an adequate social support system is positively correlated with postsurgical and posttrauma adaptation.

A confluence of factors determines functional outcome. These factors include the condition requiring surgical intervention, presurgical psychiatric status, and surgical strategy. Other factors that may improve outcome include preparation of the patient and family for surgery, detection and management of preoperative fears, respectful attitude of the surgeon and operating room personnel during surgery, detection and appropriate treatment of pain, and detection and management of various psychiatric problems following surgery, including delirium and PTSD.

## Specific Topics in Surgery

---

### Burn Trauma

The experience of being seriously burned and the treatment that follows for the survivors is one of the most frightening and painful known to humanity. Perhaps because of this, several important concepts in psychiatry and medicine have been learned from the study of burn victims. For example, Erich Lindemann (1944/1994) described the evaluation and treatment of survivors, friends, and relatives of people who died in the Coconut Grove

fire. He identified five major symptoms of normal grief: somatic distress, preoccupation with the image of the deceased, guilt, hostile reactions, and loss of patterns of conduct. These concepts continue to guide the detection and management of normal and pathological acute grief in burn units and elsewhere.

Imbus and Zawacki (1977) opened an ethical debate over prolongation of life that continues today. An unusual aspect of burns is that even mortally burned patients often have a lucid period that lasts for a few hours during which patients can participate in making decisions about their own care. For every severely burned patient, these investigators searched the literature to determine whether cases of survival had been reported, and, if not, they offered the patients a choice between a full therapeutic regimen and palliative care. They concluded that the mortality rate did not change but that this strategy increased the autonomy of patients and increased the empathy that they received. This report ignited a controversy that has grown to encompass all critical care: when is treatment futile, and who should decide?

In the United States, annually, thermal burns result in 1 million injuries, 4,500 deaths, 700,000 emergency department visits, and 45,000 general hospital admissions, half of which are to specialized burn centers (American Burn Association 2003). Patients with major burns should be treated in burn centers (Heimbach 2002). At present, the American Burn Association (1999) lists 139 burn care facilities in the United States and 17 in Canada. During the past 40 years, interdisciplinary burn centers have emerged, staffed by physicians, nurses, physical and occupational therapists, pain specialists, mental health professionals, social workers, and chaplains. Typically, the burn center is directed by either a general surgeon or a plastic surgeon.

### *Psychiatric Disorders Among Burn Patients*

Many burn patients have preexisting psychiatric disorders, the most common of which are substance use disorders and mood disorders. The classic studies of adults by Andreasen and colleagues (1972) and of children by N.R. Bernstein (1976) led to the recognition that psychiatric problems are very common among burn patients. It is now known that about 35% of patients have an Axis I psychiatric disorder prior to the burn injury (Powers et al. 2000) and that 20%–30% of patients (many of whom do not have preexisting psychiatric disorders) develop full syndromal PTSD while in the hospital or after discharge (Powers et al. 1994b; Yu et al. 1999). In addition, many patients have preexisting maladaptive coping mechanisms or dysfunctional families, and these factors are known to contribute to poor functional outcomes.

The best-studied psychiatric topics in burn care include substance use disorders (particularly alcohol use), self-immolation, and PTSD. The neuropsychiatric consequences of electrical burn injuries also have been studied (Kelley et al. 1999). There are a few reports on the long-term psychiatric and functional consequences of burns in both children and adults. Several studies have tried to compare preburn adjustment and/or immediate postburn psychiatric status with outcome. The meaning and psychological importance of burn scars (particularly of the face, hands, and genital area) have been studied as well. Equally important in burn care is the delirium that frequently occurs during the acute-care phase. Psychiatric consultants also have described effective methods for the management of pain in burn patients (N.R. Bernstein 1976; Watkins et al. 1992).

One method of conceptualizing the psychiatric problems seen in burn patients is to envision a time sequence from preexisting psychiatric problems to problems that develop after the patient leaves the hospital. Thus, there are preexisting psychiatric disorders and psychosocial problems (including those that have resolved but may be rekindled by the trauma), problems that occur at the time of the injury, problems that emerge during acute hospitalization, and psychiatric disorders that develop after discharge from the hospital. The most common psychiatric problems at each time point are illustrated in Table 30–1.

**Burns and substance use disorders.** Preinjury substance use disorders are common among burn victims. One study found that among 727 deaths from fires, blood alcohol assays were positive in 29%, with a mean blood-ethanol level of 193.9 mg/dL; 14.6% of the victims studied had positive results for other substances of abuse (Barillo and Goode 1996). Although 40% of the fatalities were in people younger than 11 or older than 70, 75% of the drug-positive and 58% of the ethanol-positive fatalities were in people between ages 21 and 50. The authors concluded that substance use disorders are a particular risk factor for death from fires in the middle-aged sector of the population.

Among patients who survive to be treated, several studies have attempted to identify the prevalence of alcohol intoxication, alcohol abuse, or alcohol dependence. One study (J.D. Jones et al. 1991) found that 27% were intoxicated at the time of the burn, and 90% of these were then identified as having an alcohol abuse diagnosis compared with 11% of the nonintoxicated burn patients. Other reports estimated the prevalence of alcohol abuse and dependence in patients with burn injuries between 6% and 11% (Powers et al. 1994a; Tabares and Peck 1997). However, L. Bernstein and colleagues (1992) reported

**TABLE 30-1. Phase of injury**

	<b>Resuscitative</b>	<b>Acute</b>	<b>Convalescent</b>
<b>Setting</b>	Emergency department, intensive care unit, burn unit	Intensive care unit, burn unit	Hospital ward, home, rehabilitation facility
<b>Surgical care</b>	Fluid resuscitation, maintenance of vital signs, urine output, debridement of necrotic tissue, antibiotic therapy	Debridement, skin grafting and reconstructive surgery, physical therapy	Skin grafting and reconstructive surgery, physical therapy, occupational therapy
<b>Patient response</b>			
Physiological	Shock, initial decrease in renal function and increase in hepatic metabolism, varied acute serum protein changes with net decrease	Stabilization of vital signs with persistent hypermetabolism, increase in renal clearance, and decrease in hepatic oxidative metabolism; variable presence of bone marrow suppression	Hypermetabolic response present up to 1-2 years
Endocrine	Dramatic increase in endorphins, corticosteroids, and catecholamines	Persistent elevation in corticosteroids, decrease in endorphins	Unknown
Psychological	Denial, projection	Regression, mourning, coping	Coping, adjustment, transition to home
Psychiatric	Substance withdrawal, delirium, cognitive disorders, posttraumatic stress disorder	Pain syndromes, posttraumatic stress disorder, secondary mood disorders, adjustment disorders, delirium	Adjustment reactions, mood disorders, posttraumatic stress disorder, marital/family/work problems, alcohol abuse
<b>Family response</b>	Shock, denial, anticipatory mourning	Mourning, coping, anger, emotional support of patient	Adjustment and acceptance, transition to home and work
<b>Psychiatric interventions</b>	Pharmacotherapy, liaison with family and burn team	Psychotherapy, pharmacotherapy, behavior therapy	Psychotherapy, pharmacotherapy, marital and group therapies

*Source.* Adapted from Bernstein LF: "Burn Trauma," in *Psychiatric Care of the Medical Patient*, Second Edition. Edited by Stoudemire A, Fogel B. New York, New York, Oxford University Press, 1993. Copyright 1993 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

that screening for alcohol problems with the usual blood screen or physician evaluation missed 70% of the patients who had positive test results for alcoholism on the CAGE questionnaire. Steenkamp and colleagues (1994) found that 57% of the patients had evidence of alcohol problems on the Michigan Alcoholism Screening Test, and of these patients, 57% thought that the use of alcohol had contributed to the accident.

Among burn patients who are identified as having alcohol or drug problems, referral for treatment occurs in fewer than half of the patients (Powers et al. 1994a), and among those who are referred, fewer than half accept treatment (Tabares and Peck 1997). Denial is a key defense mechanism in patients with substance use disorders, but the crisis of a burn trauma may be an opportunity to broach this defense. Psychiatrists (and other mental health consultants) on the burn unit are often in a unique posi-

tion to help burn patients relinquish the denial that prevents appropriate treatment. Alcohol use has been found to be associated with increased total body surface area burned, an increased likelihood of death, longer length of hospital stay, and, consequently, increased medical costs (J.D. Jones et al. 1991; Powers et al. 1994a).

Withdrawal symptoms from alcohol dependence are probably common during the acute-care phase but may be difficult to distinguish from other causes of delirium. The few available studies on this topic are case reports or case series. The best approach in a burn unit may be a standard withdrawal protocol with a relatively long-acting benzodiazepine (e.g., chlordiazepoxide). Because 90% of intoxicated burn patients abuse alcohol, and because the development of alcohol withdrawal can be particularly dangerous in a burn patient, a liberal approach to prescribing the withdrawal regimen among patients suspected of alcohol

dependence is probably the safest course of treatment. Although intermittent administration of benzodiazepines, especially the short-acting types such as lorazepam, has been advocated, so many problems in the acute phase of burn care may obscure the presence of withdrawal symptoms that this may not be wise. Haloperidol is frequently added to the regimen for psychotic symptoms during withdrawal but should not be used alone.

Even though burn patients have a high rate of preexisting drug abuse, withdrawal from narcotics is less likely because most patients require narcotic treatment for pain. However, it is helpful to remember that these patients may require a larger dose of narcotics to suppress pain, and this larger dose should be provided.

**Self-inflicted burn injuries.** The frequency of self-immolation varies widely from nation to nation. In India, for example, ritual self-immolation is a common problem (32% of married women with lethal burn injuries have self-inflicted the burn). Multiple sociopolitical problems (Kumar 2003) contribute to this high rate of self-immolation among married women in India. In Zimbabwe, 22% of the adult burn patients have been reported to have self-immolated; most of these patients are married women, and the most common reason for self-immolation is conflict in a love relationship (Mzezewa et al. 2000).

In the United States, the frequency of self-inflicted injuries among patients who are admitted to a burn center ranges from 0.067% to 9% (Daniels et al. 1991; Scully and Hutcherson 1983). Although political and cultural motivations for self-immolation may predominate in some cultures, in the United States, most severely burned patients admitted to burn centers have a preexisting Axis I psychiatric disorder, including major depression or schizophrenia. Substance abuse appears to increase the likelihood of a severe self-inflicted injury. Not all of these patients are actually suicidal. Patients with schizophrenia may be responding to command hallucinations.

Among patients who have inflicted less severe burns, personality disorders are common (Cameron et al. 1997), especially borderline personality disorder. The patient may continue to self-injure in the hospital and thereby pose a difficult management problem. The psychiatric consultant is often able to defuse these problems with judicious use of behavioral strategies known to be helpful for patients with borderline personality disorder (Wiechman et al. 2000). Close supervision may be required to prevent further self-harm when the patient moves from an ICU to a unit with less nursing supervision.

Patients who have self-inflicted their burn injuries often elicit intense countertransference reactions from the entire staff, including the psychiatric team. It is helpful to

remember that most patients seen in the burn center who have self-inflicted their injuries have a chronic mental illness and that many patients cannot access appropriate psychiatric care. Burn center teams understand chronic medical illness and the need for expert treatment, and this "medical model" analogy may help them better understand and empathize with a patient who has chronic mental illness and who has self-inflicted a burn injury.

**PTSD in burn patients.** PTSD occurs in a significant minority of patients who have been burned. Estimates range from 21% to 43% (Ehde et al. 2000; Powers et al. 1994b). The difficulties in estimating frequency were discussed earlier and are related to the confounding effects of delirium and the duration criterion requirement of 1 month. Many patients have been discharged from the hospital before a month elapses, and less severely injured patients may not be seen again, and thus a formal diagnosis is not made. Nonetheless, many patients do develop the full syndrome of PTSD, and many more have symptoms in the reexperiencing cluster even though they do not meet the other criteria. Some patients also have PTSD symptoms related to their treatment, especially the extreme pain inflicted during debridement and dressing changes. Some patients also remember psychotic experiences during the delirium that often occurs during the initial acute phase of treatment, and these memories may elicit symptoms of PTSD.

Several attempts have been made to identify factors that predispose to the emergence of PTSD in burn patients, but researchers have been unable to show an association between preinjury Axis I diagnoses and the emergence of PTSD. Fauerbach and colleagues (2000) found that the personality characteristic of neuroticism increased risk and that high extroversion was protective. Six independent risk and protective factors for PTSD were identified from assessments of 127 burn victims trapped in a ballroom fire (Maes et al. 2001). The odds of developing PTSD were increased with the number of previous traumas, a history of simple phobia, and a sense of loss of control. In contrast, odds were decreased with a sense of control, alcohol consumption, and alcohol intoxication. The duration of PTSD symptoms appears to be lengthy. For example, Taal and Faber (1998) found that 33% of 428 burn patients in the Netherlands continued to have PTSD symptoms 14–24 months after their injury.

Treatment of PTSD in burn patients is similar to treatment of PTSD in other patients and includes psychotherapeutic techniques and medication. Increasing a sense of control and alleviating pain in patients when they are being treated at the burn center also may prevent some PTSD symptoms.

**Delirium and psychosis in burn patients.** Delirium during the acute care of severely burned patients is common, although this topic has not been thoroughly studied. In one unpublished report, one-fourth of the burn patients were noted to be psychotic during their initial acute hospitalization. Most of these patients had delirium related to sepsis, pain medication, or other organic factors (Powers 1996). Other causes of delirium in burn patients include hypoxia from smoke inhalation and massive fluid shifts and electrolyte imbalance, especially hyponatremia and hypophosphatemia. The psychotic symptoms that occur most often include hallucinations (often visual and not always distressing) and delusions. The delusions are often paranoid and frequently involve nursing care personnel. Because patients with delirium are disoriented, they frequently misinterpret events and then suspect treatment personnel of malevolent intent. It is often difficult to distinguish between pain, agitation, anxiety, and confusion in the ICU, and the psychiatric consultant is invaluable in this differentiation. The principles of treatment of delirium in the burn unit are the same as described earlier for postoperative delirium (see subsection "Postoperative Delirium").

### ***Burn Pain Management***

Pain in burn care arises from both the pain from various procedures, including dressing changes and burn wound debridement, and the background pain of the injury itself. The key concept in managing pain on the burn unit is to recognize that it is often undertreated, and this can result in worsening delirium, anxiety, and other management problems. Pain is undertreated for many reasons, but the most important reasons are an unrealistic fear of addiction (both by the patient and by the physician) and fear of respiratory compromise (which, at least in the intensive care portion of most burn centers, can be adequately managed by a knowledgeable, alert nursing staff). Burn wound debridement (in which the eschar is removed) is an excruciatingly painful procedure, and various techniques are now available to alleviate much of the pain. When sharp debridement (involving use of a scalpel) is needed, general anesthesia offers the greatest relief of pain and also may facilitate a more thorough debridement (Powers et al. 1993). Parenteral narcotics, especially intravenous morphine, is often preferable for blunt debridement (in which scalpels are not used) and dressing changes. A common error is not waiting the 10–15 minutes required for adequate distribution after intravenous injection before beginning blunt debridement. Intramuscular injections are often contraindicated because they may add to the pain, and sufficient injection sites may not be available.

The background pain of burn injuries is best managed with oral narcotics whenever possible. Fentanyl is often helpful for intermittent pain because it is short acting and will allow the patient to be awake to participate in various rehabilitation activities. Meperidine is usually contraindicated because it is relatively ineffective orally and may aggravate delirium. Benzodiazepines are often used to promote sedation and reduce anxiety, but the optimal dose is not known. They are often used inappropriately to treat pain. If pain is adequately managed and the patient has anticipatory anxiety, use of benzodiazepines is then very helpful.

### ***Treatment of Burns in Children***

Several psychosocial research teams have been particularly interested in the treatment of burned children (Martin-Herz et al. 2003; Stoddard et al. 2002). These groups have emphasized the importance of the developmental stage of the burned child and the need for careful age-appropriate assessment and treatment of pain and anxiety. Emerging studies indicate that appropriate management of pain partially predicts the long-term outcome for the child. For example, one study found that receiving higher levels of morphine in the hospital was associated with fewer PTSD symptoms at follow-up 6 months later (Saxe et al. 2001).

A guideline has been proposed for the management of pain and anxiety in children (Stoddard et al. 2002). It is based on intensity of care, whether the pain is background or procedural pain, and stage in the hospital (see Table 30–2). In designing this guideline, the focus was on safe, effective medications; a limited formulary; and nursing strategies to assess pain (with age-appropriate ratings). The guideline also was designed to contain explicit recommendations. This guideline has been used in a series of 125 pediatric patients and was associated with excellent to adequate control of both pain and anxiety in most patients most of the time. One major advantage of the guideline is that the most-recommended drugs (morphine and lorazepam) are well known to most physicians. Only the use of intravenous infusion of midazolam for background anxiety in mechanically ventilated acutely ill pediatric patients would require an anesthesiologist or a critical care specialist.

Although many psychological treatments may ultimately prove to be effective for children, several are not. For example, imagery-based interventions do not seem to help, and having a parent in the room during procedures seems to make the experience worse for the child (and probably for the parent) (Foertsch et al. 1998).

Several studies have attempted to assess outcome in burned children. On the basis of rather brief follow-ups of

**TABLE 30–2. Guidelines for pain and anxiety management in children with burns**

Patient category	Background pain	Background anxiety	Procedural pain	Procedural anxiety	Transition to next clinical state
Category 1: mechanically ventilated acute	Morphine sulfate intravenous infusion	Midazolam intravenous infusion	Morphine sulfate intravenous bolus	Midazolam intravenous bolus	Wean infusions 10%–20% per day and substitute nonmechanically ventilated guideline
Category 2: nonmechanically ventilated acute	Scheduled enteral morphine sulfate	Scheduled enteral lorazepam	Morphine sulfate enteral or intravenous bolus	Lorazepam intravenous or enteral bolus	Wean scheduled drugs 10%–20% per day and substitute chronic guideline
Category 3: chronic acute patient	Scheduled enteral morphine sulfate	Scheduled enteral lorazepam	Morphine sulfate enteral bolus	Lorazepam enteral bolus	Wean scheduled and bolus drugs 10%–20% per day to outpatient requirements and pruritus medications
Category 4: reconstructive surgical patient	Scheduled enteral morphine sulfate	Scheduled enteral lorazepam	Morphine sulfate enteral bolus	Lorazepam enteral bolus	Wean scheduled and bolus drugs to outpatient requirement

small groups of children, some have concluded that children do not develop significant long-term psychological or behavioral problems (e.g., Kent et al. 2000). However, in the thoughtful report by Stoddard et al. (1992), the rate of long-term depression in children appeared to be high. One important confounding factor is that many children who are burned have preexisting psychosocial problems that influence long-term outcome. Other factors accounting for the discrepancy in findings include differences in patient populations and the hypotheses and study methodologies. A better understanding of the long-term course of burned children will require multisite studies with larger numbers of children sharing similar characteristics.

### **Psychiatric Practice Guideline for Adults With Acute Burns**

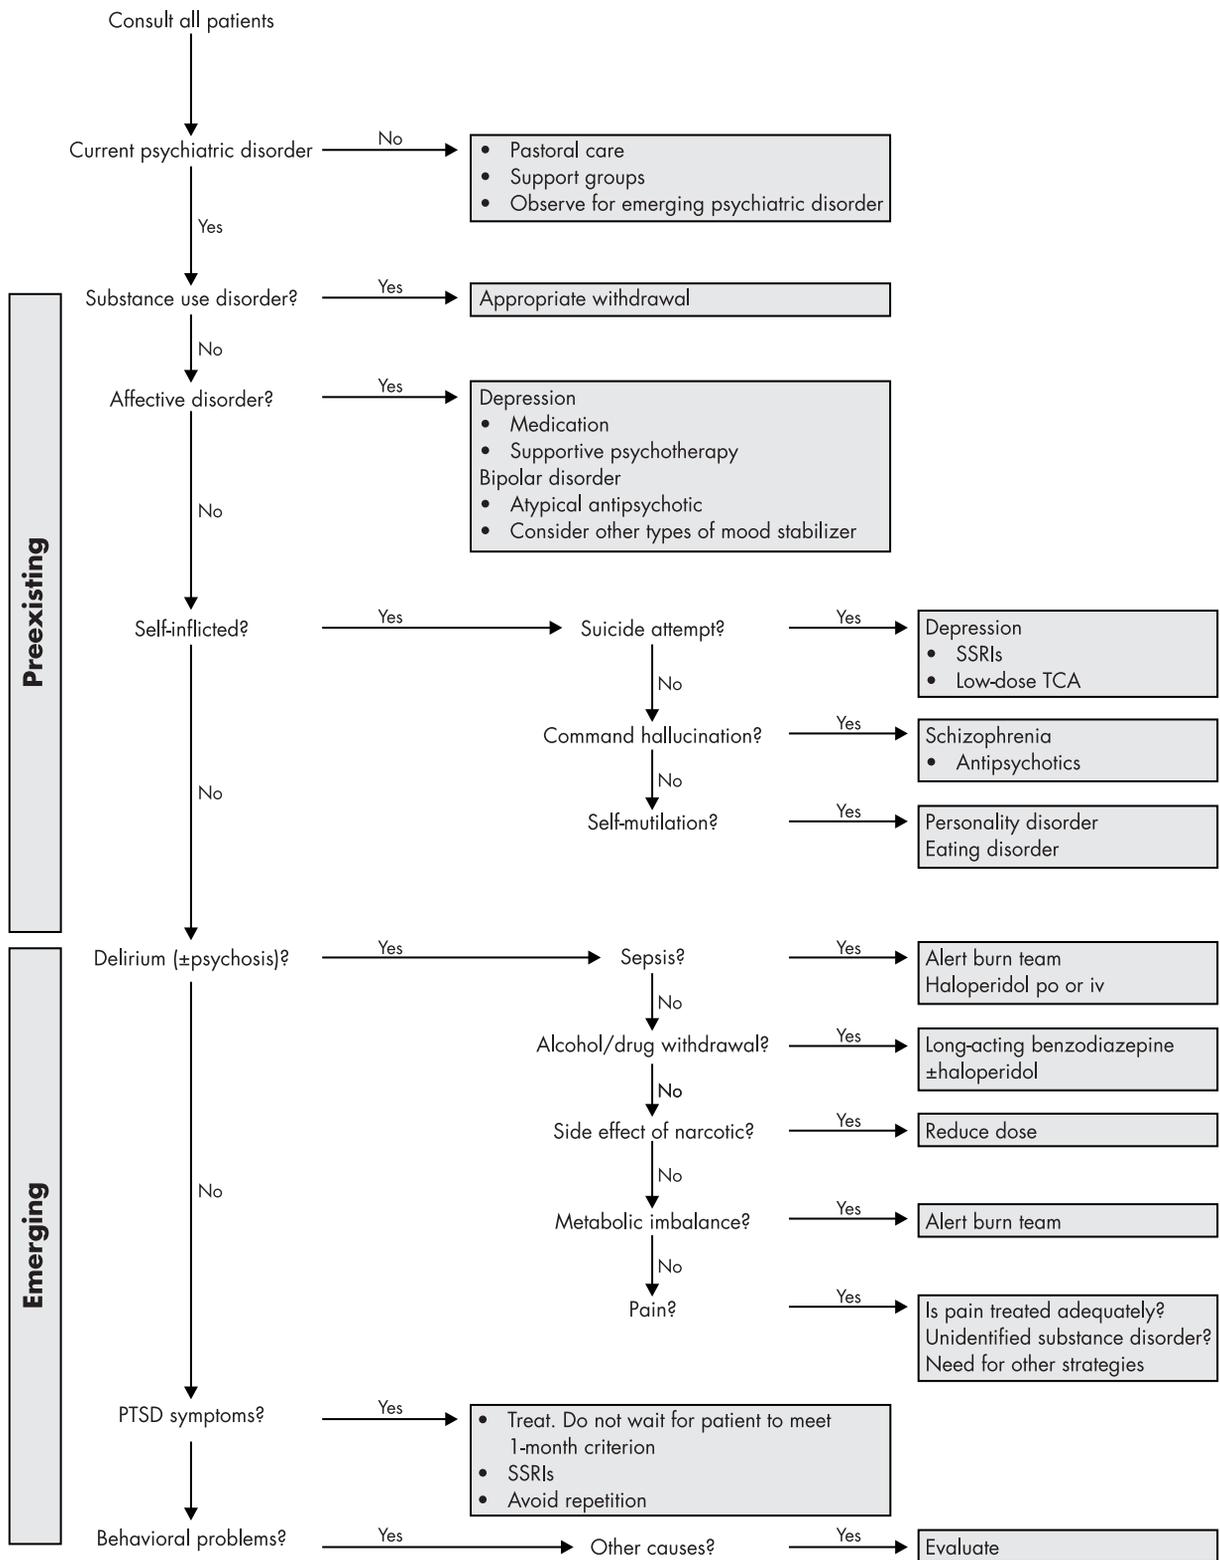

Although the evidence base is sparse, consensus guidelines have been developed for several areas of burn care, and a practice guideline has been proposed for the management of adult psychiatric disorders in burn patients during their initial hospitalization (Powers 2002). Figure 30–2 is an algorithm designed to guide the clinician in assessment and management of the burn patient with psychiatric problems.

### **Facial Disfigurement and Scars**

The adaptation to facial disfigurement depends, in part, on the age at which the disfigurement occurs. Children with congenital disfigurement often encounter significant developmental difficulties and are frequently stigmatized by peers, adults, and health care personnel. These problems may be incorporated into an enduring negative sense of self. If the child has a strong social support system and receives well-informed physiological and psychological care, these problems can be mitigated.

The adjustment to facial disfigurement also depends on the patient's preexisting personality and mental defense mechanisms. In his classic book, N. R. Bernstein (1976) described variables critical to adaptation, including adaptive versus maladaptive defenses; active coping versus passive surrender; loving exchange versus rage; leading and co-managing treatment versus resisting treatment; and denial versus overawareness. For example, a patient who participates in managing his or her own care; who has a flexible, extensive repertoire of mental defense mechanisms; and who has loving exchanges with friends and family is likely to make a successful adjustment to facial disfigurement.

Irrespective of the cause of facial disfigurement, the objective nature of the disfigurement usually is not correlated with the patient's self-perception. For example, among

**FIGURE 30-2. Algorithm for the initial psychiatric assessment of the burn patient during the initial acute hospitalization.**

*Note.* PTSD=posttraumatic stress disorder; SSRI=selective serotonin reuptake inhibitor; TCA=tricyclic antidepressant.

50 patients who received extensive multidisciplinary treatment from birth to age 18 years for cleft palate, no correlation was found between the objective measure of the residual deformities and the patient's subjective judgment of the remaining deformity (Vegter and Hage 2001). Thus, the subjective assessment of the deformity is probably more important than the actual nature of the deformity in determining quality of life. Other factors that are important include proneness to shame, body image, and self-esteem (Van Loey and Van Son 2003).

Scars that develop after burn injuries can be very extensive. Scar tissue is different from normal skin and has an aberrant color, a rough surface texture, increased thickness, and decreased pliability and may be associated with pain or pruritus. Assessment of the various treatments for scars (including surgical treatments) has been limited by the difficulty in scar measurement. Developments in computer imaging may eventually permit the objective measurement of scars (Powers et al. 1999b; Tsap et al. 1998). However, even when better physiological treatments of scars are available, the subjective experience of the scar appears to be more important than the actual physical characteristics of the scar. Sarwer and colleagues (1998) reported that a subset of patients who underwent surgical revision of their scars had a level of dissatisfaction consistent with body dysmorphic disorder.

Despite the recognition that the *emotional* experience of the facial disfigurement is one of the primary determinants of quality of life, little research is available on possible interventions. An interesting pilot study titled "Changing Faces: The Way You Face Disfigurement" was conducted by a lay group (available at: <http://www.changingfaces.co.uk>). They found that among a group of nurses managing patients with burns or with head and neck cancer, a 1-day skills training course improved their confidence so that they could provide psychosocial rehabilitation care to these patients (Clarke and Cooper 2001). These researchers also sent a self-help leaflet to half of a group of patients who had facial disfigurement and found that, compared with a group of control subjects who did not receive the leaflet, the intervention group reported decreased anxiety and depression.

## Trauma Victims of Terrorist Attacks

The psychological consequences of trauma or disaster may include a variety of clinical symptoms, including a disruption of homeostasis, a shattering of ego integrity, and a feeling of fright and being overwhelmed (Figley 1978; Wilkinson 1983).

The federal disaster mental health approach in the United States was developed largely out of experiences

with natural disasters. The 1995 Oklahoma City, Oklahoma, bombing and the events of September 11, 2001, highlighted how little we know about the provision of services in the aftermath of mass trauma caused by humans.

The United States federal approach emphasizes crisis intervention, support services, triage, referral, outreach, and public education for affected individuals (Center for Mental Health Services 1994; Myers 1994). The federal program concluded that although many individuals may have psychological reactions to a natural disaster, few actually develop diagnosable mental disorders significant enough to warrant more than crisis intervention, brief treatment, or supportive therapy (Flynn and Nelson 1998; Myers 1994). However, in the Oklahoma City bombing, 6 months after the incident, 45% of the sample had an active psychiatric disorder, and one-third had PTSD (North et al. 1999).

Experiences in Oklahoma City suggest that large-scale disasters caused by humans may result in greater psychiatric impairment of direct victims than do natural disasters (North et al. 1999). In a developing field like disaster mental health, in which experience is expanding faster than research and in which we are faced with events for which models were not designed, the learning curve is both steep and incomplete.

Consulting psychiatrists will be most effective directing their efforts toward disaster victims in their hospital's emergency department, medical-surgical units, and ICUs. The psychiatry consultation-liaison service at Walter Reed Hospital Army Medical Center provided an immediate mental health response to hospitalized victims of the Pentagon attack on September 11, 2001, and at follow-up, some patients remembered this intervention better than other aspects of their burn care (Wain et al. 2002). The practice of "critical incident stress management" has become widespread despite empirical studies that have raised concerns about both efficacy in preventing PTSD symptoms and the possibility of worsening such symptoms.

## Pelvic Surgery

### *Hysterectomy*

In patients who have undergone hysterectomy, four stages in the experience have been described (Krouse 1990):

1. The recognition/exploration stage centers on the discovery of symptoms and diagnosis.
2. The crisis/climax stage occurs when treatment is initiated.
3. The adaptation stage occurs after treatment.
4. The resolution/disorganization stage concerns the long-term sequelae.

Guilt, embarrassment, anxiety, isolation, fear, and denial of the disease are hallmarks of the first stage of the hysterectomy experience, whereas anxiety, depression, altered body image, and concerns about changing relationships characterize the second stage. Many women associate the uterus with femininity, the sex drive, sexual attractiveness, and status as a wife or mother. Thus, for some women, a hysterectomy leads to impaired self-image and self-esteem. If concerns about the quality of the marital relationship and the deleterious effect of surgery on sexual functioning arise, they must be addressed. Anxiety and depression are common and should be addressed (see also Chapter 33, "Obstetrics and Gynecology").

### ***Gynecological Cancer***

Gynecological cancer treatment leads to deterioration of sexual functioning in 30%–35% of patients in terms of sexual motivation, arousal, and orgasm. Prognostic variables include previous sexual behavior, partner-related factors, availability of education and counseling, dyspareunia, postcoital bleeding, estrogen deprivation, and vaginal stenosis or shortening. The magnitude of the surgery and psychosocial factors (including presurgical body image, pretreatment libidinal level, anxiety, attitude toward sex role, and age) contribute to postsurgical adjustment (Weigman-Schultz and van de Wiel 1992) (see also Chapter 17, "Sexual Disorders").

### ***Prostatectomy***

In prostatectomy, the frequency of postsurgical impotence and incontinence dramatically affects quality of life. Libman and colleagues (1991) reported that prostatectomy often has a negative effect on erectile function, particularly in older men. Rossignol et al. (1991) evaluated the effect of radical prostatectomy on 429 patients and found that those who were satisfied with their postsurgical sexual life were younger and had normal sexual function prior to the surgery. Braslis et al. (1995) concluded that despite fairly drastic complications (incontinence and impotence) and associated distress, radical prostatectomy is a well-accepted procedure (see also Chapter 17, "Sexual Disorders").

### ***Ostomies***

Patients with stomas face many problems, both physical and psychosocial. Anxiety and embarrassment over a stoma may lead to an alteration in lifestyle and overall self-image (Nugent et al. 1999). Successful adjustment to colostomy depends on education for ostomy self-care, psychosocial support to help accept the changes in body image, and a social support network (Piwonka and Merino 1999).

In colostomy patients, Wade (1990) reported that physical symptoms such as fatigue, nausea, diarrhea, flatulence, urinary incontinence, and stoma complications were associated with higher levels of distress. Unmarried men were more likely to enjoy better emotional health than married men and women, and this may be related to pressure to perform sexually among married men. A study by Kelly (1991) found that malfunction of the stoma, skin damage, and poor healing of the perianal wound add their toll to an already trying situation and interfere with functioning and, sometimes, identity. Accidental leakage, or the fear thereof, may limit activity or travel. Anger, depression, and anxiety are common.

Several bothersome aspects of caring for ostomies, with resulting changes in daily routines, troublesome side effects, and embarrassing accidental leakage, further stress the patient's resilience and coping skills (Thomas et al. 1988). The studies of psychosocial complications are limited by retrospective designs, small sample sizes, variable lengths of postoperative follow-up, high proportions of nonrespondents, and untested validity and reliability of the assessment tools used.

### ***Management Strategies After Pelvic Surgery***

Pelvic surgery is often associated with pain, changes in body image, self-image distortions, and fear of becoming dependent or abandoned. Patients also fear possible sexual and reproductive changes. Patients undergoing these types of surgery are at risk for poor psychosocial outcome in terms of psychological distress, limitation of activities, and sexual adjustment. Patients and physicians may feel uncomfortable discussing sexual matters, and concerns about sexual functioning may be minimized. This may create severe distress postoperatively. Patients should be fully informed about the sexual effects of surgery, provided ample opportunity to ask questions, and provided assistance in coping with the aftermath of the surgery (see also Chapter 17, "Sexual Disorders").

### ***Bariatric Surgery***

The National Heart, Lung, and Blood Institute (1998) clinical guidelines define *extreme obesity* as a body mass index (BMI) greater than 40 kg/m<sup>2</sup>. BMI is a calculated number attained by dividing weight in kilograms by height in meters squared. Extreme obesity is also called *morbid obesity* because it is associated with high premature morbidity and mortality, most commonly as a result of complications of type 2 diabetes mellitus, hypertension, hyperlipidemia, or sleep apnea. Multiple treatments have been tried for morbid obesity, but clearly the most effective is bariatric surgery (Fisher and Schauer 2002). The

current weight criterion for bariatric (or obesity) surgery is a BMI greater than 40 or a BMI greater than 35 with life-threatening comorbidities. Fifteen million people in the United States, or 1 out of 20 people, have a BMI of 35 kg/m<sup>2</sup> or greater (Buchwald and Buchwald 2002).

Bariatric surgery works in one of two ways: 1) by restricting a patient's ability to eat (restrictive procedures) and 2) by interfering with absorption of ingested food (malabsorptive procedures). Although more than five bariatric procedures are currently performed, the Roux-en-Y gastric bypass (RYGBP) and the laparoscopic adjustable gastric banding (LAGB) with the LAP-BAND system (INAMED Health, Santa Barbara, CA) are the most widely used. The RYGBP combines restriction and malabsorption principles and results in greater weight loss than the previously popular vertical banded gastroplasty (so-called stomach stapling) that was purely a restrictive procedure. The restrictive element of the RYGBP involves creation of a small gastric pouch with a small outlet; the malabsorptive element involves bypass of the distal stomach, the entire duodenum, and about 20–40 cm of the proximal jejunum. The LAGB is a purely restrictive procedure and involves placement of a silicone band around the upper stomach. The two procedures are illustrated in Figures 30–3 and 30–4.

In the bariatric surgery field, there has been a strong effort to standardize reports of weight loss following surgery by using either percent initial excess weight loss or percent initial BMI loss. Both the RYGBP and the LAGB result in approximately 33%–34% initial BMI loss at 1 year (Buchwald 2002; Fox et al. 2003). Weight loss continues during the next year, but not all weight loss is maintained during the next 5–10 years. These results mean that the average patient has a meaningful weight loss but does not achieve ideal body weight; that is, morbid obesity is exchanged for moderate obesity. Perhaps the most important question is whether bariatric surgery results in improvement in the usual physiological complications of morbid obesity. The evidence for significant and sustained improvement in type 2 diabetes mellitus is strong (Greenway et al. 2002), and, although less impressive, reduction in hypertension and improvement in lipid metabolism usually occur.

### ***Psychosocial Aspects***

Multiple studies have attempted to identify psychosocial predictors of outcome after bariatric surgery. Early studies of the vertical banded gastroplasty procedure found no relation between presurgical psychiatric diagnoses or presurgical eating pathology and degree of weight loss at follow-up (Powers et al. 1997, 1999a). This does not allow one to conclude that psychopathology will have no influ-

ence on postoperative adherence and outcome because 1) published studies are not large enough to examine the effect of each specific psychiatric disorder, and 2) patients with severe psychiatric disorders tend not to be referred by their physicians to bariatric surgeons.

More recent studies have convincingly shown that many measures of psychopathology and quality of life improve after bariatric surgery (Bocchieri et al. 2002; Guisado et al. 2002). In addition, one study showed that patients who received preoperative brief strategic therapy (average six sessions) had a greater weight loss at 1 year after LAGB than did patients who did not receive this therapy (Caniato and Skorjanec 2002).

Despite these very encouraging findings, it is worth remembering that some patients who might benefit substantially from the surgery (in terms of both weight loss and quality of life) do not receive it. Examples include patients with schizophrenia or bipolar disorder, whose obesity may have been caused by psychotropic medications. Many surgeons exclude these patients because of early reports in the literature of negative outcomes and concerns about whether they would comply with postoperative requirements. Finally, some health insurers refuse to cover, or make access difficult to, bariatric surgery.

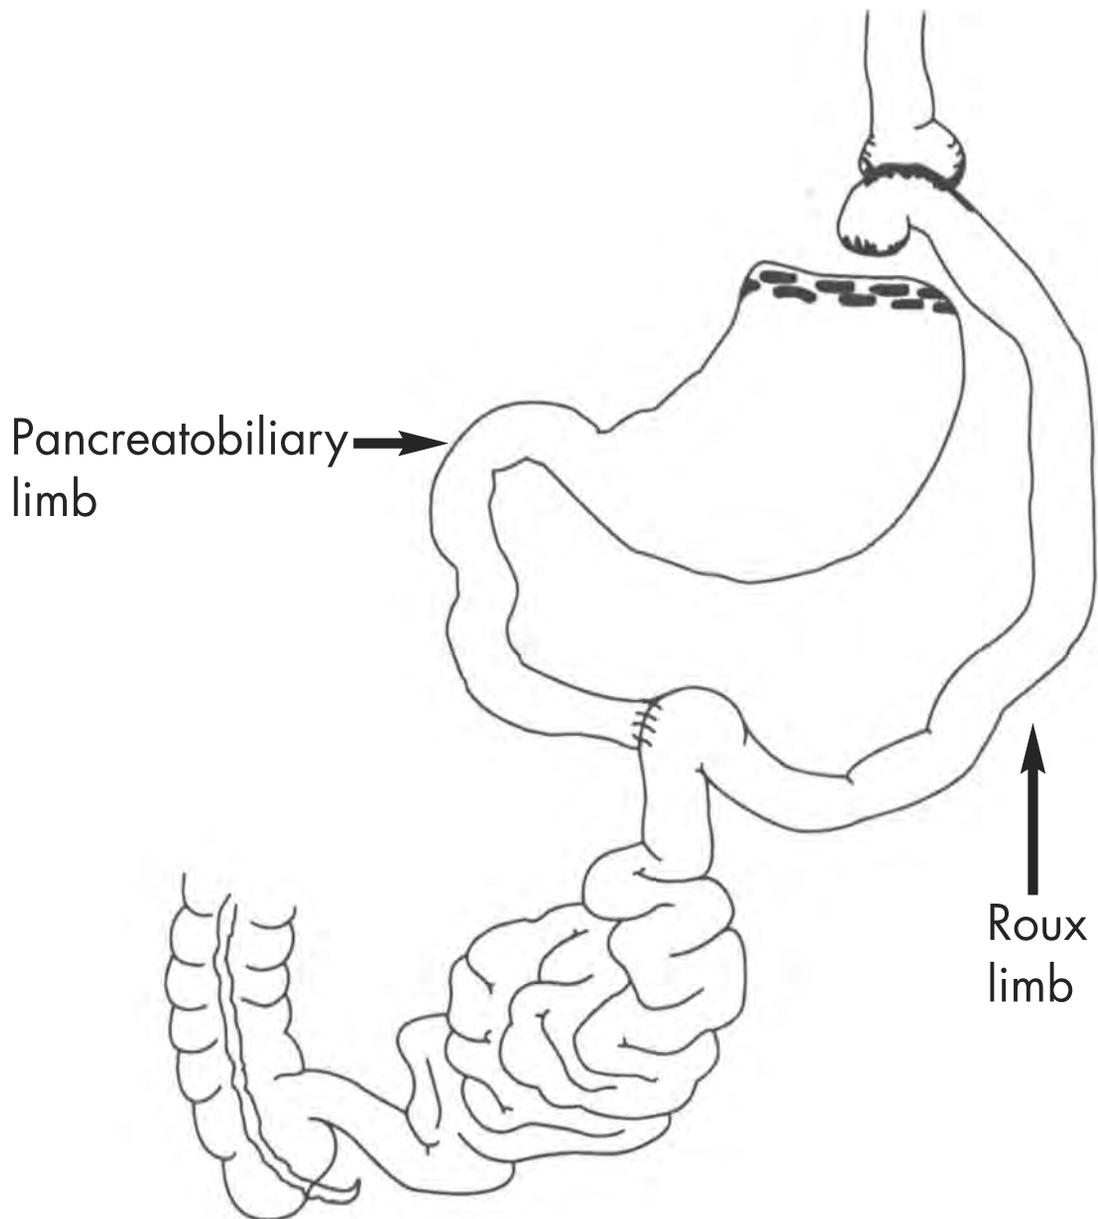

### ***Eating Disorders and Bariatric Surgery***

Presurgical binge-eating disorder occurs among 16%–33% of the patients who have bariatric surgery, and an even greater percentage binge eat (i.e., they have subsyndromal binge-eating disorder) (Powers et al. 1999a; Saunders 1999). These figures are significantly higher than those reported in the general population. Presurgical night-eating syndrome also appears to be more common among bariatric surgery patients than in the general population (Kuldau and Rand 1986). Although binge eating is usually absent after surgery, vomiting is frequent after vertical banded gastroplasty, and this may result from failed attempts to binge (Powers et al. 1999a). In other cases, such vomiting may represent a continuation of conditioned vomiting in patients who had frequently purged before surgery. However, before postgastroplasty vomiting is attributed to a behavior, a mechanical cause (i.e., overly restrictive anatomy) should be ruled out.

### **Ophthalmological Surgery**

#### ***Cataract Surgery***

Early reports by psychiatric consultants of “black patch” psychosis following cataract surgery ushered in studies of complications following eye surgery (Weisman and Hackett 1958). The initial reports focused on the sensory deprivation that occurred after bilateral cataract removal

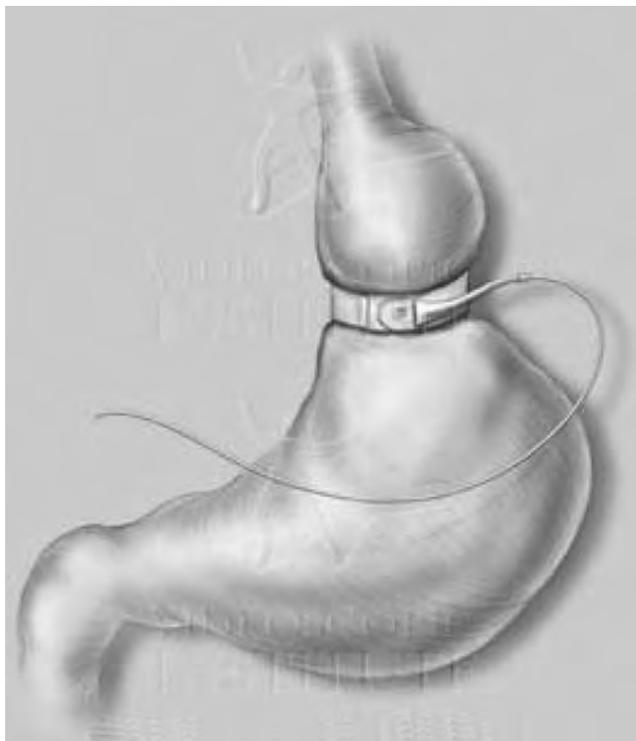

**FIGURE 30-3. Diagram of Roux-en-Y gastric bypass.**

*Source.* Reprinted from Neven K, Dymek M, leGrange D, et al.: "The Effects of Roux-en-Y Gastric Bypass Surgery on Body Image." *Obesity Surgery* 12:265–269, 2002. Used with permission.

and initially led to recommendations that only one eye be operated on at a time. Subsequently, "black patch" psychosis was identified as a postoperative delirium that was relatively uncommon. Milstein and colleagues (2002) found that following cataract surgery, 4.4% of 296 patients had an immediate postoperative delirium according to the Confusion Assessment Method (Inouye 1998), a standardized measure of delirium. Factors found to be statistically associated with postoperative delirium included very old age (82 years compared with 73 years) and frequent preoperative use of benzodiazepines.

Although cataract surgery is commonplace, relatively little is known about whether expectations of the surgery are fulfilled. One study (Tielsch et al. 1995) found that only 61% of the patients achieved or surpassed their preoperative expectations of visual function after cataract surgery. Those patients least likely to achieve their preoperative expectations were older (older than 75 years) and more likely to have ocular comorbidities. Preoperative counseling about realistic visual functional outcome is likely to be helpful in decreasing disappointment after surgery.

**FIGURE 30-4.** Diagram of laparoscopic adjustable gastric banding (LAGB) with the LAP-BAND system (INAMED Health, Santa Barbara, CA).

Cataract surgery usually is performed in an outpatient setting, and typically either topical or regional anesthesia is used. These anesthetic approaches usually result in the patient being aware during the surgery, and patients often have visual experiences. In the last few years, these experiences have been studied, and the nature of the visual experiences probably depends on the varying degrees of optic nerve blockade that result from the different anesthetics (Tranos et al. 2003). Visual experiences during cataract surgery are the norm: most patients see light; some see various colors (especially red and yellow); and a minority see vague movements, instruments, and the surgeon's hands (Au Eong et al. 1999). Almost all patients (93%) find these visual experiences acceptable, but 4% find them unpleasant, and 3% are frightened by the experiences (Prasad et al. 2003). Preoperative counseling and inclusion of the possibility of these experiences in the written informed consent for surgery have been recommended. A controlled study (Moon and Cho 2001) found that handholding during cataract surgery decreased both anxiety and epinephrine levels.

### *Stigma and Eye Abnormalities*

Facial expression and eye contact are critically important in interpersonal relationships. Thus, abnormalities are

likely to significantly influence quality of life. Several recent studies have confirmed this. For example, Bullock and colleagues (2001) showed pictures of patients with blepharoptosis and dermatochalasis to subjects without such abnormalities and asked them to rate the person in the picture on several dimensions, including friendliness, trustworthiness, mental illness, and happiness. After surgical correction of these eye abnormalities, the ratings of the pictures by the healthy subjects improved significantly.

In another study, patients with serious childhood-onset strabismus (before age 5 years) were evaluated at ages 15–25 years prior to corrective surgery (Menon et al. 2002). Eighty-five percent of the males and 75% of the females reported social problems caused by their continuous squint; they had been ridiculed at school and work, they had greater difficulty obtaining employment, and many avoided social activities. After corrective surgery, more than 90% reported improved self-confidence and self-esteem.

### *Eye Removal*

Self-removal of the eye (autoenucleation) is a form of self-mutilation that occurs very uncommonly (Shiwach 1998). When it does, the patient is usually psychotic and often has religious preoccupations associated with a literal interpretation of the Bible (“and if thy right eye offend thee, pluck it out, and cast it from thee”; Matthew 5:28–30). Conjoint management of the patient by ophthalmologists and psychiatrists is crucial, especially because some patients reinjure themselves later.

Eye gouging, an assaultive eye injury, also has been reported in a series of 10 patients (Bukhanovsky et al. 1999). Among the perpetrators, 4 were psychotic, 1 was mentally retarded, and 5 committed the act during extreme sexual violence.

### *Cosmetic Surgery*

In an age and a culture in which people have increased interest in physical attractiveness, cosmetic surgery has dramatically increased. In 1998, more than 132,000 women had breast augmentation procedures in the United States (Sarwer et al. 2000). Early studies of cosmetic surgery found that patients with psychiatric problems were common among cosmetic surgery candidates. Findings from more recent studies suggest that because more people consider cosmetic surgery a reasonable choice, the percentage of applicants with psychiatric disorders may be relatively lower. Most patients do well with cosmetic surgery, although it is thought that so-called type changes (e.g., rhinoplasty) require more extensive psychological

adjustments than do restorative changes (e.g., face-lifts) (Castle et al. 2002).

Age at the time of cosmetic surgery is also important; it may be easier to incorporate changes into body image during childhood or adolescence. Cosmetic surgery is usually helpful in adolescents with a true defect if they are selected carefully and if genuine informed consent is obtained before surgery (McGrath and Mukerji 2000).

Because quality of life is significantly influenced by body image, a philosophical question raised by the increased number of aesthetic surgeries is whether cosmetic surgery should be considered medically necessary. The focus on possible negative body image changes after life-saving surgeries for illnesses such as breast cancer has resulted in trials comparing the effectiveness (in terms of survival) of less disfiguring surgeries with that of more radical approaches. A persuasive argument can be made that improvements in body image and self-esteem may dramatically improve quality of life.

### ***Preoperative Assessment***

Even though the percentage of patients with psychiatric disorders may be lower among patients seeking aesthetic surgery than in previous decades, the percentage is probably still higher than among most other surgical candidates. Several research groups have attempted to determine which patients should not have cosmetic surgery at all and which patients should have psychiatric treatment before aesthetic surgery. A series of questions designed to detect psychiatric problems has been proposed (Grossbart and Sarwer 1999). One problem in determining who is likely to benefit from cosmetic surgery is that no widespread accepted method is available for determining patient satisfaction with the surgical results. Ching and colleagues (2003) reviewed the literature and suggested specific measures of body image and quality of life likely to provide valid evidence concerning the question of who should receive surgery.

### **Body Dysmorphic Disorder**

Body dysmorphic disorder also has been called the *disorder of imagined ugliness*. Patients with body dysmorphic disorder frequently consult plastic surgeons for correction of trivial or nonexistent defects. The diagnostic criteria include impairment in functioning, in addition to preoccupation with an imagined defect in appearance not accounted for by another mental disorder. The prevalence of body dysmorphic disorder is unknown but in clinical mental health settings is under 5% (American Psychiatric Association 2000). Phillips and her colleagues (Phillips 1991; Phillips and Dufresne 2002) have been in-

strumental in showing that body dysmorphic disorder is relatively common and that treatment should be psychiatric, not surgical. There are case reports of patients with body dysmorphic disorder becoming violent toward surgeons or committing suicide in a dermatology setting (Cotterill and Cunliffe 1997). Current promising nonsurgical treatments include selective serotonin reuptake inhibitors in addition to cognitive-behavioral strategies (Hollander et al. 1999; Phillips and Dufresne 2002) (see also Chapter 13, "Somatization and Somatoform Disorders").

### **Conclusion**

Psychiatric problems occur in a significant minority of surgical patients. We have discussed common problems that occur during the preoperative, intraoperative, and postoperative periods. Preoperatively, issues around capacity and consent are important, as well as planning for the surgical and postoperative management of psychiatric disorders known to be present. Preoperative anxiety is common, and appropriate treatment can improve postoperative recovery. Psychiatric reactions to intraoperative recall can often be ameliorated through careful preparation for surgery. Postoperatively, delirium is a key issue, often related to alcohol or drug withdrawal syndromes. Postoperative pain, problems related to discontinuation of ventilator support, and PTSD are common reasons for psychiatric intervention. An awareness of specific issues that can arise in burn care, pelvic surgery, bariatric surgery, ophthalmological surgery, and cosmetic surgery is also important.

**THE BENEFIT OF** solid organ transplantation was realized in 1954 when Dr. Joseph E. Murray performed the first successful kidney transplant, with the patient's identical twin as donor. However, for most patients an identical-twin donor was not an option, and more than a decade passed before immunosuppressive medications were available to conquer the immunological barrier. In 1967, the first successful liver transplant was performed, followed a year later by the first successful heart transplant. Yet despite the fact that the surgical challenges of solid organ transplantation had been overcome, it was not until the early 1980s, with the advent of improved immunosuppression, that organ transplantation changed from an experimental procedure to a standard of care for many types of end-stage organ disease.

In that decade, the National Organ Transplant Act established the framework for a national system of organ transplantation, and the United Network of Organ Sharing (UNOS) was contracted by the U.S. Congress to administer the nation's only Organ Procurement and Transplantation Network (OPTN) (United Network of Organ Sharing 2004). Currently, UNOS administers the OPTN under contract with the U.S. Department of Health and Human Services. In addition to facilitating organ matching and placement, UNOS collects data about every transplant performed in the United States and maintains information on every organ type (e.g., wait-list counts, survival rates) in an extensive database available on the OPTN Web site (<http://www.OPTN.org>) (United Network of Organ Sharing 2004).

Although immunological barriers still exist for transplant recipients, the greatest obstacle to receiving a transplant is the shortage of donated organs. The number of wait-listed individuals is increasing far beyond the avail-

ability of donated organs. As illustrated in Figure 31-1, the numbers of wait-listed patients for kidney (the most frequent) and liver transplants increased steadily between 1995 and 2001 (United Network of Organ Sharing 2004). By contrast, the numbers of patients waiting for heart, lung, and pancreas transplants increased only marginally during the same period. The median wait-listed time depends on the organ type, the blood type of the recipient, and the severity of the recipient's illness at the time of listing. For example, as of 2001, the median wait time for a heart transplant candidate initially listed as a category heart status 2 was 374 days, whereas that for a liver transplant candidate listed as a UNOS 2B was 282 days (United Network of Organ Sharing 2004). Figure 31-2 shows the numbers of transplant recipients in 2001 for each solid organ type (United Network of Organ Sharing 2004), which ranged from a low of 924 for lung to a high of 11,502 for kidney. These numbers are much lower than the 2001 wait-listed values, and ratios of transplant recipients to wait-listed patients are lowest for kidney, liver, and lung (about 1:4 to 1:5). Each year, 10%–15% of liver, heart, and lung transplant candidates will die while on the waiting list (United Network of Organ Sharing 2004). Additionally, posttransplantation graft survival rates can be significantly lower (e.g., 36.4% kidney and 45% liver graft survival after 10 years) than patient survival rates, which means that many transplant recipients will have to face a second transplant 5–10 years after their first (Figure 31-3) (United Network of Organ Sharing 2004).

These stark facts highlight the enormous stresses facing transplant candidates, transplant recipients, and their caregivers. These issues have also created a particular environment in which hospitals must evaluate, treat, and se-

Source. United Network of Organ Sharing (UNOS; <http://www.optn.org>).

lect patients for organ transplantation. The scarcity of donated organs has driven efforts to select candidates believed to have the best chance for optimal posttransplant outcomes. Additionally, the organ shortage has increasingly led to the consideration of living kidney donors and, more recently, living liver donors (and, more rarely, living lung donors) as transplantation options.

Pretransplant psychosocial evaluations are commonly requested to assist in candidate and donor selection, and psychiatric consultation is often needed for clinical input during the pre- and posttransplant phases. Although a wide body of knowledge has been developed in the clinical care of transplant candidates and recipients, little longitudinal research is available to answer questions about long-term outcomes or the impact of psychiatric factors (assessed pretransplant and/or in the early years posttransplantation) on outcomes. Research primarily has focused on kidney, heart, and liver transplantation, which in combination currently account for almost 90% of transplants performed in the United States.

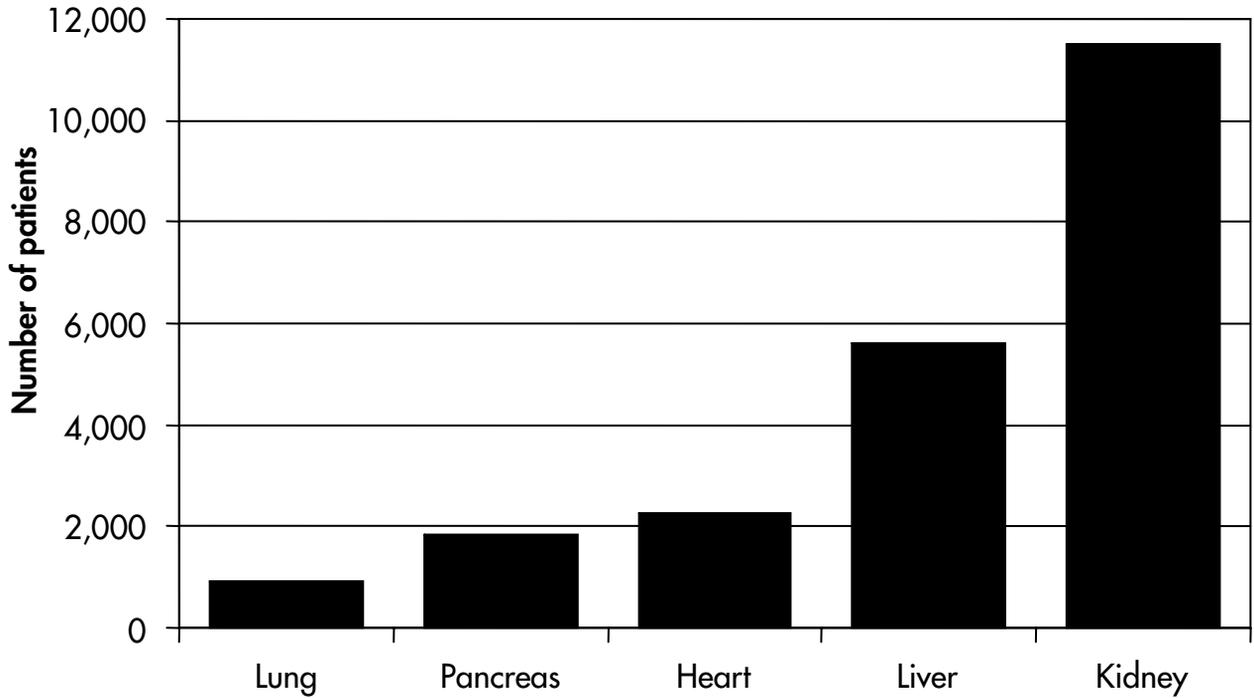

In this chapter, we outline the essential areas of the field for psychosomatic medicine specialists and other mental health clinicians involved in the care of transplant pa-

tients—pretransplant assessment and candidate selection, emotional and psychological aspects of the transplant process, therapeutic issues, patients with complex or controversial features, psychopharmacological treatment, and neuropsychiatric side effects of immunosuppressive medications. Special pretransplantation topics of emerging importance to psychosomatic medicine specialists are also discussed (i.e., hepatic encephalopathy, ventricular assist devices in heart transplantation, tobacco use, and living donors). The neuropsychiatric sequelae of end-stage organ disease are not covered in this chapter, because those aspects are addressed in the respective chapters on each organ system. Specific transplant issues are also discussed in Chapter 19, “Heart Disease”; Chapter 20, “Lung Disease”; Chapter 22, “Renal Disease”; and Chapter 34, “Pediatrics.”

## Pretransplantation Issues

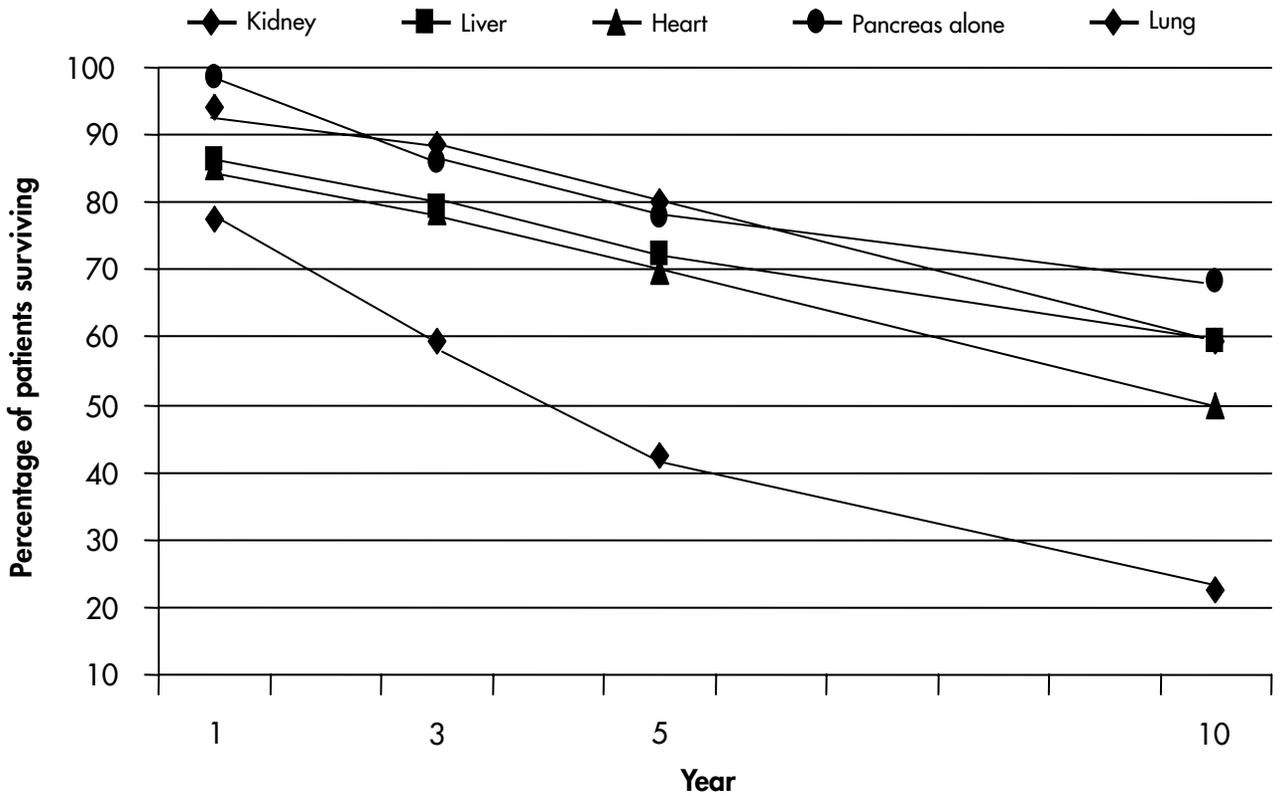

### Psychosocial/Psychiatric Assessment

Pretransplant psychosocial evaluations have been a traditional role of the psychiatric consultation team in the

**FIGURE 31-2.** Numbers of transplant recipients in 2001, by organ type.

transplantation process. These evaluations are frequently used to assist in the determination of a candidate's eligibility for transplantation, to identify psychiatric/psychosocial problems that may need to be addressed to prepare the candidate and family for transplantation, and to identify pre- and posttransplant psychiatric and/or psychosocial needs of the candidate. These evaluations are also critical for the identification of psychiatric, behavioral, and psychosocial risk factors that may portend poor transplant outcomes (Crone and Wise 1999; Dew et al. 2000b).

Transplant programs will often refer for evaluation candidates with a known history of psychiatric problems or those who are identified during the initial clinical interviews with the transplant team as having such problems. Pretransplant psychosocial evaluations are also usually requested for patients with substance use disorders (including tobacco) and other poor health behaviors (e.g., obesity, noncompliance).

Although a truly comprehensive assessment of a potential transplant candidate would require a full psychiatric consultation, the current high numbers of candidates preclude this. To handle the increasing volume of evaluations, some centers employ screening batteries of patient-rated measures to identify candidates with elevated levels of psychological distress, who then undergo a full psychiatric evaluation. Screening instruments can provide baseline cognitive, affective, and psychosocial ratings for candidates; use of these instruments maximizes staff resources and minimizes costs. For example, using this strategy, Jowsy et al. (2002) identified 20%–44% of liver transplant candidates who had mild to severe symptoms on a range of measures, which prompted a higher level of evaluation.

Emerging evidence shows that preoperatively assessed psychosocial variables can predict posttransplantation psychiatric adjustment among recipients of most organ types (Dew et al. 2000b). These variables are increasingly being investigated as contributing to medical outcomes as well, although a consistent predictive effect has not yet been demonstrated (Dew et al. 2000b). Thus, psychosocial assessment of transplant candidates provides an opportunity to identify potential problems and intervene prior to transplantation, with the goal of improving posttransplant outcomes. Transplant programs vary considerably in their psychosocial assessment criteria and procedures (see Olbrisch and Levenson 1995 for a review of methodological and philosophical issues); in general, however, psychosocial evaluations have 10 objectives (although a given assessment may not include all 10), as enumerated in Table 31–1 (see Levenson and Olbrisch 2000).

---

**TABLE 31–1. Goals of psychosocial screening**

---

1. Assess coping skills; disqualify or intervene with patients who appear to be unable to cope effectively.
  2. Diagnose comorbid psychiatric conditions; provide for pre- and posttransplant monitoring and treatment.
  3. Determine the candidate's capacity to understand the transplant process and to provide informed consent.
  4. Evaluate the candidate's ability to collaborate with the transplant team and to adhere to treatment.
  5. Assess substance use/abuse history, recovery, and ability to maintain long-term abstinence.
  6. Identify health behaviors that may influence posttransplant morbidity and mortality (i.e., tobacco use, poor eating or exercise habits) and evaluate the candidate's ability to modify these behaviors over the long term.
  7. Help the transplant team to understand the patient better as a person.
  8. Evaluate the level of social support available to the candidate for pre- and posttransplant phases (including stable family/others committed to assisting the candidate, adequate insurance and financial resources, and logistical support).
  9. Determine the psychosocial needs of the patient and family and plan for services during the waiting, recovery, and rehabilitation phases of the transplant process.
  10. Establish baseline measures of mental functioning in order to be able to monitor postoperative changes.

Because information on all of these domains may not be obtainable during a single clinical interview, a follow-up reassessment may be necessary to clarify relevant issues, solidify a working relationship with the patient and family, and resolve problems. A multidisciplinary approach is often used with input from psychiatrists, psychologists, psychiatric nurse clinical specialists, addiction specialists, social workers, transplant surgeons, and transplant coordinators to construct a comprehensive picture of the patient and develop a coordinated treatment plan. As with any psychiatric evaluation, verbal feedback provided to the patient and family will serve to solidify the expectations of the transplant team and the requirements of the patient for listing if indicated. Some centers also use written "contracts" to formalize these recommendations (Cupples and Steslowe 2001; Stowe and Kotz 2001). In difficult cases, these contracts serve to document expectations, thereby minimizing misinterpretation. Written contracts outline a treatment plan that can be referred to with each follow-up appointment. These contracts are

particularly useful with transplant candidates who have alcohol or substance abuse/dependence problems, specifying the transplant program's requirements for addiction treatment, monitoring of compliance (e.g., documented random negative blood alcohol levels), and length of abstinence (see subsection "Alcohol and Other Substance Use Disorders" later in this chapter).

## Psychosocial Instruments and Measures

Transplant-specific (e.g., Psychosocial Assessment of Candidates for Transplant [Olbrisch et al. 1989], Transplant Evaluation Rating Scale [Twillman et al. 1993]), disease-specific (e.g., Miller Health Attitude Scale for cardiac disease [Miller et al. 1981], Quality of Life Questionnaire—Chronic Lung Disease [Guyatt et al. 1987]), and disorder-specific (e.g., High Risk Alcohol Relapse Scale for alcoholism [Yates et al. 1993]) instruments have been used to evaluate transplant candidates and monitor their posttransplant recovery. These instruments have been used in conjunction with general instruments for rating behavior, coping, cognitive and affective states, and quality of life. Psychosocial instruments can be used to identify individuals who require further assessment (as described earlier) or to pursue evaluation of patients already identified as requiring additional screening. The evaluator's purpose for using such instruments will determine the type and specificity of the instruments chosen; for instance, in the subsection "Hepatic Encephalopathy" later in this chapter, we discuss the use of neuropsychiatric tests to aid in the identification of cognitive impairment. Some instruments are more applicable to transplant populations than others. For example, although there are many instruments and measures for assessing alcoholism, none of these instruments are tailored to transplant candidates; they are focused on general issues of detection and treatment of addiction rather than on issues important in evaluating appropriateness for transplantation.

Because psychosocial selection criteria differ significantly by program and organ type, development and use of structured evaluation instruments may help to direct and standardize the transplant selection protocols used nationally. The two instruments most commonly used to assess candidates for transplantation are the Psychosocial Assessment of Candidates for Transplantation and the Transplant Evaluation Rating Scale.

The Psychosocial Assessment of Candidates for Transplantation (PACT) was the first published psychosocial structured instrument specifically designed for screening transplant candidates (Olbrisch et al. 1989). It provides an overall score and subscale scores for psychological

health (psychopathology, risk for psychopathology, stable personality factors), lifestyle factors (healthy lifestyle, ability to sustain change in lifestyle, compliance, drug and alcohol use), social support (support system stability and availability), and patient educability and understanding of the transplant process. The PACT can be completed in only a few minutes by the consultant following the evaluation but requires scoring by a skilled clinician, without which the instrument's predictive power could be diminished (Presberg et al. 1995). The final rating for candidate acceptability is made by the clinician, with the freedom to weigh individual item ratings variably (Presberg et al. 1995). Thus, a single area, such as alcohol abuse, could be assigned greater weight and thus could disproportionately influence the final rating.

The PACT has been used to predict mortality in bone marrow recipients (independent of age, gender, or diagnosis), as well as to predict hospital lengths of stay following liver transplantation (Levenson et al. 1994). Its "risk for psychopathology" subscale identifies psychopathology that may require referral and treatment after liver, heart, and bone marrow transplantation (Levenson et al. 1994).

The Transplant Evaluation Rating Scale (TERS) is used to rate patients' level of adjustment in 10 areas of psychosocial functioning: prior psychiatric history, DSM-III-R Axis I and Axis II diagnoses, substance use/abuse, compliance, health behaviors, quality of family support, prior history of coping, coping with disease and treatment, quality of affect, and mental status (Twillman et al. 1993). In one study, the TERS was significantly correlated with several clinician-reported outcome variables (compliance, health behaviors, substance use), with particularly high correlations between pretransplant TERS scores and posttransplant substance use ( $r=0.64$ ) (Twillman et al. 1993). The instrument requires administration by a skilled clinician to maintain accuracy (Presberg et al. 1995). The TERS summary score is derived from a mathematical formula in which individual item scores are multiplied by theoretical, predetermined weightings.

Although individual candidates do not always easily fit within one of the three categories of each item on the TERS, the TERS has more items than the PACT, a feature that may prove useful in future research (Presberg et al. 1995). However, the PACT is the more flexible of the two instruments, both in the range of rating individual items and in the manner in which the summary score is determined (Presberg et al. 1995). Together, these instruments are useful in the organization of patient information and can be helpful both as tools for increasing the evaluator's understanding of the candidate and for research purposes.

## The Unique Role of the Psychiatric Consultant

Unlike in most psychiatric interviews, the psychiatrist performing the pretransplant assessment primarily serves the needs of the transplant team rather than those of the patient (a possible exception is the evaluation of living organ donors; see subsection “Living Donor Transplantation” later in this chapter). The psychiatric consultant must be candid with the patient about this role. Careful delineation of specific transplant-related expectations, explanation of the importance of these requirements to the success of transplantation, and exploration of the implications of these criteria for the individual candidate serve to establish a meaningful dialogue with the patient from which the therapeutic alliance necessary for future intervention can develop.

For the clinician, the seemingly reverse nature of this role can be uncomfortable or even anxiety provoking. This is especially true if the clinician is not recommending the candidate for transplantation. Fortunately, many programs do not reject patients outright for psychosocial reasons; rather, they offer such patients the opportunity to work to bring their problematic areas into compliance with the recommendations (i.e., through addiction counseling, behavioral changes, psychiatric treatment, identification of appropriate social supports) and then undergo reevaluation for candidacy. In these cases, the psychiatric consultant can often function as an advocate for the patient and assist in referral for appropriate treatment if indicated. Nevertheless, some patients will be unable to comply with the specified transplant requirements or will not survive to complete their efforts to meet candidacy requirements.

Philosophical, moral, ethical, legal, and therapeutic dilemmas are inherent in the role of transplant psychiatrist, as conflicting team opinions present themselves in the course of work with potential transplant candidates. Team discussions and consultation with other colleagues are the rule in complicated cases. In these instances, team discussions not only aid in resolving candidacy quandaries but also can help alleviate team members' anxiety and discomfort over declining a patient for transplantation. Group or team debriefing may also be desirable, and occasionally consultation with risk management and the legal department of the hospital is needed (e.g., when a candidate is challenging candidacy requirements or the candidacy decision of the transplant team). Thorough documentation is essential in order to delineate the issues involved, the expectations of the team for transplantation candidacy, and the efforts to work with the patient.

## Psychological and Psychiatric Issues in Organ Transplantation

---

### Psychiatric Symptoms and Disorders in Transplant Patients

Similar to other medically ill populations, transplant candidates and recipients experience a significant amount of psychological distress and are at heightened risk of developing psychiatric disorders. The prevalence rates of major depression range from 4% to 28% in liver transplant patients, 0% to 58% in heart transplant patients, and 0.4% to 20% in kidney transplant patients (Dew 2003; Dew et al. 2000b). The range of rates for anxiety disorders appears to be 3% to 33% (Dew 2003; Dew et al. 2000b), but there are not enough studies to identify specific types of anxiety disorders. One study found that 10% of a cohort of heart or lung transplant recipients experienced posttraumatic stress disorder (PTSD) related to their transplant experience (Köllner et al. 2002). In a prospective study of 191 heart transplant recipients, the cumulative prevalence rates for psychiatric disorders during the 3 years posttransplantation were 38% for any disorder, including 25% with major depression, 21% with adjustment disorders, and 17% with PTSD (Dew et al. 2001a). Factors that increased the cumulative risk for psychiatric disorders included a pretransplant psychiatric history, a longer period of hospitalization, female gender, greater impairments in physical functioning, and fewer social supports (Dew et al. 2001a).

Several studies have suggested an association between psychiatric disorders and transplant health outcomes, although the results have been mixed. A study of wait-listed liver transplant candidates found that candidates with Beck Depression Inventory (BDI) scores higher than 10 (64% of patients) were significantly more likely than non-depressed candidates to die while awaiting transplantation (Singh et al. 1997). The higher BDI scores were due more to psychological distress than to somatic symptoms. However, for candidates who reached transplantation, pretransplant depression was not associated with poorer posttransplant survival (Singh et al. 1997). These results were not affected by the severity of and complications from liver disease, or by patients' social support, employment, or education (Singh et al. 1997). A study of lung transplant recipients found that those with a pretransplant psychiatric history (anxiety and/or depressive disorders) were more likely than those without such a history to be alive 1 year after transplantation (Woodman et al. 1999). However, in a study of 191 heart transplant recipients, a DSM-III-R diagnosis of PTSD (with the traumatic event being trans-

plant related) was associated with higher mortality (odds ratio=13.74) (Dew and Kormos 1999). Another study of heart transplant recipients found that patients with ischemic cardiomyopathy and high self-rated depression scores pretransplant had significantly higher posttransplant mortality compared with the low-depression group after adjustment for sociodemographic and somatic symptoms (Zipfel et al. 2002). Although causal directions cannot be inferred from these data, studies in other medically ill populations have demonstrated the substantial contribution of depression and anxiety to health outcomes (see Chapter 9, "Depression," and Chapter 12, "Anxiety Disorders"). Whether treating these disorders will affect patient outcomes is unclear. However, the role of the psychiatrist in evaluating, diagnosing, and treating psychiatric disorders both pre- and posttransplantation is critical.

## Adaptation to Transplantation

Transplant candidates typically experience a series of adaptive challenges as they proceed through evaluation, waiting, perioperative management, postoperative recuperation, and long-term adaptation to life with a transplant (Olbrisch et al. 2002). With chronic illness, there can be progressive debility and gradual loss of vitality and of physical and social functioning. Adapting to these changes can elicit anxiety, depression, avoidance, and denial and requires working through of grief (Olbrisch et al. 2002). Patients who are wait-listed may develop contraindications to transplantation (i.e., infection, serious stroke, progressive organ dysfunction), and both patients and families should be made aware that a candidate's eligibility can change over time for many reasons (Stevenson 2002). During this phase, psychiatrists may provide counseling to patients and families to help them prepare for either transplantation or death.

The summons for transplantation can evoke a mixture of elation and great fear. Many programs use electronic pagers to contact recipients, and some patients can develop anxiety related to anticipation of the pager's ring. Patients may experience a panic attack when they are called for transplantation, and some may even decline the offer of an organ.

Much of illness behavior depends on the coping strategies and personality style of the individual. In our experience, the adaptive styles of adult transplant recipients often depend on whether patients' pretransplant illness experience was chronic or acute, as delineated in the following broadly generalized profiles.

Patients who have dealt with chronic illness for years may adapt psychologically to the sick role and can develop

copied strategies that perpetuate a dependency on being ill (Olbrisch et al. 2002). For these patients, transplantation may psychologically represent a transition from one state of illness to another, and such patients can have difficulty adjusting to or transitioning into a "state of health." They often complain that the transplant team is expecting too fast a recovery from them, and they may describe feeling pressured to get better. Some patients may develop unexplained chronic pain or other somatic complaints or may begin to evidence noncompliance with transplant team directives.

For patients with good premorbid functioning who become acutely ill, with only a short period of pretransplant infirmity, the transplant can be an unwelcome event. These patients can experience a heightened sense of vulnerability, and they may deny the seriousness of their medical situation (Olbrisch et al. 2002). These patients often wish to return to normal functioning as quickly as possible posttransplantation, and they may in fact recover more rapidly than the transplant team expects; however, they may suffer later as the result of pushing themselves too much (e.g., returning to work before they are physically ready). They may resent being a transplant recipient, with all of the restrictions and regimens inherent in that role, and may act out their anger or denial in episodes of noncompliance (Olbrisch et al. 2002).

## Treatment Modalities

A prospective study of kidney transplant recipients demonstrated that individual psychotherapy was effective in resolving transplant-related emotional problems, with significant reductions in BDI scores after therapy (Baines et al. 2002). Three recurring psychological themes were expressed by patients in this study: 1) fear of organ rejection, 2) feelings of paradoxical loss after surgery despite successful transplantation, and 3) psychological adaptation to the new kidney (Baines et al. 2002).

In addition to traditional therapies and pharmacotherapy (see section "Psychopharmacological Treatment in End-Stage Organ Disease" later in this chapter), various innovative strategies have been employed to deal with specific issues of transplantation and also to address logistical and staffing resource issues. At the University of Toronto, a mentoring program was developed for heart transplant recipients. Mentorship by an already transplanted recipient augmented patient care by providing information and support from a peer perspective (Wright et al. 2001). The four topics most commonly discussed between mentors and mentees were postoperative complications (70%), medications (70%), wait on the transplant list (70%), and the surgery itself (50%) (Wright et al.

2001). Participants less frequently discussed psychiatric topics such as anxiety (40%) and depression (10%) and personal topics such as sexual relations (20%) and marital problems (10%). The program was well received, and patients were very satisfied with the experience. To increase patient satisfaction with the mentor program, Wright and colleagues recommend early introduction of a mentor and matching of mentors with mentees according to demographics and clinical course (Wright et al. 2001).

Group therapy for organ transplantation patients and family members has also been successfully used. At the Toronto Hospital Multi-Organ Transplantation Program, group psychotherapy is organized along three dimensions: course of illness (pre- vs. posttransplantation), homogeneous versus heterogeneous group membership (e.g., separate groups for patients and caregivers vs. integrated groups, organ-specific groups vs. cross-organ groups), and group focus (issue-specific vs. unstructured) (Abbey and Farrow 1998). Increasing levels of group therapy intensity are used, depending on the needs of the patient. Educational groups are mandatory for pretransplant candidates to prepare them for transplantation. From these groups, candidates at risk for psychosocial problems are referred to supportive and psychoeducational groups. Interpersonal and supportive-expressive psychotherapy groups are available to those who require them and have the psychological capacity to benefit from them. Group therapy participants report decreases in negative affect, increases in positive affect and happiness, less illness intrusiveness, and improved quality of life (Abbey and Farrow 1998). Transplant coordinators also report that patients in group therapy require less contact, both in clinic and by telephone for social support (Abbey and Farrow 1998).

Dew and colleagues (2004) have developed an innovative strategy for managing the logistical problem of recipients living at a distance from the transplant program. These researchers designed and evaluated an Internet-based psychosocial intervention for heart transplant recipients and their families. This multifaceted Web-based intervention included stress and medical regimen management workshops, monitored discussion groups, access to electronic communication with the transplant team, and information on transplant-related health issues (Dew et al. 2004). Compared with heart recipients without access to the Web site, intervention patients reported significant reductions in depressive and anxiety symptoms and improved quality of life in the social functioning domain; in addition, caregivers of intervention patients reported significant declines in anxiety and hostility symptoms ( $P < 0.05$ ). Mental health and quality-of-life benefits were greater among more-frequent users of the Web site. The

subgroup using the Web site's medical regimen workshop showed significantly better compliance at follow-up than did all other patients in attending clinic appointments, completing blood work, and following diet (Dew et al. 2004). Dew and colleagues concluded that a Web-based intervention could improve follow-up care, compliance, and mental health in patients and families as they adjust to heart transplantation.

## **Patients With Complex or Controversial Psychosocial and Psychiatric Issues**

---

The stringency of selection criteria for transplantation appears to depend on the type of organ transplant being considered, and transplant programs often have strongly formed beliefs about the suitability of candidates with certain types of mental illness. Cardiac transplant programs are more likely than liver transplant programs to consider psychosocial issues as contraindications, and liver transplant programs in turn are more stringent than kidney transplant programs (Corley et al. 1998; Levenson and Olbrisch 1993). These differences may be attributable to the relative availability of specific types of organs (Yates et al. 1993); alternatively, the extent of experience with specific organ transplants allowing programs to feel more comfortable with less stringent criteria (e.g., kidney transplantation, with more than three decades of experience and nearly 300,000 kidney transplants performed in the United States) (United Network of Organ Sharing 2004). In addition, for kidney transplantation, cost-effectiveness research has clearly demonstrated the long-term cost savings of kidney transplantation relative to dialysis (Eggers 1992). With such unequivocal evidence, insurance payers have a strong financial incentive to refer patients early for preemptive transplantation, before the high costs of dialysis begin to accumulate (Eggers 1992). In such a setting, psychosocial factors may have less impact on transplantation candidacy. Other issues influencing the selection process include moral and ethical beliefs, societal views, personal beliefs, and even financial constraints.

Although increasing numbers of poor prognostic indicators during the perioperative period may increase risk for noncompliance posttransplantation (Dew et al. 1996; see subsection "Posttransplant Compliance" below), it should be emphasized that candidates with any one of these features are not categorically poor recipients or that patients without any of these features do not categorically make the best candidates. What little research is available provides some support for clinical assumptions that pa-

tients with certain personality disorders, substance use disorders, poor coping skills, poor compliance, and poor social supports can have worse posttransplant outcomes. Nevertheless, case reports have demonstrated that even some patients who might seem inappropriate for transplant (e.g., patients with active psychosis or with severe personality disorders) (Carlson et al. 2000; DiMartini and Twillman 1994) can undergo transplantation and maintain adequate compliance after the procedure. Such patients should be carefully assessed pretransplant with optimization of their pretransplant condition and ongoing psychiatric monitoring and treatment posttransplantation. Prospective longitudinal studies are needed to clarify pretransplant factors that contribute to increased risk of poor outcomes (both psychological and medical) and the contribution of posttransplant factors on outcomes as well.

### Posttransplant Compliance

Lifelong immunosuppression is a prerequisite for good graft function, and noncompliance with immunosuppressive medication is often associated with late acute rejection episodes, chronic rejection, graft loss, and death. It might be assumed that transplant patients, in general, constitute a highly motivated group and that their compliance would be high. Unfortunately, overall posttransplant medical noncompliance rates of all organ types range from 20% to 50% (see Laederach-Hofmann and Bunzel 2000 for a complete review). With organ transplantation, noncompliance impairs both life quality and life span, as it is a major risk factor for graft-rejection episodes and may be responsible for up to 25% of deaths after the initial recovery period (Bunzel and Laederach-Hofmann 2000). Noncompliance leads to waste, as it reduces the potential benefits of therapy and adds to the costs of treating avoidable consequent morbidity. Graft loss from noncompliance is also tragic, given the large numbers of patients on the waiting lists. The global assessment of transplant patient compliance is difficult, and patients can manifest varying degrees of adherence to medical recommendations. For transplant recipients, compliance is commonly conceptualized as adherence to immunosuppressive medications. Yet the occurrence of clinically measurable events such as rejection episodes, organ loss, or death underrepresents the true amount of noncompliance, as some patients who are only partially compliant have not yet experienced a clinically adverse event (see Bunzel and Laederach-Hofmann 2000; De Geest et al. 1995). Although such “subclinical” noncompliance is undetectable as a medical event, it is important as an indicator of those patients having difficulty following their medical regimens (Feinstein 1990).

De Geest et al. (1995) reported a medication noncompliance rate of 22.3% in kidney transplant patients, whereas Paris et al. (1994) found a rate of 47% among heart transplant recipients. Shapiro et al. (1995) observed that of 93 heart transplant recipients, about one-third (34.4%) were noncompliant in at least some areas over the course of long-term follow-up. Dew and colleagues (1996) examined compliance in eight domains of posttransplant care in a cohort of 101 heart recipients. During the first postoperative year, the degree of noncompliance varied across time. However, they found persistent noncompliance in the domains of exercise (37%), blood pressure monitoring (34%), immunosuppressive medication (20%), smoking (19%), diet (18%), blood work completion (15%), clinic attendance (9%), and heavy drinking (6%). These studies also identified associations between noncompliance and increased risk of morbidity and mortality in transplant recipients (De Geest et al. 1995; Dew and Kormos 1999; Dew et al. 1996; Paris et al. 1994).

Dew et al. (1996) carried out a “dose–response” analysis of specific factors found to contribute to noncompliance in a preliminary regression analysis. A “dose” variable was created by determining how many of these six psychosocial risk factors—*anxiety, anxiety–hostility, poor support from caregivers, poor support from friends, failure to use active cognitive coping strategies, and use of avoidance coping strategies*—a recipient possessed. The logistic regression model showed a strong dose effect, in that if 0 to 1 psychosocial risk factor was present, the probability of having postoperative compliance difficulties was less than 30%. With 2 to 3 factors present, the probability rose to about 50%, and if 4 or more risk factors were present, more than 80% of patients encountered significant compliance difficulties. This means that if predictors cumulate, compliance problems are likely to rise dramatically.

Other studies have determined that psychiatric problems that persist after transplantation are highly associated with noncompliance (Paris et al. 1994; Phipps et al. 1997). In an extensive literature review of posttransplant compliance for all organ types, Bunzel and Laederach-Hofmann (2000) found that anxiety disorders—and, in particular, untreated major depression—were significantly associated with noncompliance. In a study of 125 heart transplant recipients (Shapiro et al. 1995), compliance problems were associated with a history of substance abuse ( $P=0.0007$ ).

### Alcohol and Other Substance Use Disorders

Compared with other solid organ transplant candidates, liver transplant (LTX) candidates more often require psy-

chiatric consultation for substance addiction assessment, due to the prevalence of alcoholic liver disease (ALD) and viral hepatitis transmitted through contaminated needles. An estimated 50% of LTX recipients have a pre-LTX history of alcohol and/or drug abuse/dependence (DiMartini et al. 2002). A survey of 69 U.S. liver transplant programs found that 83% of programs have a psychiatrist or addiction medicine specialist routinely see each patient with ALD during the evaluation phase (Everhart and Beresford 1997). In the optimal situation, the psychiatric clinician is an integral member of the transplant clinical care team and can integrate the addiction treatment plan into the patient's pre- and posttransplant care. The Cleveland Clinic Foundation has formed a chemical-dependence transplant team to assess, treat, and monitor transplant patients with addictive disorders (Stowe and Kotz 2001). This program is a model for the integration of such services.

Psychiatric consultation provides a thorough evaluation of the candidate's addiction history; their understanding of their addiction (especially in the context of their health and need for transplantation, their stability in recovery, and their need for further or ongoing addiction treatment), and the presence of other psychiatric disorders. Family and social support for the candidate's continued abstinence both pre- and posttransplantation must also be evaluated. In one study of LTX candidates, those with a history of substance abuse revealed significantly more distress, less adaptive coping styles, and more character pathology than their counterparts (Stilley et al. 1999). Because these features may heighten the potential for relapse, periodic reassessment by the psychiatric consultant provides follow-up on the candidate's progress in recovery, including verifying ongoing participation in rehabilitation as well as monitoring for psychological and affective distress and poor coping styles with therapeutic interventions targeting these problems as they arise. Documentation of treatment participation is desirable, as is random toxicological screening for alcohol and other substances. These measures are especially important for patients early in recovery and for those with a short period of abstinence, denial over their problem, resistance to seeking treatment, or poor social support for continuing abstinence. One study of pretransplant wait-listed ALD candidates found that 15% of candidates had used alcohol at some point after the initial transplant evaluation (Weinrieb 2003).

One-year post-LTX drinking rates (i.e., the percentage who used any alcohol by 1 year post-LTX) range from 8% to 37% (DiMartini 2000b; Everson et al. 1997), with cumulative rates estimated at 30%–40% by 5 years post-LTX (Lucey 1999). Rates of pathological drinking, de-

finied as drinking that results in physical injury or alcohol dependence, are 10%–15% (Everson et al. 1997; Fireman 2000). Although the rate of alcohol use appears to attenuate with the passage of time, post-LTX (Berlakovich et al. 1994; Campbell et al. 1993), dependent drinking can occur years post-LTX (DiMartini 2000a). In one study, 15% of LTX recipients had their first drink within the first 6 months post-LTX, a finding that highlights the importance of early and intensive clinical follow-up to identify alcohol use at its onset (DiMartini et al. 2001).

Consistent predictors of posttransplant alcohol use have been difficult to identify. This may be due to the heterogeneity of the ALD transplant population and the potential selection bias whereby the most stable candidates are chosen, making this population different from the general alcohol-abusing/dependent populations (DiMartini et al. 2002). For example, a pretransplant history of illicit drug use has not been consistently associated with increased risk for posttransplant alcohol relapse in ALD recipients (Coffman et al. 1997; DiMartini et al. 2002; Fireman 2000; Foster et al. 1997; Newton 1999), possibly because many ALD recipients had discontinued their drug use many years prior to transplantation (Coffman et al. 1997). In one of the few prospective studies to examine posttransplant alcohol use, a pretransplant history of alcohol dependence, a family history of alcoholism, and prior rehabilitation experience (thought to be a marker for those with more severe addiction) were all found to be associated with posttransplant alcohol use ( $P < 0.05$ ). A prior history of other substance use was associated with a higher (but non-statistically significant) risk of posttransplant drinking (DiMartini 2000b).

Compared with LTX candidates with alcohol dependence, LTX candidates with polysubstance dependence are more likely to have multiple prior addiction treatments; more likely to be diagnosed with personality disorders, especially cluster B type (antisocial, narcissistic, histrionic, borderline); and less likely to have stable housing, a consistent work history, or stable social support (Fireman 2000). Yet despite evidence that this specific population could be at higher risk for relapse, there are few published outcome studies addressing the issue of posttransplant nonalcohol substance use. Most studies have investigated the rates of relapse only in ALD recipients who also had a nonalcohol other substance use disorder. One of the few studies to investigate all patients with a pre-LTX addiction history found not only that patients with a pre-LTX history of polysubstance use disorders had a higher relapse rate compared with those with alcohol dependence alone (38% vs. 20%), but also that the majority of polysubstance users demonstrated ongoing post-LTX substance use (Fireman 2000). Studies investi-

gating all transplant recipients are needed to identify the true posttransplant rates of other substance use.

After transplantation, maintaining an open, nonjudgmental dialogue with transplant recipients appears to be the most effective way to identify alcohol and/or other substance use in the posttransplant period, and most recipients are open to discussing their substance use habits with the transplant team (DiMartini et al. 2001; Weinrieb et al. 2000). A review of liver enzymes and biopsy results and a candid discussion of the damage caused by alcohol and other substances provide an opportunity to explore the patient's denial of the consequences of their use. Even in the most difficult cases, patients wish to maintain their health and are willing to listen to advice and recommendations on addiction treatment. In our experience, the transplant team has established a powerful emotional bond with the recipient. Many patients who have resumed substance use were relieved to learn that the transplant team would not abandon them. On the other hand, it is important not to condone or dismiss small amounts of alcohol or other substance use. What may seem supportive can be distorted by the patient with an addiction and become an excuse to use more regularly. In the case of alcohol use, we have found that few patients with alcoholism can drink "socially" posttransplantation (Tringali et al. 1996) and that those who take their first drink often consume moderate to heavy amounts of alcohol (DiMartini et al. 2002). Therefore, total alcohol abstinence is recommended for these patients.

Medications that may reduce cravings and potentially diminish relapse risk for alcohol (e.g., acamprosate, ondansetron, naltrexone) or opioids (naltrexone) have not been studied in transplant patients. One study that attempted to use naltrexone in actively alcohol-relapsing LTX recipients found that patients were reluctant to use naltrexone as a result of its potential, albeit small, risk of hepatotoxicity (Weinrieb et al. 2001). Naltrexone can be a direct hepatotoxin at dosages higher than recommended (>300 mg/day) and is not recommended for patients with active hepatitis or liver failure. Disulfiram has been used in nontransplant populations to provide a negative reinforcement to drinking alcohol. This agent blocks the oxidation of alcohol at the acetaldehyde stage and can create severe nausea, vomiting, and hemodynamic instability. It requires hepatic metabolism for conversion into an active drug. A metabolite of disulfiram is an inhibitor of cytochrome P450 3A4 (Madan et al. 1998), and posttransplantation may cause immunosuppressive medication toxicity. Use of disulfiram in transplant recipients could place these individuals at risk for serious harm and is not recommended. In nontransplant patients, selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants

(TCAs) can stabilize mood and improve abstinence rates in depressed relapsing alcoholic individuals (Cornelius et al. 2003) and may be the most appropriate pharmacological interventions for transplant recipients if concurrent mood symptoms are present.

## Methadone-Maintained Candidates

Transplant program acceptance of opioid-dependent patients receiving methadone maintenance treatment (MMT) is a controversial issue. Recent studies have examined candidate selection processes and posttransplant outcomes for this population.

In a recent survey of U.S. liver transplant programs (Koch and Banys 2001), of the 56% of programs that reported accepting patients for evaluation who were taking methadone, a surprising 32% required patients to discontinue their methadone use prior to transplantation. Of even more concern was the overall lack of experience with such patients (i.e., only 10% of the programs had treated more than five MMT patients). Although there are no studies of pretransplant methadone cessation in liver transplant patients, there exists an abundance of evidence showing that tapering methadone in stable methadone-maintained patients results in relapse to illicit opiate use in up to 82% of these individuals (Ball and Ross 1991). In our opinion, an attempt to taper a recovering opiate addict from methadone should not be made at a time when the patient is struggling with the stresses and pain associated with end-stage liver disease. Until data to the contrary emerge, requiring methadone tapering in stable opiate-dependent patients as a prerequisite for transplant candidacy could be considered unethical. This strategy potentially heightens the risk for relapse, and those that relapse would be denied transplantation.

In regard to posttransplant outcomes of MMT patients, Koch and Banys (2001) found that of the approximately 180 transplant patients on methadone maintenance at the time of the survey, relapse to illicit opiate use was reported for less than 10% of patients. Similar to other reports of noncompliance in transplant patients (see subsection "Posttransplant Compliance" earlier in this chapter), approximately 26% of MMT patients had compliance difficulties with immunosuppressive medications (Koch and Banys 2001). However, it was not reported whether those who used illicit drugs were also among those who had problems with compliance. In general, the transplant programs did not consider that the noncompliance necessarily affected outcomes, and the transplant coordinator's impressions were that only 7 of 180 patients had poor outcomes (Koch and Banys 2001). In two small series of MMT LTX recipients (5 in each), overall long-

term patient and graft survival were found to be comparable to those of other LTX recipients at the transplant centers, with none of the MMT patients evidencing post-transplant noncompliance or illicit drug use (Hails and Kanchana 2000; Kanchana et al. 2002). Liu et al. (2003), in a study of the largest single cohort ( $N=36$ ) of MMT LTX recipients to date, concluded that patient and graft survival were comparable to national averages (they did not use a control group, however). Although four patients (11%) reported isolated episodes of heroin use posttransplantation, relapses were not considered to have resulted in poorer outcomes.

These descriptive studies demonstrate that MMT transplant recipients can successfully undergo transplantation and do well; however, the lack of control groups makes it difficult to prove that MMT patients' rates of complications and survival are no different from those of transplant recipients in general. Although the small numbers of MMT candidates and recipients preclude large-scale prospective studies, a case-control study conducted by Gordon et al. (1986) found that posttransplant patient and graft survival rates in the 20 heroin-addicted kidney recipients were similar to those in the control group. The leading cause of death (infection) was the same in both groups. In the study group, only one patient returned to heroin use. Two other study patients who were not suspected of using heroin lost their grafts as a result of medication noncompliance, whereas no patient in the control group lost a graft as a result of noncompliance (Gordon et al. 1986). In summary, the data to date justify neither automatic exclusion of MMT patients from transplantation nor any requirement that such patients be tapered off methadone prior to transplant.

## Personality Disorders

Personality disorders are characterized by persisting and inflexible maladaptive patterns of subjective experience and behavior that may create emotional distress and interfere with the individual's interpersonal relationships and social functioning. The requirements of successful transplantation can be too difficult for such an individual, as the process requires a series of adaptations to changes in physical and social functioning and significant ability to work constructively with both caregivers and the transplant team. By identifying personality traits and disorders, the psychiatrist can potentially predict patterns of behavior, recommend treatment, develop a behavioral plan with the team to work constructively with the patient, and render an opinion as to the candidate's ability to proceed with transplantation. Patients with personality disorders can require excessive amounts of time from the

transplant team, which raises the issue of resource allocation as a potential selection criterion (Carlson et al. 2000). Not surprisingly, a majority of programs (50%–60% across organ types) consider personality disorders to be a relative contraindication to transplantation (Levenson and Olbrisch 1993). Yet all personality disorders should not be viewed similarly, as the behavioral and coping styles of different personality disorders can present varying degrees of concordance with the needs of transplantation. For example, the need for structure and orderliness of a candidate with obsessive-compulsive personality disorder would be more adaptive to the demands of transplantation than the coping style of a patient with borderline personality disorder.

The incidence of personality disorders in transplant populations is similar to that in the general population, ranging from 10% to 26% (Chacko et al. 1996; Dobbels et al. 2000), although in some cohorts estimates have been as high as 57% (Stilley et al. 1997). However, the identification of personality disorders depends on the definition and measurement methods used. Unfortunately, studies investigating personality disorders and transplantation outcomes have not distinguished among the various personality disorder types (perhaps because of the low prevalence of each type), which makes generalizations difficult. Nevertheless, case reports of patients with severe character pathology demonstrate the extent of compliance problems that can arise from these disorders, resulting in significant morbidity and recipient death (Surman and Purtilo 1992; Weitzner et al. 1999). The disturbances in interpersonal relationships that can occur with personality disorders also can decrease the likelihood that patients will have stable and reliable social supports during the pre- and posttransplant phases (Yates et al. 1998). Of the personality disorders, borderline personality disorder is considered to represent the highest risk for posttransplant noncompliance (Bunzel and Laederach-Hofmann 2000).

Whereas sociopathy has not consistently been associated with substance relapse in the addiction literature (Vaillant 1997), a survey of transplant programs in the United States revealed that 4 of 14 programs (29%) would reject a candidate with comorbid antisocial personality disorder and alcohol dependence (Snyder et al. 1996). In a study of 73 ALD transplant candidates, patients with severe personality disorders had higher rates of divorce, higher rates of comorbid drug abuse/dependence, lower IQs, higher scores on indicators of emotional impairment, and were more likely, although not significantly so, to return to drug use during the pretransplant follow-up period (Yates et al. 1998). However, of this cohort, 3 patients with serious personality disorders underwent liver

transplantation and did not relapse or become noncompliant in the early postoperative phase (Yates et al. 1998). In contrast, another study of 91 patients transplanted for ALD and followed for up to 3 years identified 18 patients exhibiting antisocial behavior (Coffman et al. 1997). Of those with antisocial behavior, 50% returned to either alcohol ( $n=6$ ) or prescription narcotic addiction ( $n=3$ ) post-transplantation, which was significantly higher than the 19.8% alcohol use by the total group (Coffman et al. 1997). In a prospective study of 125 heart transplant recipients, personality disorders were associated with post-transplant compliance problems ( $P=0.007$ ) (Shapiro et al. 1995). Although personality disorders were not associated with survival, those individuals with personality disorders tended to have more graft rejection ( $P=0.06$ ) (Shapiro et al. 1995).

Although not identified as specific personality disorder styles, various coping and behavioral styles have also been shown to influence survival. A study by Chacko et al. (1996) of survival post-heart transplant found that whereas the presence of clinician-rated Axis II disorders (26% of the group) was not associated with survival time, some of the strongest predictors of survival were health behaviors, maladjustment, and coping styles. Using the same measure of health behavior and coping (Millon Behavioral Health Inventory [Millon et al. 1982]), Coffman and Brandwin (1999) found that wait-listed heart transplant candidates with high scores on the Life Threat Reactivity subscale had significantly higher mortality before transplantation (42% vs. 18%;  $P=0.0001$ ) but not after transplantation. These investigators suggested that one possible explanation was that the detrimental psychological traits of the high-risk group were ameliorated by surviving to be transplanted (Coffman and Brandwin 1999).

Patients with personality disorders do best with ongoing pre- and posttransplant psychotherapy, specifically cognitive and behavioral interventions to promote compliance with the care regimen and to establish a working alliance with transplant team members (Dobbels et al. 2000). These patients should be given clear and consistent instructions on rules and requirements of transplantation, reinforced by regular outpatient appointments. A limited number of transplant center staff should maintain contact with the patient, and staff should communicate regularly among themselves and the outpatient psychiatric team (Carlson et al. 2000) to coordinate care and to reduce opportunities for cognitive distortions and splitting by the patient. A formal written contract can document the expectations of the transplant team and serve as a therapeutic treatment plan whereby the patient and team agree to work together toward common goals for the transplant recipient's health (Dobbels et al. 2000).

## Psychotic Disorders

Although chronic and active psychosis is thought by many to be incompatible with successful transplantation, case reports of carefully selected patients with psychosis demonstrate that such patients can successfully undergo transplantation and survive after the procedure (DiMartini and Twillman 1994; Krahn et al. 1998). A recent survey of transplant psychiatrists at national and international transplant programs identified only 35 cases of pretransplant psychotic disorders in transplant recipients from 12 transplant centers (Coffman and Crone 2002), suggesting that such patients are highly underrepresented among transplant recipients. Results of this survey confirmed previously expressed stipulations that patients with psychotic disorders be carefully screened before acceptance. Candidates should have demonstrated good compliance with both medical and psychiatric follow-up; possess adequate social supports, especially in-residence support; and be capable of establishing a working relationship with the transplant team. In this survey (Coffman and Crone 2002), risk factors for problems with compliance after transplantation included antisocial or borderline personality disorder features, a history of assault, living alone, positive psychotic symptoms, and a family history of schizophrenia. Posttransplant noncompliance with nonpsychiatric medications was found in 20% of patients (7 of 35), and noncompliance with laboratory tests was found in 17% (6 of 35 patients) (Coffman and Crone 2002); however, these numbers are similar to percentages of medication and laboratory testing noncompliance in general transplant populations. Overall, noncompliance resulted in rejection episodes in 5 patients (14%) and in reduced graft function or loss in 4 patients (12%) (Coffman and Crone 2002). Thirty-seven percent of patients experienced psychotic or manic episodes post-transplantation (not necessarily associated with immunosuppression), 20% attempted suicide (with two completed suicides), 20% experienced severe depression or catatonia, 5.7% committed assaults, 5.7% were arrested for disorderly conduct, and 8.6% required psychiatric commitment (Coffman and Crone 2002).

Although concerns have been raised in regard to the potential of immunosuppressive medications to produce or exacerbate psychotic symptoms, patients with a prior psychiatric history are not necessarily more susceptible to "steroid psychosis" than are patients without such a history (Hall et al. 1979), and appropriate use of antipsychotic medication is usually adequate to manage these symptoms if they emerge. Because transplant teams often overlook the early postoperative reinstatement of antipsychotic medications, it is essential that the psychiatrist de-

vote careful attention to this issue during the immediate postoperative phase. If quick reintegration of the patient into his or her pretransplant outpatient psychiatric treatment regimen is not possible because of infirmity, interim in-home psychiatric follow-up care should be instituted.

## Special Issues During the Pretransplant Phase

---

### Hepatic Encephalopathy

Hepatic encephalopathy (HE), a neuropsychiatric syndrome commonly encountered in liver transplant candidates, is characterized by a constellation of signs and symptoms, such as alteration of consciousness (including stupor or coma), cognitive impairment, confusion/disorientation, affective/emotional dysregulation, psychosis, behavioral disturbances, bioregulatory disturbances, and physical signs such as asterixis. Identification of HE is important, because its symptoms directly affect patient quality and quantity of life; fulminant HE is associated with intracranial hypertension, cerebral edema, and death pretransplant (Ferenci et al. 2002). It is also critical to differentiate between the fluctuating course of HE and more persistent cognitive deficits that may indicate a preexisting dementia rather than delirium. Recent efforts to define HE have emphasized that it reflects a continuum of symptoms, with subclinical HE lying at the minimal end of the spectrum. Even subclinical HE is clinically important, because it can impair patient safety (Schomerus et al. 1981) and is associated with persistent cognitive deficits post-LTX (Tarter et al. 1990). In one study, 85% of patients with subclinical HE were found to be either of questionable fitness or unfit to drive on psychometric testing of driving capacity (Schomerus et al. 1981). By definition, subclinical HE is not identifiable on a typical clinical examination; detection may require additional neuropsychological tests of psychomotor speed, praxis, concentration, and attention. The Trail Making Test (A and B) and the Digit Symbol and Block Design tests from the Wechsler Adult Intelligence Scale—Revised are commonly used to identify subclinical HE impairment. Whereas the prognostic significance of HE is well known, the long-term impact of subclinical encephalopathy on cognitive functioning requires further investigation.

The predominant strategy for treating HE involves reducing the production and absorption of ammonia from the intestinal tract, although a variety of compounds and metabolites (e.g., mercaptans, false neurotransmitters, manganese, endogenous benzodiazepines, increased concentrations of central nervous system [CNS] gamma-aminobutyric

acid [GABA]) have also been implicated in HE (Chung and Podolsky 2003; Riordan and Williams 1997). Psychiatric consultants should be familiar with ammonia-reducing strategies, because they are often the ones who must recognize and monitor HE symptoms, identify whether patients are being treated for HE, and make recommendations regarding the need for initiating or improving treatment. HE can be precipitated by gastrointestinal hemorrhage, uremia, use of some psychoactive medications or diuretics, dietary indiscretions, dehydration, or electrolyte imbalance (Chung and Podolsky 2003; Riordan and Williams 1997), and these problems should be corrected first. Treatment should strive to normalize ammonia levels, despite the fact that blood ammonia levels are not well correlated with symptoms of HE (Riordan and Williams 1997). Treatment strategies include administration of a nonabsorbable disaccharide, lactulose, that acts as an osmotic laxative to flush out ammonia; adherence to a protein-restricted diet to decrease the production of ammonia from protein; and prescription of nonabsorbable antibiotics to reduce intestinal bacteria that convert protein to ammonia. Some patients require all three treatments simultaneously. Medications that can contribute to symptoms of HE—anticholinergic drugs, tranquilizers, and sedatives—should be avoided.

### Ventricular Assist Devices in Heart Transplantation

Progress in the development of implantable left ventricular assist devices (LVADs) has dramatically improved both the physical and the psychological health of potential cardiac transplant candidates. The new LVADs consist of a mechanical pump implanted in the abdomen with conduits from the apex of the left ventricle to the ascending aorta. Blood returning from the lungs to the left side of the heart exits through the left ventricular apex into the LVAD pumping chamber. Blood is then actively pumped through the LVAD outflow valve into the ascending aorta. One transcutaneous line carries an electrical cable to an external battery pack and electronic controls, which are worn on a shoulder holster or belt.

Prior to the use of LVADs, the need for prolonged inotrope infusions before transplantation could lead to very lengthy hospitalizations for cardiac transplant candidates. These patients would become deconditioned and were at risk for deep vein thrombosis, pulmonary emboli, multiple organ dysfunction, and sudden cardiac death. However, recent experience with newer LVADs reveals improvement in mechanical/electrical failure rates and lessened risks for thromboembolism (Rose et al. 2001a, 2001b). Patients on LVADs can achieve better hepatic, re-

nal, cerebral, and peripheral perfusion, leading to improvement in overall physical function, exercise tolerance, and well-being (Goldstein et al. 1998; Morrone et al. 1996). These devices are now portable, permitting discharge from the hospital before transplantation and a generally acceptable quality of life (Dew et al. 2000a; Frazier 1993; Loisanche et al. 1994). Patients on LVADs can undergo physical and physiological rehabilitation, develop exercise tolerance, and rebuild muscle mass, thus stabilizing their cardiac condition (Goldstein et al. 1998; McCarthy 2002; Morrone et al. 1996). The lack of mobility restriction means that patients often can return to work and engage in activities such as dancing and driving (Catanese et al. 1996). With the urgency for transplantation diminished, the transplant team can wait for an optimal donor organ.

On the downside, however, the logistics of arranging outpatient care require a well-trained medical team whose members are available at all times, resulting in significant patient, caregiver, and medical system burden. All persons involved in the patient's care must receive extensive training, arrangements for outpatient housing or maintenance at home must be coordinated, and local emergency paramedical personnel must also be trained. Infection can occur in more than 60% of LVAD recipients (Gordon et al. 2001); in one study of patients with permanent LVADs, 41% of deaths were related to infection (Rose et al. 2001b). Not surprisingly, in a study of recipients of ventricular assist devices (including both LVADs and biventricular assist devices), the most common concern was risk of infection (52%) (Dew et al. 2000a). In addition, 52% had difficulty sleeping because of the driveline, 46% had pain at the driveline site, 40% worried about device malfunction, and 32% were bothered by the noise (Dew et al. 2000a). In posttransplantation comparisons with heart recipients who did not receive a ventricular assist device (VAD), patients who were bridged to transplantation with a VAD showed similar improvements in physical functioning and emotional well-being, significantly lower rates of anxiety, but poorer cognitive status (Dew et al. 2001b). The cognitive impairments observed in the VAD recipients were believed to be attributable to neurological events that occurred during the period of VAD support and were higher than that of non-VAD patients during the waiting period before transplantation. Although mild, these impairments appeared to persist during the first year following transplantation and were associated with less likelihood of returning to employment (Dew et al. 2001b). In the future, as the technology continues to improve, selected patients may receive LVADs as permanent implants rather than as bridges to transplantation (Rose et al. 2001a, 2001b).

## Tobacco Use and Transplantation

Tobacco use by transplant candidates and recipients has received surprisingly little attention. Even in lung and heart transplantation, tobacco use is not routinely reported. Tobacco use coupled with immunosuppressive therapy, which also increases cancer risk (Nabel 1999), may result in higher rates of cancer posttransplantation. For ALD liver transplant recipients in one study, the rates of oropharyngeal cancer and lung cancer were 25 and 3.7 times higher, respectively, than rates in the general nontransplant population matched for age and gender (Jain et al. 2000), presumably as a result of tobacco use.

One study of heart transplant recipients found that 26%–50% of smokers resumed smoking posttransplantation (Bell and Van Triget 1991; Nagele et al. 1997). Compared with nonsmokers, smokers had higher rates of vasculopathy and of malignancies (Nagele et al. 1997); they also had significantly worse survival, with none of the smokers surviving 11.5 years posttransplantation (vs. 80% of the nonsmokers surviving). When patients were grouped by carboxy-hemoglobin level, investigators found that no patients with a level higher than 2.5% were surviving 4 years after transplantation (Nagele et al. 1997). In this cohort, smoking appeared to be much more important than other classical risk factors (Nagele et al. 1997). Similarly, a study of liver transplant recipients found a higher rate of vascular complications in patients with a history of smoking (17.8% vs. 8% in patients without such a history;  $P=0.02$ ); furthermore, having quit smoking 2 years prior to transplantation reduced the incidence of vascular complications by 58% (Pungpapong et al. 2002). In a prospective study of ALD liver transplant recipients, 53% were found to be using tobacco posttransplantation (DiMartini et al. 2002). A study of 60 heart transplant recipients reported that 3 patients had resumed smoking within 6 months following transplantation and that all 3 had also relapsed to drug or alcohol abuse (Paris et al. 1994). Another study of heart transplant recipients found that elevated posttransplant anxiety was associated with a higher risk of resuming smoking (Dew et al. 1996).

The cessation of tobacco use (both smoked and smokeless) prior to transplantation is strongly recommended, given that many pretransplant users resume use posttransplantation. Treatments for smoking cessation include bupropion, nicotine replacement (patches, gum, lozenges, and aerosolized formulations), and behavioral therapies (Hurt et al. 1997; Jorenby et al. 1999). Because of its association with seizure risk, bupropion should be used with caution in transplant recipients, who are already at increased risk from immunosuppressive medications, particularly during the early posttransplant period, when

immunosuppressive levels are higher. A good alternative would be nortriptyline, which in combination with cognitive-behavioral therapy in general-population studies has been demonstrated to have a smoking cessation success rate similar to that of bupropion (Hall et al. 1998). Notwithstanding, the anticholinergic side effects of nortriptyline could be problematic in candidates or recipients at risk for delirium, and although the drug's  $\alpha$ -adrenergic, antiarrhythmic, and negative inotropic effects are tolerated post-heart transplant (Kay et al. 1991; Shapiro 1991), these effects should be carefully monitored in heart transplant candidates.

## Living Donor Transplantation

Despite the physical risks, discomfort and pain, expense and inconvenience, and potential psychological consequences of donating an organ, increasing numbers of people are becoming donors, and transplant programs are considering living donation as one solution to the organ shortage. In fact, in 2001 the number of living donors exceeded the number of cadaveric donors (6,526 vs. 6,081) for the first time, with the majority from kidney donors, although an increasing number are coming from living liver donors in the form of a partial hepatectomy (United Network of Organ Sharing 2004). Currently, more than 50% of kidney transplants come from living donors (United Network of Organ Sharing 2004). Kidneys and portions of the liver, lung, pancreas, intestine, and even the heart (through a domino procedure in which a heart-lung recipient donates their heart) are donated for transplantation (Oaks et al. 1994; Rodrigue et al. 2001; Taguchi and Suita 2002).

Donation of an organ—putting one's life at risk to help another—is an incredibly generous and altruistic gift. Yet the evaluation of such donors is complex process requiring assessment of the circumstances and motives of the donor, the dynamics of the relationship between donor and recipient, the severity of the recipient's illness, and family and societal forces. Current practice guidelines require a psychosocial evaluation for each potential donor to thoroughly examine these and other issues (Table 31-2) (Olbrisch et al. 2001; Surman 2002). Donors must be fully willing, independently motivated, and completely informed about the surgery. Yet for liver donors in particular, long-term sequelae that may affect the donor's future health, functioning, and even ability to obtain health insurance (due to the presence of a preexisting condition) are not known.

Living liver donation is a much more surgically complex, invasive, and potentially more dangerous procedure than kidney donation. Although mortality rates have been

**TABLE 31-2. Areas of assessment for living donor evaluation**

Personality disorders
Coping resources/style
Pain syndromes
Prior psychological trauma/abuse
Substance use

---

less than 1% for both kidney and liver donors (Brown et al. 2003; Najarian et al. 1992), about one-third of liver donors have complications, with serious complications occurring in 14% of donors (Brown et al. 2003; Grewal et al. 1998). There have been consensus recommendations that all potential live liver donors be evaluated by an independent physician advocate (i.e., not a member of the transplant team responsible for the recipient's care) as part of the informed consent process (Abecassis et al. 2000; Conti et al. 2002) to avoid conflicts of interest. However, in only 50% of programs does a physician who is not part of the transplant team evaluate the potential donor (Brown et al. 2003). Kidney donors should expect to miss 4–6 weeks of work and liver donors 8–12 weeks of work, especially if the job involves heavy lifting. Since the late 1990s, laparoscopic donor nephrectomy has been increasingly used, a procedure that results in less postoperative pain, shorter hospital stays, overall quicker recovery times, and more favorable cosmetic results. Future research may also show this approach has psychosocial benefits as well.

Adult-to-adult living donor liver transplantation (LDLT) is a relatively new procedure in the United States, preceded by adult-to-child transplants. Whereas only 9 such procedures had been performed in the United States prior to 1998, in 2001 more than 400 adult-to-adult LDLTs were performed. Unfortunately, too few procedures are performed at any one center—and approaches to recipients and donors are too diverse across centers—to provide reliable and generalizable information about donor and recipient outcomes. In one study that examined outcomes of parent-to-child liver donation, psychological testing

was found to be useful in identifying families that were more likely to experience problems postdonation (Goldman 1993). Although donor outcomes were reported as good, with donors experiencing increased self-esteem and satisfaction, marital dissolution occurred in 2 of the 20 families following donation (Goldman 1993). In another study, one donor committed suicide 2 years after donation, and although this event was deemed by the transplantation center to be unrelated to the donation, the details were not known (Brown et al. 2003).

A U.S. live organ donor consensus group recommended the development of a living donor registry to collect demographic, clinical, and outcome information on all living organ donors. The rationale for the development of such a registry includes concern for donor well-being, limitations of current knowledge regarding the long-term consequences of donation, the potential to evaluate the impact of changes in criteria for donor eligibility on the outcome of donors, and the need within the transplant community to develop mechanisms to provide for quality assurance assessments (Abecassis et al. 2000). In the near future, a multicenter study of adult-to-adult living liver donor outcomes commissioned by the National Institute of Diabetes and Digestive and Kidney Diseases should help provide answers to these questions (see “Adult-to-Adult Living Donor Liver Transplantation Cohort Study [A2ALL]” 2003).

In contrast with the United States, Japan has extensive experience with living liver donation as a result of cultural beliefs (lack of acceptance of brain death criteria) that hamper cadaveric donation. This created an environment in which living liver donation was necessary for LTX. More than 1,500 adult-to-adult LDLTs have been performed in Japan, with no reported donor mortality (Surman 2002). Fukunishi et al. (2001) first reported on psychiatric outcomes in LDLT donors and recipients, identifying post-LTX psychiatric disorders (excluding delirium) in 37% of LDLT recipients and “paradoxical reactions” (including guilt over receiving donation, avoidant coping behaviors, and psychological distress) in 34% of recipients, despite favorable medical outcomes for both recipient and donor. Ten percent of liver donors experienced major depression within the first month after donation. Fukunishi and colleagues speculated that predonation, the stronger sense of duty of adult children donating to their parents masked their true concerns and fears. Following donation, these concerns manifested as anxiety, fear, and pain (Fukunishi et al. 2003). The prevalence of psychiatric disorders was higher in LDLT recipients than in a comparison group of living donor kidney recipients, suggesting a potential greater need for psychiatric evaluation and care of LDLT patients.

Altruistic donors—those donating to an unknown recipient—pose one of the most complex challenges to transplant evaluation. In these cases, the psychosocial evaluation has particular importance in determining the suitability of the donor, and some believe that the medical standards for such donors should be higher (Friedman 2002). Altruistic donors are commonly viewed with some skepticism and are evaluated with greater caution than related donors. A detailed evaluation is critical, both to understand the motives and psychological meaning of the donation to the donor and to identify any financial or other types of compensation expected for the donation. A recent study of nondirected donors reported that 21% were excluded for psychological reasons (Matas et al. 2000). Psychological outcomes of altruistic liver donors are unknown.

## Psychopharmacology in End-Stage Organ Disease

---

Given the high prevalence of psychiatric disorders in transplant candidates and recipients, pharmacological treatment is often required. Unfortunately, psychotropic medications are often not provided because of concerns about patients’ medical fragility and the potential risks of psychotropic medications. The fact that psychiatric symptoms may evolve from complex, intertwined psychological and physiological processes should not preclude treatment. Although the treatment of transplant candidates and recipients can be complicated, a thorough knowledge of psychotropic pharmacokinetics in specific types of end-stage organ failure, coupled with careful attention to medication dosing, side effects, and drug interactions, can provide the necessary foundation for pharmacological management (see also Chapter 37, “Psychopharmacology”; Robinson and Levenson 2001; Trzepacz et al. 2000).

### Liver Disease

Liver failure affects many key steps of medication pharmacokinetics, from absorption to metabolism, distribution, and elimination, causing changes in drug levels, duration of action, and efficacy. As the liver becomes cirrhotic, collateral blood vessels develop that circumvent the liver. Intrahepatic and extrahepatic physiological (and, in many patients, surgical) shunts create portal-systemic diversion that reduces liver perfusion and particularly affects first-pass metabolism as less drug is delivered to hepatic enzymes. Loss of functional parenchyma and hepatic enzymes decreases phase I metabolism (such as the cytochrome P450 enzyme system) or phase II metab-

olism (conjugation enzymes). Most psychotropic medications require hepatic metabolism and are highly bound to plasma proteins. The liver's production of plasma proteins is reduced, with a resulting increase of the free and pharmacologically active fraction of highly protein-bound drugs. These processes will raise effective drug levels, increasing the risk of drug side effects or toxicity (Leipzig 1990; Levy 1990; Pond and Tozer 1984). Increased volume of distribution resulting from fluid retention (ascites, peripheral edema) can lower effective levels of both water-soluble and highly protein-bound drugs (because more will be in the unbound state due to hypoproteinemia) (Klotz 1976).

The etiology and severity of liver disease will determine changes in drug pharmacokinetics, including changes in enzymatic activity that affect drug metabolism. In addition, the type of disease (e.g., cholestatic vs. noncholestatic liver disease), the type of disease process (e.g., periportal [affecting phase II enzymes] vs. pericentral [affecting phase I cytochrome P450 enzymes] disease processes), and the type of drug (high-clearance or flow-dependent vs. low-clearance or enzyme-saturating drugs) all play an important role in pharmacokinetics.

One semiquantitative measure of liver functioning, the Child-Pugh Score (CPS), uses commonly available clinical and biochemical indices to rate the severity of end-stage liver disease. The CPS provides a readily reproducible and standardized method for assessing the degree of liver failure and is generalizable to patients with liver disease regardless of its etiology (Albers et al. 1989). Although the categories of the CPS may overgeneralize the complexities of drug pharmacokinetics, the indices used identify impairment in pharmacokinetic functions (i.e., protein production, portal-systemic shunting, ascites), making the CPS total rating a useful guideline for psychotropic medication dosing (see Table 31-3). Nevertheless, for the newer medications the pharmaceutical companies typically publish detailed information on drug

absorption, metabolism, and elimination, with suggested guidelines for patients with hepatic disease (often using the CPS), and these documents should be referred to for specific medication dosing. In our clinical experience, we have found that patients rated as having CPS class A liver failure are early in the disease process and can usually tolerate 75%–100% of a standard dosage. Those with CPS class B should be dosed more cautiously, starting with a 50%–75% reduction in the normal starting dose. As a result of the prolongation of the elimination half-life and the subsequent delay in reaching steady state, more gradual increments in dosing are required. Patients with CPS class B liver failure can often obtain relief or remission of symptoms with 50% of a typical psychotropic medication dosage. Those with CPS class C commonly have some degree of hepatic encephalopathy, and medication usage must be cautiously monitored to avoid worsening of the hepatic encephalopathy symptoms. Sometimes distinguishing whether depressive symptoms represent primary depression or the affective dysregulation of hepatic encephalopathy may not be possible, in which case a cautious empirical trial of medication may be warranted.

## Renal Disease

Reduced renal clearance of drugs can occur in renal insufficiency due to primary renal disease or from hypoperfusion in hepatorenal syndrome (McLean and Morgan 1991) or severe heart failure (Shammas and Dickstein 1988). Reduced renal clearance is especially important for psychotropic medications that are predominantly excreted by the kidneys (e.g., lithium, gabapentin, topiramate, methylphenidate) and also for psychotropic drugs for which renal excretion of active metabolites is the primary route of elimination (e.g., venlafaxine and its active metabolite *O*-desmethylvenlafaxine). In uremia, drug oxidation is normal or accelerated, reduction and hydrolysis are slowed, glucuronide and glycine conjugations are normal-

**TABLE 31-3. Grading of liver disease severity using the Child-Pugh Score (CPS)**

	<b>1 Point</b>	<b>2 Points</b>	<b>3 Points</b>
Bilirubin (mg/dL)	<2.0	2–3	>3.0
Albumin (g/dL)	>3.5	2.8–3.4	<2.7
Protine (INR)	<1.5	1.6–2.4	>2.5
Ascites	None	Mild	Moderate
Encephalopathy	None	Stage 1–2	Stage 3–4

*Note.* Grading: A = 5–6 points; B = 7–9 points; C = 10–15 points.

*Source.* Adapted from Albers et al. 1989.

and acetylation may be slowed (Reidenberg 1977). Excess urea may cause gastric alkalinizing effects, decreasing intestinal absorption of some medications (Levy 1990). In renal failure, hypoalbuminemia, coupled with the inhibition of drug-protein binding from uremia and the accumulation of endogenous protein-binding inhibitors (Wilkinson 1983), can increase free drug concentrations, especially for drugs with protein binding greater than 80% (i.e., most psychotropics). The effect of diminished renal clearance was demonstrated in a study of TCAs in which inactive metabolites reached 500% to 1,500% of normal levels (Lieberman et al. 1985). Although these metabolites are thought to be clinically inert, they can alter disposition of the active drug by displacing it from protein binding, competing for active transport mechanisms, and inhibiting drug metabolism (Lieberman et al. 1985). For patients in severe renal failure, dosing can be complicated (see Chapter 37, "Psychopharmacology"), and renally excreted psychotropic medications should be used very cautiously.

### Heart Disease

In cardiac insufficiency and congestive heart failure, organ hypoperfusion (especially the liver and kidneys) and increased volume of distribution of drugs due to "third spacing" into interstitial tissues result in decreased drug metabolism and clearance (Shammas and Dickstein 1988). In one study of patients with congestive heart failure, the half-life of midazolam was prolonged by 50% and the plasma clearance was reduced by 32% (Patel et al. 1990). Right-sided heart failure can lead to intestinal and hepatic venous congestion, which can impair drug absorption and metabolism, respectively (Shammas and Dickstein 1988). Acute hypoxia can change blood flow dynamics. Splanchnic blood flow is reduced in the liver, decreasing metabolism, and renal blood flow is also reduced (du Souich and Erill 1978). Hepatically cleared drugs are more affected than renally cleared drugs in congestive heart failure (Woosley 1987). Patients with severe right-sided heart failure with passive congestion of the liver should be treated as patients with hepatic insufficiency and dosages initially reduced by 50%.

### Lung Disease

In pulmonary disease, the binding of some drugs to plasma proteins may be increased, resulting in a lengthened time course of the drug effect, increased drug distribution, and more rapid hepatic and renal clearance (du Souich and Erill 1978). As with heart disease, acute hypoxia can reduce splanchnic blood flow to the liver,

decreasing drug metabolism, and can reduce renal blood flow (du Souich and Erill 1978). Increased pulmonary vascular resistance, leading to decreased cardiac output (cor pulmonale), causes increased systemic venous pressures, which in turn decrease perfusion of the liver and kidneys. The lungs also contain cytochrome P450 isoenzymes, which may play a minor role in first-pass and overall drug metabolism (Pond and Tozer 1984). Additionally, high-affinity binding sites for both imipramine and SSRIs have been identified in the lungs, perhaps reflecting the high affinity of these drugs for the serotonin transporter (Suhara et al. 1998). The significance of these findings in heart and lung disease patients is unknown, although it is speculated that the lungs act as a reservoir for medications with a high affinity to the serotonin transporter (Suhara et al. 1998).

## Neuropsychiatric Side Effects of Immunosuppressive Agents

---

Recent advances in our understanding of immunology and the development of newer strategies for immunosuppression may significantly reduce the need for—if not obviate completely—long-term maintenance immunosuppression. In the future, transplant recipients of all organ types may require immunosuppressive medication dosages only one or two times a week, or not at all (Starzl 2002). This achievement would remove the final obstacle to long-term successful outcomes for transplant recipients, given that the majority of long-term morbidity and mortality is due to chronic immunosuppression (e.g., infections, renal failure, cancer). Additionally, reduced requirements for immunosuppressive medication would aid in medication compliance and relieve some of the financial burden of long-term immunosuppression. However, for now, transplant recipients will continue to require immunosuppressive therapy and to be subject to their potential neurotoxic and neuropsychiatric side effects. Psychiatrists should be familiar with the signs, symptoms, differential diagnosis, neuroimaging findings, and management of immunosuppressive neurotoxicity and secondary psychiatric disorders in solid organ recipients (Strouse et al. 1998).

### Cyclosporine

Cyclosporine (Gengraf, Neoral, Sandimmune), a lipophilic polypeptide derived from the fungus *Tolypocladium inflatum* Goma, is used as a primary immunosuppressive agent. Side effects are usually mild and include tremor,

restlessness, and headache (Wijdicks et al. 1999). A smaller proportion of patients (12%) experience more serious neurotoxicity characterized by acute confusional states, psychosis, seizures, speech apraxia, cortical blindness, and coma (deGroen 1987; Wijdicks et al. 1995, 1996; Wilson et al. 1988). A higher incidence (33%) of serious neurotoxic side effects was reported in one study of 52 liver transplant recipients. Seizures were experienced by 25%; less commonly reported effects included central pontine myelinolysis, delirium, cerebral abscess, and psychosis (Adams et al. 1987).

More recent evidence suggests that earlier reports of serious neurological side effects may have been attributable to intravenous administration and higher dosages (Wijdicks et al. 1999). The use of the oral form of cyclosporine (Neoral) results in fewer serious neurological side effects (Wijdicks et al. 1999). Cyclosporine trough levels correlate poorly with cyclosporine neurotoxicity (Wijdicks et al. 1999), although in most studies symptoms resolved when the cyclosporine was discontinued and subsequently reinstated at a lower dosage (Wijdicks et al. 1999). Anticonvulsants can successfully treat cyclosporine-induced seizures but are not required long-term (Wijdicks et al. 1996), and seizures may cease with reduction or discontinuation of cyclosporine. A few patients with serious clinical neurotoxic side effects have been found to have diffuse white matter abnormalities, predominantly in the occipitoparietal region, on computed tomography (CT) scanning (deGroen et al. 1987; Gijtenbeek et al. 1999; Wijdicks et al. 1995). In one case, symptoms of cyclosporine-induced cortical blindness resolved with drug discontinuation, although pathological evidence of CNS demyelination persisted for months afterward (Wilson et al. 1988).

Several mechanisms may contribute to the CNS neurotoxicity of cyclosporine. Hypocholesterolemia has been found in a high percentage of patients with serious neurotoxicity (deGroen et al. 1987; Wijdicks et al. 1995). Access may be particularly high in the white matter, with a relatively high density of low-density lipoprotein receptors (Wijdicks et al. 1995). In addition to hypocholesterolemia, hypertension, hypomagnesemia, and the vasoactive agent endothelin may play a role in the pathogenesis of cyclosporine neurotoxicity (Gijtenbeek et al. 1999).

## Tacrolimus

Tacrolimus (FK506, Prograf), a macrolide produced by *Streptomyces tsukubaensis*, is used as primary immunosuppressive therapy, as rescue therapy for patients who fail to respond to cyclosporine, and as treatment for graft-versus-host disease. It is more potent and possibly less toxic than

cyclosporine, although the neuropsychiatric side effects appear to be similar (DiMartini et al. 1991; Freise et al. 1991). As with cyclosporine, neuropsychiatric side effects are more common with intravenous administration and diminish with oral administration and dosage reduction. Common symptoms include tremulousness, headache, restlessness, insomnia, vivid dreams, hyperesthesias, anxiety, and agitation (Fung et al. 1991). Cognitive impairment, coma, seizures, dysarthria, and delirium occur less often (8.4%) and are associated with higher plasma levels (DiMartini et al. 1997; Fung et al. 1991). FK506 can produce symptoms of akathisia (Bernstein and Daviss 1992). However, a prospective study of 25 renal transplant recipients found no correlation between FK506 plasma levels and scores on an akathisia rating scale, although higher plasma levels were associated with higher levels of subjective restlessness, tension, and autonomic and cognitive symptoms of anxiety (DiMartini et al. 1996).

FK506 has low aqueous solubility and cannot be detected in the cerebrospinal fluid of patients with suspected neurotoxicity (Venkataramanan et al. 1991). However, because FK506 has been identified in the brain tissue of animals, it is believed to cross the blood-brain barrier in humans. In addition, more serious neurotoxic side effects (focal neurological abnormalities, speech disturbances, hemiplegia, and cortical blindness) may occur from higher CNS levels in patients who have a disrupted blood-brain barrier (Eidelman et al. 1991). In a study of 294 consecutive transplant recipients on FK506, those with preexisting CNS damage (e.g., from stroke, multiple sclerosis) were at higher risk for neurotoxic side effects (Eidelman et al. 1991). A rare syndrome of immunosuppression-induced leukoencephalopathy, involving demyelination (particularly in the parieto-occipital region and centrum semiovale), has been described in transplant recipients receiving FK506 (Small et al. 1996). The clinical presentation includes generalized seizures without a clear metabolic etiology and radiographic abnormalities in the cerebral white matter of the parietal/occipital lobes. Like other serious neurotoxic side effects, this syndrome is not associated with the absolute serum level of FK506 but does resolve on discontinuation of FK506 (Small et al. 1996). The mechanism of FK506 neurotoxicity is unclear but may include direct activity at the CNS neuronal level (Dawson and Dawson 1994) or an immune-mediated cause (Wilson et al. 1994).

## Corticosteroids

Although chronic corticosteroid use has become less essential in immunosuppression for most patients post-transplantation, high dosages of corticosteroids are still

employed in the early postoperative phase and also as “pulsed” dosages to treat acute rejection. Behavioral and psychiatric side effects are common, but conclusions regarding the incidence or characteristics of these effects—or the specific dosages required to cause such effects—are not well established. Serious psychiatric side effects have a reported incidence of 5%–6% (Kershner and Wang-Cheng 1989; Lewis and Smith 1983) and include a wide range of cognitive, affective, psychotic, and behavioral symptoms (Hall et al. 1979; Kershner and Wang-Cheng 1989; Lewis and Smith 1983; Varney et al. 1984). These side effects are reviewed elsewhere in this book, particularly in Chapter 9, “Depression”; Chapter 11, “Mania, Catatonia, and Psychosis”; Chapter 23, “Endocrine and Metabolic Disorders”; and Chapter 25, “Rheumatology.”

### Sirolimus

Sirolimus (SRL, rapamycin, Rapamune), a macrocyclic lactone isolated from *Streptomyces hygroscopicus*, is a recent addition to the posttransplant immunosuppressive armamentarium. The side-effect profile of sirolimus so far does not include neurotoxicity (Watson et al. 1999), perhaps because sirolimus does not block calcineurin (Sindhi et al. 2001). However, a systematic evaluation of sirolimus neurotoxicity has yet to be conducted.

### Azathioprine

Azathioprine (Imuran) is a purine analog first used in organ transplantation in 1968. It is primarily used as an adjunctive immunosuppressive agent and is less widely used today because of the availability of alternative agents. Specific neuropsychiatric side effects have not been reported for this agent, although CNS complications of immunosuppression are a mechanism to keep in mind. Several reports of depressive symptoms in patients receiving azathioprine have been complicated by the concurrent use of other medications (specifically cyclosporine and prednisone) that may have contributed to mood disturbance. Nevertheless, caution is recommended when using azathioprine in patients with a history of depression.

### Mycophenolate Mofetil

Few neuropsychiatric symptoms have been reported with mycophenolate mofetil (CellCept), a relatively new immunosuppressant promoted as an improvement over azathioprine. Adverse CNS events (>3% to <20% incidence) included anxiety, depression, delirium, seizures, agitation, hypertonia, paresthesias, neuropathy, psychosis, and somnolence (Roche Pharmaceuticals 2003); however, because

the patients in whom these symptoms occurred were being treated with mycophenolate in combination with cyclosporine and corticosteroids, the precise contribution of mycophenolate to the symptoms is difficult to interpret.

### Drug Interactions Between Psychotropic and Immunosuppressive Medications

Many of the immunosuppressive medications (i.e., tacrolimus, cyclosporine, and mycophenolate) are metabolized by cytochrome P450 3A4; thus, concurrent use of psychotropic medications that strongly inhibit 3A4 should be avoided. Specific cytochrome P450 3A4 inhibitors capable of interacting adversely with immunosuppressive medications, in decreasing order of inhibition, are as follows: fluvoxamine, nefazodone > fluoxetine > sertraline, TCAs, paroxetine > venlafaxine (see also Table 37–1 in Chapter 37, “Psychopharmacology”). There are case reports in which nefazodone has caused toxic tacrolimus levels (Campo et al. 1998) and a 70% increase in the trough plasma level of cyclosporine (Helms-Smith et al. 1996). In a study in which fluoxetine and TCAs were used to treat depressed transplant recipients, no difference in cyclosporine blood level-to-dosage ratios and dose-response relationships was found between those treated and those not treated with antidepressants (Strouse et al. 1996). This finding suggests that antidepressants with less cytochrome P450 3A4 inhibition may not have clinically meaningful drug interactions with these immunosuppressive medications.

Psychotropic medications theoretically may alter immune function. Some psychotropic medications induce a variety of neuroendocrine and cellular actions that could have immunological effects, yet this area has not been well investigated (Surman 1993). For example, lithium has been shown to enhance neutrophil migration, increase phagocytosis by macrophages, and amplify mitogen stimulation of lymphocytes (Surman 1993). Although the role of these effects in allograft function is not known, lithium has been used to increase the number of peripheral neutrophils (Ballin et al. 1998) to reduce neutropenia. The modulatory effects of psychotropic drugs on the immune system are largely unexplored but may provide valuable information for the future care of transplant patients (see Kradin and Surman 2000 for a complete review).

# 32 Neurology and Neurosurgery

---

Alan J. Carson, M.Phil., M.D., M.R.C.Psych.

Adam Zeman, M.A., D.M., M.R.C.P.

Lynn Myles, B.Sc., M.D., F.R.C.S.Ed.

Michael C. Sharpe, M.A., M.D., F.R.C.P., M.R.C.Psych.

**THE DIVIDE BETWEEN** neurology and psychiatry is viewed by many as a historical artifact (Baker et al. 2002). Psychiatrists have taken on primary responsibility for caring for brain injury, epilepsy, early-onset dementias, and sleep and movement disorders while retaining their more traditional role of diagnosing and treating “psychiatric” disorders in patients with neurological disease. Some neurologists have developed interests in cognitive and behavioral neurology and have focused on disorders traditionally considered to be psychiatric. New developments in neuroscience are bringing an understanding of the mechanisms of interaction between biological, psychological and social aspects of illness, making this one of the most intellectually fascinating areas of work for a psychiatrist.

Psychiatrists working in a clinical neurosciences center are likely to be required to address four main categories of clinical problems:

1. Cognitive impairment—either as a primary presentation or as a secondary complication of a known condition such as multiple sclerosis.
2. Neurological disease accompanied by emotional disturbance in excess of the clinical norm.
3. Physical symptoms that do not correspond to any recognized pattern of neurological disease.
4. Postneurosurgery complications—usually involving behavioral, cognitive, or emotional disturbance.

In this chapter, we concentrate on commonly encountered neurological conditions—stroke, Parkinson’s dis-

ease, multiple sclerosis, amnesic syndromes, dementias with additional prominent neurological signs, epilepsy, headache, movement disorders, and conversion disorder—as well as on selected psychiatric aspects of neurosurgery. The principles of assessment applicable to these disorders are also relevant to other, rarer neurological conditions. Psychopharmacological and psychological treatments are not discussed in detail here because they are covered in other chapters. Although we refer to drug therapies, we wish to remind the reader that for many neuropsychiatric conditions, behavioral management and environmental manipulation are of equal importance.

Neuropsychiatric topics covered elsewhere in this book include the mental status examination (Chapter 1, “Psychiatric Assessment and Consultation”), neuropsychological testing (Chapter 2, “Neuropsychological and Psychological Evaluation”), delirium (Chapter 6, “Delirium”), dementia (Chapter 7, “Dementia”), traumatic brain and spinal cord injuries (Chapter 35, “Physical Medicine and Rehabilitation”), pain syndromes (Chapter 36, “Pain”), and psychopharmacological interventions in neurological disease (Chapter 37, “Psychopharmacology”).

## Stroke

---

A cerebrovascular accident, or stroke, is a rapidly developed clinical sign of a focal disturbance of cerebral function of presumed vascular origin and of more than 24 hours’ du-

ration. One of two main pathological processes is responsible: cerebral infarction or hemorrhage. *Infarction* may result from thrombosis of vessels or emboli lodged within them. *Hemorrhage* can be either into brain tissue directly or into the subarachnoid space. Infarctions are four times more common than hemorrhages and, as a result of a lower immediate fatality rate, are a much greater source of enduring disability, with approximately 75% survival, compared with 33% survival at 1 year after hemorrhage. Strokes are the third most common cause of death in the Western world. The Oxfordshire Community Stroke Project reported a population incidence of 2 per 1,000 for first-ever stroke (Bamford et al. 1988). Age is the major risk factor, although one-quarter of persons affected are younger than 65 years. Stroke occurs more commonly in men.

Psychiatrists are not usually involved in the diagnosis of acute stroke but occasionally are consulted when alterations in cognition, affect, or behavior dominate the clinical picture.

## Clinical Features

The classical presentation of *middle cerebral artery* infarction is contralateral hemiparesis and sensory loss of a cortical type. These are often accompanied by hemianopsia if the optic radiation is affected. If the lesion is in the dominant hemisphere, then aphasia may be expected, whereas a lesion in the nondominant hemisphere may be accompanied by neglect or perceptual disturbance.

Infarctions affecting the distribution of the *anterior cerebral artery* will lead to contralateral hemiparesis affecting the leg more severely than the arm. A grasp reflex and motor dysphasia may be present. Cognitive changes resembling a global dementia may occur, with incontinence. Residual personality changes (apathy and/or dys-executive function) of a frontal type can also result.

*Posterior cerebral artery* infarction presents with a contralateral hemianopsia sometimes accompanied by visual hallucinations, visual agnosias, or spatial disorientation. Transient confusion may obscure the detection of hemianopsia. Vital memory structures are supplied from the posterior cerebral artery, and in some neurologically normal individuals both medial thalamic areas are supplied by a single penetrating artery. Dense amnesic symptoms occur if the hippocampus and other limbic structures are involved bilaterally. Diagnosis may be difficult, because early computed tomography (CT) scan findings are often negative; however, magnetic resonance imaging (MRI) will show the bilateral lesions.

*Internal carotid artery occlusion* can be entirely asymptomatic, but much depends on the collateral circulation.

The clinical picture is often that of middle cerebral artery infarction. However, in some situations, cognitive and behavioral symptoms are predominant, with general slowing, decreased spontaneous activity, and dyspraxia.

*Vertebrobasilar strokes* can be extremely diverse in their manifestations. Total occlusion of the basilar artery is usually rapidly fatal. Partial occlusions typically affect the brain stem, with a combination of uni- or bilateral pyramidal signs and ipsilateral cranial nerve palsies. One variant of brain-stem stroke is the “locked in” syndrome, in which total paralysis is accompanied by full alertness and awareness. Occlusions of the rostral branches of the basilar artery can result in infarction of the midbrain, thalamus, and portions of the temporal and occipital lobes. A striking example of basilar artery occlusion is peduncular hallucinosis, in which patients have vivid, well-formed hallucinations that they recognize as unreal. One patient described seeing his wife growing a full and bushy black beard! States of bizarre disorientation can also occur and can be mistaken for confabulation or even deliberate play-acting.

## Cognitive Impairment and Delirium

Delirium affects 30%–40% of patients during the first week after a stroke, especially after a hemorrhagic stroke (Gustafson et al. 1993; Langhorne et al. 2000; Rahkonen et al. 2000). It is important to distinguish delirium from focal cognitive deficits affecting declarative memory. The presence of delirium after stroke is associated with poorer prognosis, longer duration of hospitalization, and increased risk of dementia (see Gustafson et al. 1991; Henon et al. 1999).

Dementia following stroke is common, occurring in approximately one-quarter of patients at 3 months after stroke (Desmond et al. 2000; Tatimichi et al. 1994a, 1994b). This figure rises significantly if focal impairments also are considered. *Vascular dementia* is an imprecise term referring to a heterogeneous group of dementing disorders caused by impairment of the brain's blood supply. These disorders fall into three principal categories: subcortical ischemic dementia, multi-infarct dementia, and dementia due to focal “strategic” infarction. Several sets of diagnostic criteria (e.g., the National Institute of Neurological Disorders and Stroke–Association Internationale pour la Recherche et l'Enseignement en Neurosciences [NINDS-AIREN] criteria) are available, with high specificity but low sensitivity for pathologically defined vascular dementia (Chui et al. 1992; Hachinski et al. 1974; Roman et al. 1993). The common occurrence of relatively subtle cognitive decline, falling short of frank dementia, in the context of cerebrovascular disease has

given rise to the broader concept of “vascular cognitive impairment.” Subcortical ischemic dementia and multi-infarct dementia are described in more detail in Chapter 7 (“Dementia”). The term *strategic infarction* describes the occurrence of unexpectedly severe cognitive impairment following limited infarction, often in the absence of classic signs such as hemiplegia. Sites at which infarctions can have such an effect include the thalamus, especially the medial thalamus; the inferior genu of the internal capsule; the basal ganglia; the left angular gyrus (causing Gerstmann’s syndrome of agraphia, acalculia, left–right disorientation, and finger agnosia); the basal forebrain; and the territory of the posterior cerebral arteries (Clark et al. 1994; Kumral et al. 1999; Rockwood et al. 1999; Tatimichi et al. 1992, 1995).

## Behavioral Changes

The diverse behavioral changes following stroke are not unique to this condition and can therefore serve as a helpful model for understanding the clinical consequences of focal cerebral lesions of other causes (Bogousslavsky and Cummings 2000).

### *Aphasia*

Global aphasia leads to the abolition of all linguistic faculties. Consequently, the physician must draw inferences about mental state from the patient’s behavior and non-verbal communication. Some accounts associate Broca’s aphasia with intense emotional frustration that may be secondary to problems in social interaction (Carota et al. 2000). Wernicke’s aphasia has been characterized as lack of insight accompanied by irritability and rage, with recovered patients reporting that they believed the examiner was being deliberately incomprehensible (Lazar et al. 2000).

### *Anosognosia*

Anosognosia refers to partial or complete unawareness of a deficit. It may coexist with depression (Starkstein et al. 1990), a finding that both implicates separate neural systems for different aspects of emotions (Damasio 1994) and suggests that depression after stroke cannot be explained solely as a psychological reaction to disability (Ramasubbu 1994). Anosognosia for hemiplegia is perhaps the most often described form of the condition, but anosognosia can occur with reference to any function and is commonly associated with visual and language dysfunction. Patients with anosognosia for hemiplegia have no spontaneous complaints and may indeed claim normal movements in the paralyzed limb. Behavioral correlates

include attempting to walk normally despite the hemiplegia and paradoxical acceptance of a wheelchair while simultaneously maintaining that one has normal function. In extreme cases, ownership of the limb is denied or, exceptionally, phantom limb sensations can occur. Anosognosia occurs more frequently with right-sided lesions, particularly those in the region of the middle cerebral artery (Breier et al. 1995; Jehkonen et al. 2000; Meador et al. 2000).

### *Affective Dysprosodia*

Affective dysprosodia is impairment of the production and comprehension of those language components that communicate inner emotional states in speech. These components include stresses, pauses, cadence, accent, melody, and intonation. Affective dysprosodia is not associated with an actual deficit in the ability to *experience* emotions; rather, it is associated with a deficit in the ability to *communicate* or *recognize emotions in the speech of others*. Affective dysprosodia is particularly associated with right-sided lesions. A depressed patient with dysprosodia will appear depressed and say that he is depressed, but he or she will not “sound” depressed. This is in contrast to a patient with anosognosia, who will both appear and sound depressed but may deny that he or she is depressed.

### *Apathy*

Patients with apathy show little spontaneous action or speech; their responses may be delayed, short, slow, or absent (Fisher 1995). Apathy is frequently associated with hypophonia, perseveration, grasp reflex, compulsive motor manipulations, cognitive and functional impairment, and older age. Hypoactivity of the frontal and anterior temporal regions has been observed (Starkstein et al. 1993a).

### *Depression*

Although depression following stroke is commonly defined according to DSM-IV-TR (American Psychiatric Association 2000) or ICD-10 criteria (Starkstein and Robinson 1989), the imposition of these categorical diagnoses on patients who have suffered a stroke is problematic, because it is often unclear which symptoms are attributable to the stroke and which are attributable to depression (Gainotti et al. 1997, 1999). One solution is to focus on symptoms other than somatic ones, and scales such as the Hospital Anxiety and Depression Scale have been designed to do this. However, this is not an adequate solution, because the neurobehavioral consequences of cerebral lesions—such as aphasia, indifference, denial, cognitive impairment, and dissociation of subjective from displayed

emotion—can obscure and complicate the diagnosis of depression. Most clinicians take a pragmatic approach, treating depression if the patient has symptoms suggestive of low mood or anhedonia accompanied by some somatic symptoms (e.g., insomnia, anorexia) as well as signs of lack of engagement with the environment (e.g., poor participation in physiotherapy).

Most epidemiological studies have suggested an association between depression and increased disability (Andersen et al. 1994b; Herrmann et al. 1995; Parikh et al. 1990; Pohjasvaara et al. 2001) and possibly mortality (House et al. 2001; Morris et al. 1993a). However, the direction of causality is unclear and is most probably circular. Some, but not all, pharmacological treatment studies have suggested that effective treatment of the depression leads to a reduction in overall disability (Andersen et al. 1994a; Lipsey et al. 1984).

There has been much speculation over the etiological mechanisms of depression after stroke, and emphasis has been placed on the site of the stroke lesion. One hypothesis put forward is that left frontal lesions are associated with an increased rate of depressive illness (Starkstein and Robinson 1989). There are, however, several limitations to this theory. First, it has been consistently found that patients with a premorbid history of depression are at higher risk of developing depression after stroke (Andersen et al. 1995). Second, it has proved impossible to clinically distinguish left frontal depression from depression associated with lesions in other brain regions (Gainotti et al. 1997). Finally, a recent meta-analysis reported that the available scientific literature does not support the left frontal hypothesis (Carson et al. 2000a).

It is generally recommended—but has not been conclusively demonstrated—that treatment for depression should be started early, in order to maximize functional outcome. However, disappointingly few randomized, controlled trials have tested this recommendation. Most studies suggest an improved outcome in mood with early treatment, but findings on measures of function have been contradictory (Andersen et al. 1994a; Chemerinski et al. 2001; Gainotti et al. 2001; Lipsey et al. 1984; Robinson et al. 2000; Wiart et al. 2000). Although both selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) have been reported to be effective, the SSRIs are probably preferable because of fewer adverse effects, particularly if cognitive or cardiac function is compromised. Nonetheless, this greater tolerability must be balanced against the finding that nortriptyline was more effective than fluoxetine in the only trial that compared these agents (Robinson et al. 2000). What is clear is that all stroke patients receiving antidepressants should be closely monitored for both treatment effectiveness and

adverse drug effects. Psychological treatment—in particular, cognitive-behavioral therapy (CBT)—potentially offers a solution for cases in which pharmacotherapy is ineffective or contraindicated, but thus far psychological approaches have received only limited evaluation (Kneebone and Dunmore 2000; Lincoln and Flannagan 2003). It is likely that only a minority of patients with poststroke depression are suitable for such treatment (Lincoln et al. 1997).

### *Anxiety*

Anxiety disorders are common after stroke and probably share the same risk factors as depression (Astrom 1996). Estimates of prevalence have varied markedly, depending on whether the investigators subsumed anxiety symptoms within the construct of major depressive disorder. Thus, the reported prevalence of generalized anxiety disorder ranges from 4% to 28% (Astrom 1996). However, the percentage of patients experiencing anxiety symptoms appears to be 25%–30% (Burvill et al. 1995).

Stroke is a sudden and unpredictable life-threatening stressor and, not surprisingly, a highly aversive experience (McEwen 1996). Poststroke anxiety states may include posttraumatic stress symptoms, with compulsive and intrusive revisiting of the event, as well as health worries, with checking and reassurance seeking about the risk of recurrence (Lyndsay 1991). These worries can be associated with agoraphobia and the misinterpretation of somatic anxiety symptoms, especially headache and dizziness, as evidence of recurrence. Phobic states have a prevalence of 5%–10%, with an excess found in women (Burvill et al. 1995). Although there is a paucity of controlled-trial evidence, it is our experience that these symptoms respond to standard drug and behavioral therapies.

### *Emotional Lability*

Emotionalism, or emotional lability, is an increase in laughing or crying that occurs with little or no warning. It is frequent in acute stroke but can also occur with delayed onset (Berthier et al. 1996). The displayed emotions are not related to the patient's internal emotional state. Whether emotional lability is associated with depression is a moot point; both conditions can exist independently (House et al. 1989; Robinson et al. 1993).

It has been suggested that the neurological basis is in serotonergic systems and that there is a specific response to SSRIs (Andersen et al. 1994a). In practice, the evidence is contradictory, with reports of response to TCAs as well (Robinson et al. 1993). There is no consistently reported associated lesion location: pontine, subcortical, and fron-

tal lesions have all been found (Andersen et al. 1994a; Derex et al. 1997; Morris et al. 1993b).

### ***Catastrophic Reactions***

Catastrophic reactions manifest as disruptive emotional behavior precipitated when a patient finds a task unsolvable (Goldstein 1939). The sudden, dramatic appearance of such marked self-directed and stereotypical anger or frustration can be startling for both staff and relatives. This symptom is often associated with aphasia, and it has been suggested that damage to language areas is a critical part of the etiology (Carota et al. 2001). Catastrophic reactions generally occur independently of depression in acute stroke; however, many patients who show early catastrophic reactions go on to develop depression (Starkstein et al. 1993b).

### ***Psychosis***

Psychosis—and, in particular, mania—has been observed following acute stroke. Its true incidence is unknown, although a rate of 1% has been reported (Starkstein et al. 1987). Psychotic symptoms have generally been associated with right-sided lesions (Cummings and Mendez 1984), although the failure to substantiate the proposed association of lesion location with depression should lead to caution in evaluating such claims. Old age and preexisting degenerative disease seem to increase the risk (Starkstein 1998) (see Chapter 11, “Mania, Catatonia, and Psychosis,” for further details and treatment considerations). Reduplicative paramnesias can occur: One memorable patient believed he was being treated on a cruise liner; on looking out of the window and seeing hospital porters delivering goods, he surmised that the ship must be in “dry dock.” Such paramnesias are usually short-lived, although a small number of chronic cases have been reported (Vighetto et al. 1980).

### ***Obsessive-Compulsive Disorder***

Obsessive-compulsive disorder has been reported after cerebral infarctions, particularly those affecting the basal ganglia (Maraganore et al. 1991; Rodrigo et al. 1997).

### ***Hyposexuality***

Hyposexuality is a common complaint after stroke in both men and women (see also Chapter 17, “Sexual Disorders”). The symptoms generally are nonspecific, although health worries concerning body image and fear of recurrence may also be relevant. A relationship between reduced libido and emotionalism has also been proposed, suggesting a common serotonergic dysfunction (Kim and Choi-Kwon 2000).

### ***Executive Function Impairment***

Executive function is regulated by complex systems that are relatively resistant to damage after stroke (Carota et al. 2002), although executive function is commonly impaired as part of a general dementia.

### ***Inhibition Dyscontrol***

Deficit of inhibition control occurs with impulsive behavior. The most striking examples of inhibition dyscontrol are grasp reflexes, but utilization behavior (a tendency to use objects present in the environment automatically), hyperphasia, and hypergraphia have all been described. Such behavior tends to improve during the first few months after stroke (Carota et al. 2002).

### ***Loss of Empathy***

Loss of empathy has been reported after bilateral orbitofrontal lesions (Stone et al. 1998). It has been suggested that this difficulty in understanding and adapting to the needs of others may underlie many of the personality changes associated with frontal lesions. These changes include lack of tact, inappropriate familiarity, loss of initiative and spontaneity, childish behavior, sexual disinhibition, and poverty of emotional expression (Carota et al. 2002).

## **Parkinson's Disease**

---

Parkinson's disease (PD) is a degenerative condition characterized by tremor, rigidity, and bradykinesia.

### **Incidence**

Two recent incidence studies of PD, one from Minnesota (Bower et al. 1999) and one from Finland (Kupio et al. 1999), estimated 10.8 cases per 100,000 person-years and 17.2 per 100,000 population, respectively. Both studies found a slight excess in men and confirmed that incidence increases with age. The Finnish study also suggested that PD was more common in rural areas.

### **Etiology**

The cause of PD remains unknown. Genetic forms of the disease have been described, but the implicated genes are not identified in most patients. Similarly, environmental causes have been suggested, but no single exposure has been consistently replicated, with the exception of cases associated with MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) (Tanner and Aston 2000). Cigarette smoking appears to decrease risk (Gorell et al. 1999).

## Clinical Features

The core feature of PD is the triad of tremor, rigidity, and bradykinesia (Sethi 2002). Bradykinesia—usually of insidious onset and easily misdiagnosed as depression or boredom—is the most common first sign and ultimately is the most disabling symptom. Resting tremor is the most characteristic feature of PD, affecting more than 70% of patients. In the early stages of the disease, the tremor is described as “pill-rolling.” The rigidity manifests as fixed abnormalities of posture and resistance to passive movement throughout the range of motion. Concurrent tremor creates a “cogwheel” sensation. Postural instability is a common additional feature, giving rise to an increasing liability to falls as the disorder progresses. Abnormal involuntary movements are a result both of the disease process and of dopaminergic therapy. Freezing of gait is particularly distressing to patients, but it is one of the most poorly understood features of PD. Because such freezing may occur in response to visual cues (especially freezing during “off” periods), it can be misdiagnosed as willful behavior.

Nonmotor manifestations are common in PD and include autonomic (in particular, orthostatic hypotension and bladder and gastrointestinal dysfunction), sensory (pain), cognitive, and other psychiatric symptoms.

## Cognitive Features

Dementia with Lewy bodies (DLB), PD, and PD with dementia share common features, motor symptoms, and responses to treatment. The boundaries between these disorders may be less distinct than originally thought. Hallucinations and delusions occur in 57%–76% of DLB cases, in 29%–54% of cases of PD with dementia, and in 7%–14% of cases of PD without dementia (Aarsland et al. 2001). Delusions are often paranoid in type and mainly involve persecution and jealousy. Hallucinations usually occur in the presence of intact insight and frequently are visual and phenomenologically similar to those of Charles Bonnet syndrome (Diederich et al. 2000).

In the early days of levodopa (L-dopa) treatment, adverse psychiatric reactions were reported in 10%–50% of patients (Goodwin 1971). Psychosis occurred in about 10% of patients initially, but this percentage rose to 60% after 6 years of treatment (Sweet et al. 1976). The addition of carbidopa to L-dopa made this adverse effect less common. More recent studies have suggested that dopaminomimetic medication is a significant risk factor for psychosis (Aarsland et al. 1999). Other studies have shown correlations between psychotic symptoms and higher rates of cognitive dysfunction and depression, but no association

with dosage or length of exposure to dopaminomimetic medication has been found (Giladi et al. 2000). The most likely etiology of psychosis in PD is a combination of cortical PD pathology and age-related loss of central cholinergic function. This is corroborated by the fact that psychotic symptoms in PD are often part of nondopaminomimetic medication-induced toxic (i.e., delirious) states and that psychosis was commonly reported in the pre-levodopa era (Wolters and Berendse 2001). Cognitive impairment and sleep disruption are predictive of the development of psychosis (Arnulf et al. 2000).

Clinically, one should distinguish a delirium of acute onset with disorientation, impaired attention, perceptible and cognitive disturbance, and alterations in the sleep-wake cycle from true dopaminomimetic psychosis, which is a subacute, gradually progressive psychotic state unaccompanied by a primary deficit of attention. The former may be induced by drugs used in the treatment of PD, such as selegiline and anticholinergic medication. For the latter, active treatment is recommended only if symptoms begin to interfere with daily functioning. Dose reduction of dopaminomimetic drugs is seldom effective, and antipsychotic drugs are often required (Wolters and Berendse 2001). The atypical antipsychotic drugs clozapine and quetiapine are preferred (Cummings 1999; Rabinstein and Shulman 2000), and high-potency typical antipsychotics should be avoided (see Chapter 11, “Mania, Catatonia, and Psychosis”). There is also increasing interest in the role of cholinesterase inhibitors in the treatment of dementia in PD, with early studies showing promising results (McKeith et al. 2000).

## Emotional Symptoms

Depression is a common symptom in PD, with a prevalence of around 40%–50%. Timing of onset shows a bimodal distribution, with peaks during early and late stages of the disease (Cummings and Masterman 1999). Several large-scale studies have demonstrated that depression is one of the major determinants of quality of life in PD (Findlay 2002; Peto et al. 1995). The extent to which depression is caused by brain pathology as opposed to a psychological reaction to disability is unknown.

The diagnosis of depression in PD is difficult, because many depressive symptoms overlap with the core features of PD—motor retardation, attention deficit, sleep disturbance, hypophonia, impotence, weight loss, fatigue, preoccupation with health, and reduced facial expression. However, anhedonia and sustained sadness are important diagnostic features, particularly if they are out of proportion to the severity of motor symptoms (Brooks and Doder 2001).

Mood changes can accompany the late-stage fluctuations in response to levodopa (known as “on–off” phenomena), and some patients fulfill criteria for major depressive disorder during the “off” phase but not during the “on” phase (Cantello et al. 1986; Menza et al. 1990). Bipolar mood changes reflecting the on–off phases have also been described (Keshavan et al. 1986). There is currently insufficient evidence to offer definitive recommendations for treatment of depression in PD (Olanow et al. 2001). Although SSRIs are popular, there have been case reports of exacerbation of motor symptoms with fluoxetine, citalopram, and paroxetine (Ceravolo et al. 2000; Chuinard and Sultan 1992; Jansen Steur 1993; Leo 1996; Tessei et al. 2000). In recent small-scale trials, TCAs have led to better motor outcomes than have SSRIs; however, TCAs with marked anticholinergic activity (e.g., amitriptyline) should be used with caution because of their potential adverse effects on cognition and autonomic function (Olanow et al. 2001). It may be that newer drugs such as mirtazapine will offer a compromise. The non-ergot dopamine agonist pramipexole has been found to improve both mood and motivation in PD (Armin et al. 1997). Case report data suggest that both electroconvulsive therapy (ECT) and transcranial magnetic stimulation (TMS) can be used to treat depression in PD, although TMS is associated with short-lived adverse effects and seizures (George et al. 1996; Olanow et al. 2001). The use of ECT in PD is reviewed at length in Chapter 39, “Electroconvulsive Therapy.”

Anxiety phenomena are common in PD; they tend to occur later in the disease process than depression and are more closely associated with severity of motor symptoms (Witjas et al. 2002). In particular, marked anticipatory anxiety related to freezing of gait is common. Treatment with antidepressant drugs (Olanow et al. 2001) and CBT, particularly if delivered in conjunction with an active physiotherapy program, can be helpful. Occasionally, benzodiazepines may be required.

## Multiple Sclerosis

---

Multiple sclerosis (MS) is a demyelinating disorder of the central nervous system (CNS) that causes some degree of cognitive impairment in almost half of cases and that can present with unexplained subcortical dementia. It can also be accompanied by affective disorders. The presence of high signal abnormalities on T2-weighted MRI and of oligoclonal bands of immunoglobulin in the cerebrospinal fluid (CSF) helps to confirm the diagnosis.

Demyelinating diseases are the most common non-traumatic cause of chronic neurological disability in young

adults. Although a number of inflammatory demyelinating diseases can affect the CNS after vaccinations or systemic viral infection (collectively referred to as acute disseminated encephalomyelitis [ADEM]), MS is by far the most common of these.

MS can occur at any age, but the median age at onset is 24 years, with a tendency for relapsing–remitting disease to present earlier than primary progressive MS. MS is more common in women. Epidemiological studies suggest that an exogenous or environmental factor, possibly viral infection, plays a part, although its nature remains unclear. The prevalence of the disorder rises with increasing distance from the equator. Genetic factors appear to influence susceptibility. A family history in a first-degree relative increases the risk some 30- to 50-fold: the risk for siblings is usually estimated to be 3%–5%, with that for children slightly lower (Franklin and Nelson 2003).

Common neurological syndromes occurring at or close to the onset of MS include optic neuritis (unilateral visual impairment, usually painful), ascending sensory loss, and upper-motor-neuron or cerebellar disorders of the limbs and gait. These deficits typically develop and remit over the course of weeks and result from conduction block in regions of inflammation. Transient worsening of function, lasting for minutes, can occur in partially demyelinated axons as a result of physiological changes (e.g., increase in body temperature). Positive symptoms, including L’hermitte’s phenomena (electric shock–like sensations on flexing the neck) and trigeminal neuralgia, can also occur. Over time, the remissions and relapses of MS tend to give way to a progressive worsening of disability. A minority of patients present with a primary progressive form of the disease, with gradual worsening from onset without remissions (McDonald et al. 2001).

Pathologically, MS is characterized by multifocal areas of demyelination with relative preservation of axons, loss of oligodendrocytes, and astroglial scarring. Although axons are relatively spared, axonal loss and cortical atrophy occur, and their development probably contributes to the permanent disability, including cognitive dysfunction, caused by the disorder (Lucchinetti et al. 2001).

Patients with unsuspected MS may first present to psychiatrists with changes in cognitive function, mood, or personality. More often, however, psychiatrists are involved in the treatment of established cases. MS demonstrates the interactive nature of many of the common symptoms of diffuse neurological disease, in particular the “vicious cycle” of mood symptoms, pain, and fatigue, necessitating intervention across the spectrum of complaints in order to improve outcome.

## Cognitive Impairment

Cognitive impairment affects at least half of all patients with MS (Beatty et al. 1989a; Heaton et al. 1985; Rao 1986; Rao et al. 1991). The impairment is generally described as a subcortical dementia characterized by problems with memory, speed of processing, and executive functions (Beatty et al. 1989b; Litvan et al. 1988b; Rao et al. 1984, 1989). Cortical syndromes such as aphasia, apraxia, and agnosia are relatively rare. It has been suggested that greater impairments may occur in secondary progressive MS, although this has been disputed (Rao 1986; Rao et al. 1991). Disorders of working memory may be prominent, particularly verbal but sometimes visuospatial memory (Litvan et al. 1988a; Rao et al. 1993). It is important to bear in mind that depression, anxiety, and fatigue all may affect cognitive function; thus, neuropsychological testing can be helpful in determining whether true deficits are present.

## Mood Disorders

Mood disorders are common in MS, with more than half of patients reporting depressive symptoms. Mania and emotional lability are also frequently reported (Joffe et al. 1987; Sadovnick et al. 1996) (see also Chapter 9, "Depression," and Chapter 11, "Mania, Catatonia, and Psychosis").

It is important to distinguish depression from the fatigue and pain that are commonly associated with MS (see subsections "Fatigue" and "Pain" below). As in stroke, there has been an attempt to separate out a "biological" depression from a "psychological reactive" depression (Patten and Metz 1997) and to link symptoms to the site of the brain lesions (Fassbender et al. 1998; Honer et al. 1987; Pujol et al. 1997). However, supporting evidence has been inconsistent and hampered by small study samples; for this reason, it appears to be more productive to consider depression in MS as multifactorial. There are few randomized, controlled trials of antidepressant drug therapy in MS, but those available suggest modest efficacy for these agents (Feinstein 1997), similar to their efficacy for depression associated with neurological illness in general (Schiffer and Wineman 1990).

Interferon-beta therapy was reported to cause depression (and fatigue) in 40% of MS patients in an open-label trial (Neille et al. 1996). However, depression is highly prevalent in untreated MS, and more recent studies have found no increase in depression following interferon-beta therapy (Patten and Metz 2001; Zephir et al. 2003). In one prospective study, the rate of depression actually fell with interferon-beta treatment (Feinstein et al. 2002).

## Fatigue

Fatigue is the most common single symptom in MS, affecting 80% of those with the disease (Fisk et al. 1994; Freal et al. 1984). It is generally a disabling and aversive experience and affects motivation as well as physical strength. It is important to differentiate fatigue from depression, adverse medication side effects, or pure physical exhaustion secondary to gait abnormalities, because management may differ (Multiple Sclerosis Council for Practice Guidelines 1998). The mechanism of fatigue is poorly understood and almost certainly multifactorial. Amantadine 100 mg twice daily has been reported to be of some benefit (Krupp et al. 1995), and pemoline has also been suggested as useful (Krupp et al. 1995). A number of other agents, including 4-aminopyridine (Polman et al. 1994), 3,4-diaminopyridine (Sheean et al. 1997), and modafinil (Rammohan et al. 2002), have been advocated, but results of studies with these drugs have been inconclusive. Some patients respond to SSRIs, and cognitive-behavioral treatments have also been used (Mohr et al. 2003).

## Pain

Pain, both acute and chronic, is a common and disabling complication of MS. A recent study found that one-quarter of MS patients in a large community-based sample had severe chronic pain (Ehde et al. 2003). Mechanisms may include dysesthesia, altered cognitive function, and other MS complications such as spasticity. Of the acute pain syndromes, trigeminal neuralgia is the most common and usually responds to carbamazepine (Thompson 1998). Widespread chronic pain is more frequent and harder to manage. Dysesthetic limb pain is particularly troublesome; treatment is usually with amitriptyline or gabapentin (Samkoff et al. 1997). Pain in the lumbar area, by contrast, usually tends to respond better to physiotherapy than to analgesia (Thompson 1998; see also Chapter 36, "Pain").

## Amnestic Syndromes

---

The amnestic or amnesic syndrome is an abnormal mental state in which learning and memory are affected out of proportion to other cognitive functions in an otherwise alert and responsive patient (Victor et al. 1971). The most common cause of amnestic states is Wernicke-Korsakoff syndrome, which results from nutritional depletion, particularly thiamine deficiency. Other causes include carbon monoxide poisoning, herpes simplex encephalitis and

other CNS infections, hypoxic and other acquired brain injuries, stroke, deep midline cerebral tumors, and surgical resections, particularly for epilepsy. In the majority of cases, the pathology lies in midline or medial temporal structures, but there are also case reports of amnesic disorder following frontal lobe lesions.

## Wernicke-Korsakoff Syndrome

Wernicke-Korsakoff syndrome results from thiamine depletion, and any cause of such depletion can lead to the syndrome. However, the overwhelming majority of cases are associated with chronic alcohol abuse, which results in both decreased intake and decreased absorption of thiamine. A genetic defect for thiamine metabolism has been described in a small proportion of patients (Blass and Gibson 1977).

The syndrome presents acutely with Wernicke's encephalopathy, which is characterized by confusion, ataxia, nystagmus, and ophthalmoplegia. Peripheral neuropathy can also be present. Parenteral administration of high-dose B vitamins is required as *emergency* treatment if the chronic state of Korsakoff's syndrome is to be avoided. The majority of cases of Korsakoff's syndrome occur following Wernicke's encephalopathy.

On clinical examination, patients with Korsakoff's syndrome may perform well on standard tasks of attention and working memory (serial sevens and reverse digit span) (Kopelman 1985) but may struggle on more complex tasks involving shifting and dividing attention. A severe memory impairment involving both anterograde and retrograde deficits is present (Kopelman et al. 1999). The defective encoding of new information is the core component of this memory disorder (Meudell and Mayes 1982). This results in a dense anterograde amnesia affecting declarative functions, and inconsistent, poorly organized retrieval of retrograde memories with a temporal gradient (more impairment for relatively recent than for more remote memories). The retrograde amnesia is more pronounced in diencephalic amnesic syndromes such as Korsakoff's than in amnesic syndromes of hippocampal origin, in which retrograde amnesia is present but with a deficit measured in months rather than years (Kopelman et al. 1999). A limited degree of new learning may be possible, particularly if patients are given a strategy to follow. Confabulation commonly occurs, particularly early in the disorder. Procedural memory remains relatively intact (Schacter 1987).

Other cognitive impairments and behavioral changes may accompany the amnesia. Executive functions are commonly mildly affected, but this impairment may be secondary to chronic alcoholism rather than representing

a specific deficit. Disorientation and apathy, often with lack of curiosity about the past, are common, yet such disengaged patients frequently demonstrate labile irritability.

The pathological process is neuronal loss, microhemorrhages, and gliosis in the paraventricular and periaqueductal gray matter (Victor et al. 1971). The mammillary bodies, mammillothalamic tract, and the anterior thalamus are the main structures affected (Mair et al. 1979; Mayes et al. 1988). There is often a degree of generalized cortical atrophy, more marked in the frontal lobes (Jacobson and Lishman 1990). The atrophy may, however, be nonspecific and secondary to alcohol abuse. MRI indicates specific atrophy in diencephalic structures (Colchester et al. 2001).

With vitamin replacement and abstinence from alcohol, the prognosis is fair: one-quarter of patients will recover, half will improve but with some persistent impairment, and one-quarter will show no change (Victor et al. 1971). High-dose B vitamins should be given to all patients acutely and probably continued, but it is unclear how long this therapy should be maintained.

## Transient Amnesic Syndromes

Transient amnesia can occur in several contexts. Transient global amnesia (TGA) is a distinctive benign disorder affecting middle-aged or elderly persons, who become amnesic for recent events and unable to lay down new memories for a period of around 4 hours (Hodges and Ward 1989). Repetitive questioning by patients of their companions is a characteristic feature. Episodes can be provoked by physical or emotional stress and are usually isolated; the medium-term recurrence rate is 3% per year (Hodges 1991). There is good evidence that TGA results from reversible medial temporal lobe dysfunction, but the etiological mechanism is uncertain (Stillhard et al. 1990). Although temporal lobe epilepsy occasionally mimics TGA ("transient epileptic amnesia"), episodes are typically briefer (lasting less than an hour), recurrent (several per year), and tend to occur on waking (Zeman et al. 1998). Other causes of transient amnesia include transient cerebral ischemia (usually accompanied by other neurological symptoms and signs), migraine, drug ingestion, and head injury.

## Dementias Accompanied by Neurological Signs

---

Dementia refers to a deterioration of intellectual faculties, such as memory, concentration, and judgment, that is some-

times accompanied by emotional disturbance and personality changes. An approach to management of dementing conditions (including Alzheimer's disease, vascular dementia, Lewy body dementia, frontotemporal dementia, Huntington's disease, Parkinson's disease, and normal-pressure hydrocephalus, among others) is described in detail in Chapter 7, "Dementia." In this section, we concentrate on those disorders that are particularly likely to present with other neurological symptoms, often a movement disorder. Other causes of dementia are also discussed elsewhere in this volume: HIV (see Chapter 28, "HIV/AIDS"), other infections (see Chapter 27, "Infectious Diseases"), alcohol and other substance use (see Chapter 18, "Substance-Related Disorders"), toxic and metabolic conditions (see Chapter 23, "Endocrine and Metabolic Disorders"), rheumatological and inflammatory conditions (see Chapter 25, "Rheumatology"), and traumatic and brain injury (see Chapter 35, "Physical Medicine and Rehabilitation").

## Huntington's Disease

Huntington's disease (HD), also known as Huntington's chorea, was first described in Long Island in 1872 by George Huntington. This dominantly inherited disorder, which causes a combination of progressive motor, cognitive, psychiatric, and behavioral dysfunction, results from an abnormality in the *IT15* gene on chromosome 4 encoding the protein huntingtin.

### *Epidemiology*

HD occurs at a prevalence of 5–7 per 100,000 population in the United States, with wide regional variations (Chua and Chiu 1994). The sexes are affected equally. Onset can be at any age but most commonly is in young or middle adulthood (Adams et al. 1988; Farrer and Conneally 1985). The disorder exhibits the phenomenon of *anticipation*, in which the age at onset tends to decrease over the generations, especially with paternal transmission (Brinkman et al. 1997) (see subsection "Pathology and Etiology" below).

### *Clinical Features*

Chorea—involuntary fidgety movements of the face and limbs—is the characteristic motor disorder. As the disease progresses, other extrapyramidal features can develop, including rigidity, dystonia, and bradykinesia, as well as dysphagia, dysarthria, and pyramidal signs (Harper 1991). Childhood-onset HD tends to be dominated by rigidity and myoclonus (the "Westphal variant"). Epilepsy can occur. Cognitive dysfunction goes hand in hand with the motor disorder. The dementia of HD is predominantly

"subcortical," with impairment of attention, executive function, speed of processing, and memory (Zakzanis 1998). Psychiatric symptoms and behavioral changes are the norm (Mendez 1994; Zappacosta et al. 1996), with depression, apathy, and aggressiveness present in most cases (Burns et al. 1990; Levy et al. 1998) and psychosis, obsessional behavior, and suicide in a significant minority (Almqvist et al. 1999; Cummings and Cunningham 1992; Folstein et al. 1979). Progression to a state of immobility and dementia typically occurs over a period of 15–20 years (Feigin et al. 1995). Cognitive and behavioral changes may predate the clear-cut emergence of symptomatic HD (Kirkwood et al. 1999).

### *Pathology and Etiology*

The key pathological processes of HD occur in the striatum, caudate, and putamen. The loss of small neurons in the striatum is accompanied by neuronal loss in the cerebral cortex, cerebral atrophy, ventricular dilatation, and, eventually, neuronal depletion throughout the basal ganglia (De la Monte et al. 1988; Vonsattel and DiFiglia 1998).

The underlying genetic abnormality is expansion of a "base triplet repeat" within the huntingtin gene. The normal gene contains 10–35 CAG (cytosine–adenine–guanine) repeats; repeat lengths beyond 39 give rise to symptomatic HD over the course of a normal life span (Duyao et al. 1993). Repeat lengths between 36 and 39 can cause disease. Repeats in the 27–35 range appear to be unstable and liable to increase into the pathological range in the next generation. The tendency for pathologically expanded repeats to increase in length between generations, especially in paternal transmission, underlies the clinical phenomenon of *anticipation*. The function of huntingtin remains uncertain.

### *Investigation and Differential Diagnosis*

A number of disorders can cause the combination of chorea and cognitive change seen in HD, including other inherited disorders such as neuroacanthocytosis and dentato-rubro-pallido-luysian atrophy (DRPLA) and acquired disorders such as systemic lupus erythematosus. However, the diagnosis of HD can now be made with confidence by DNA analysis. Counseling by a clinical geneticist is mandatory before presymptomatic testing and should be considered in other circumstances as well (Codori et al. 1997).

### *Management*

Chorea may require treatment. However, given the cognitive and extrapyramidal side effects of the agents used

(neuroleptics, dopamine depletors such as tetrabenazine or benzodiazepines), this is often best avoided (Rosenblatt et al. 1999). Other psychiatric symptoms should be treated along standard lines (Leroi and Michalon 1998).

## Wilson's Disease (Hepatolenticular Degeneration)

First described by Wilson in 1912, Wilson's disease is a very rare, autosomal recessive, progressive degenerative brain disease caused by a disorder of copper metabolism, producing personality change, cognitive decline, extrapyramidal signs, and cirrhosis of the liver.

### *Clinical Features*

The onset of Wilson's disease most commonly occurs in childhood or adolescence but can occur as late as the fifth decade (Bearn 1957). Patients may present to psychiatrists with personality change, behavioral disturbance (including psychosis), or dementia (Akil and Brewer 1995; Denning and Berrios 1989) or to neurologists with a variety of extrapyramidal signs, including tremor, dysarthria and drooling, rigidity, bradykinesia, and dystonia (Walsh 1986; Walsh and Yelland 1992). Careful examination reveals these features and also, in virtually all symptomatic cases, the presence of *Kayser-Fleischer rings*—rings of greenish-brown copper pigment at the edge of the cornea (Wiebers et al. 1997). (In suspected cases, an ophthalmologist should be asked to look for this feature with a slit lamp.) The liver failure and the neuropsychiatric syndrome can occur together or independently.

### *Pathology and Etiology*

The causative genetic mutation is in the copper-transporting P-type ATPase coded on chromosome 13 (Bull et al. 1993). The result is excessive copper deposition in the brain, cornea, liver, and kidneys and increased copper excretion in urine. The caudate and putamen are the brain regions most severely affected, but other parts of the basal ganglia and the cerebral cortex are also involved (Mochizuki et al. 1997; Starosta-Rubinstein et al. 1987).

### *Investigation and Differential Diagnosis*

Ninety-five percent of patients with Wilson's disease have low serum levels of the copper-binding protein ceruloplasmin. Normal ceruloplasmin levels and an absence of Kayser-Fleischer rings render the diagnosis very unlikely in cases with neuropsychiatric features (Ferenci 1998). Uncertain cases may require measurement of urinary copper excretion and liver biopsy for measurement of copper content (Pfeil and Lynn 1999). DNA analysis

is becoming increasingly available. The differential diagnosis varies with the type of presentation. The combination of psychological disturbance and unusual neurological features has led to misdiagnosis as conversion disorder.

### *Management*

Several copper-chelating agents (penicillamine, tetraethylene tetramine, zinc acetate) are available to treat patients with Wilson's disease, but the risk of significant side effects mandates care by a specialist (Pfeil and Lynn 1999).

## Leukodystrophies

Leukodystrophies—recessively inherited or X-linked disorders of myelination—can be accompanied by neuropsychiatric syndromes, usually with associated neurological features. Metachromatic leukodystrophy, caused by a deficiency of the enzyme arylsulfatase A (Hyde et al. 1992), and adrenoleukodystrophy (see also Chapter 23, "Endocrine and Metabolic Disorders"), an X-linked disorder associated with abnormalities of very-long-chain fatty acids (James et al. 1984), are the most commonly encountered types.

## Progressive Supranuclear Palsy

Progressive supranuclear palsy is characterized by supranuclear gaze palsy (an inability to direct eye movements voluntarily, especially vertical eye movements, in the presence of normal reflex eye movements); truncal rigidity, akinesia, postural instability, and early falls; bulbar features, with dysarthria and dysphagia; subcortical dementia; and alteration of mood (including pathological crying and laughing), personality, and behavior (De Bruin and Lees 1992). Neurofibrillary tangles, consisting of tau protein, are found in neurons of the basal ganglia and brain stem. Midbrain atrophy may be apparent on MRI.

## Corticobasal Degeneration

Corticobasal degeneration typically manifests as a combination of limb apraxia, usually asymmetric at onset, alien limb phenomena, limb myoclonus, parkinsonism, and cognitive decline (Rinne et al. 1994). The pathology involves neuronal loss in both the basal ganglia and the frontal and parietal cortex, with intraneuronal accumulations of tau protein resembling that seen in progressive supranuclear palsy. MRI usually reveals frontoparietal atrophy.

## Transmissible Spongiform Encephalopathies (Prion Dementias)

The transmissible spongiform encephalopathies are a group of rare dementias caused by an accumulation of abnormal prion protein within the brain. Related illnesses occur in animals: indeed, one recently described disorder, variant Creutzfeldt-Jakob disease, is thought to result from infection of humans by consumption of beef products from cattle with bovine spongiform encephalopathy (BSE) (Will et al. 1996). The term *prion*, coined by Stanley Prusiner, stands for “proteinaceous infectious pathogen” (Prusiner 1994, 2001).

### *Epidemiology*

All of the transmissible spongiform encephalopathies are rare. Sporadic Creutzfeldt-Jakob disease, the most common human transmissible spongiform encephalopathy, occurs with an annual incidence of one per million, usually affecting people between the ages of 55 and 70 years (P. Brown et al. 1987). At the time of this writing, variant Creutzfeldt-Jakob disease has been diagnosed in some 150 individuals, almost all of them in the United Kingdom. Variant Creutzfeldt-Jakob disease more often develops in younger subjects than does sporadic Creutzfeldt-Jakob disease: most cases have occurred during the second through fourth decades of life (Will et al. 1996).

### *Clinical Features*

Sporadic Creutzfeldt-Jakob disease typically causes a rapidly progressive dementia, with early changes in behavior, visual symptoms, and cerebellar signs. Within weeks to months, marked cognitive impairment develops, often progressing to mutism, with pyramidal, extrapyramidal, and cerebellar signs and myoclonus (P. Brown et al. 1994). The median duration of symptom onset to death is only 4 months, although in rare cases the disorder evolves over several years. Iatrogenic cases of Creutzfeldt-Jakob disease have occurred when CNS tissue from patients with sporadic Creutzfeldt-Jakob disease has unwittingly been transferred from patient to patient by surgical instruments or used in medical procedures as a source of growth hormone, gonadotropins, dura mater, or corneal grafts (P. Brown et al. 2000).

Variant Creutzfeldt-Jakob disease differs markedly from sporadic Creutzfeldt-Jakob disease (Spencer et al. 2002). The initial symptoms are usually psychiatric, most commonly anxiety or depression, and often of sufficient severity to lead to psychiatric referral. Limb pain or tingling is common early in the course of the illness. After

some months, cognitive symptoms typically develop, causing difficulty at school or work, together with varied neurological features including pyramidal, extrapyramidal, and cerebellar signs and myoclonus. The disorder evolves more slowly than does sporadic Creutzfeldt-Jakob disease, with an average duration of 14 months from symptom onset to death.

Three other varieties of human transmissible spongiform encephalopathy have been described. *Kuru*, now extremely rare, causes a cerebellar syndrome with progression to dementia. It is confined to the Fore Indians of Papua New Guinea and was caused by cannibalism of CNS tissues from affected relatives (Gajdusek 1977). *Gerstmann–Straussler–Scheinker syndrome* is an autosomal dominant prion dementia characterized primarily by cerebellar dysfunction and dementia with a protracted clinical course (Piccardo et al. 1998). *Fatal familial insomnia* is a very rare autosomal dominant prion disorder with severe insomnia and autonomic disturbance manifesting early in the course of the disease (Gambetti et al. 1995).

### *Pathology and Etiology*

The light microscope reveals “spongiform change” in the brains of patients with transmissible spongiform encephalopathies; this change is associated with neuronal loss, gliosis, and deposition of “amyloid.” Immunocytochemistry and direct biochemical analysis indicate that the amyloid is composed of a protease-resistant form of prion protein (PrP) (Prusiner 2001).

### *Investigation and Differential Diagnosis*

In sporadic Creutzfeldt-Jakob disease, the electroencephalogram (EEG) shows 1- to 2-per-second triphasic waves in 80% of cases at some time during the course of the illness (Steinhoff et al. 1996). Detection of 14–3–3 protein in CSF has a sensitivity and specificity of approximately 90% for sporadic Creutzfeldt-Jakob disease (Hsich et al. 1996). Brain biopsy is usually diagnostic but is rarely performed. In variant Creutzfeldt-Jakob disease, the EEG and CSF examination are less useful, but characteristic MRI abnormalities (especially high signal in the pulvinar nucleus) are found in a substantial proportion of cases, with a reported sensitivity of 78% and a specificity of 100% (Zeidler et al. 2000). Tonsillar biopsy has also been used as a confirmatory test, because prion protein scrapie (PrP<sup>Sc</sup>) is found in lymphoid tissue in variant Creutzfeldt-Jakob disease (Hill et al. 1999). In suspected cases of familial transmissible spongiform encephalopathy, sequencing of the PrP gene will identify the causative mutation.

### Management

At present, there is no proven remedy for the disease.

### Whipple's Disease

Whipple's disease is rare but important, because it is treatable. Infection with *Tropheryma whippelii* typically causes a multisystem disorder with prominent steatorrhea, weight loss, and abdominal pain (Fleming et al. 1988). CNS involvement is common, and neurological and psychiatric symptoms and signs occur in the absence of systemic features (A.P. Brown et al. 1990; Louis et al. 1996). Small-bowel biopsy, lymph node biopsy, brain MRI, and CSF examination, including polymerase chain reaction studies to identify the causative organism, can all be helpful in diagnosis (Louis et al. 1996). Antibiotic treatment can be effective.

### Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare complication of childhood measles in which intraneuronal persistence of a defective form of the virus in the CNS results in a continuing immune response, with high levels of measles antibody in the CSF. Neurological signs, including myoclonus, accompany the dementia (Lishman 1997; Risk et al. 1978). Average life expectancy from onset is 1–2 years.

### Progressive Multifocal Leukodystrophy

Progressive multifocal leukodystrophy is caused by activation of JC papovavirus within the CNS in an immunocompromised patient. The resulting demyelination gives rise to pyramidal signs, visual impairment, and a subcortical dementia, usually with progression to death within months (Lishman 1997; Richardson 1961).

### Paraneoplastic Syndromes

Paraneoplastic “limbic encephalitis” results from an immunological cross-reaction between tumor antigens and antigens present within the CNS. It can cause a range of psychiatric presentations, including cognitive deficits, confusional states, a pure amnesic syndrome, and affective symptoms. There are also paraneoplastic syndromes that affect the cerebellum, spinal cord, and peripheral nerves (Darnell and Posner 2003). Small-cell lung cancer is the most common cause of paraneoplastic syndromes, but breast, ovarian, renal, and testicular carcinoma and lymphoma can also be responsible. The tumor may be small and sometimes initially undetectable by imaging. The

diagnosis is supported by detection of antineuronal antibodies in serum or CSF, most commonly “anti-Hu”; the CSF often contains oligoclonal bands of immunoglobulin.

### CNS Tumors, Hydrocephalus, and Subdural Hematoma

CNS tumors, hydrocephalus, and subdural hematoma are discussed in the section “Neurosurgical Issues” later in this chapter.

## Epilepsy

Epileptic seizures are transient cerebral dysfunctions resulting from an excessive and abnormal electrical discharge of neurons. The clinical manifestations are numerous. As a result, psychiatrists commonly encounter epilepsy, both when considering whether epilepsy is the primary cause of paroxysmal psychiatric symptoms and when treating its significant psychiatric complications.

### Epidemiology

Problems with case definition and ascertainment complicate epidemiological estimates. However, incidence rates of 40–70 per 100,000 population in developed countries and 100–190 per 100,000 in developing countries are generally accepted. The prevalence of active epilepsy is around 7 per 1,000 population in the developed world (Bell and Sander 2001; Kotsopoulos et al. 2002; Sander and Shorvon 1996). Reasons for the higher incidence in developing nations are believed to include increased rates of birth trauma and head injury and lack of health services to manage them, and poor sanitation leading to high rates of CNS infection (e.g., cysticercosis; see Chapter 27, “Infectious Diseases”). Most studies show a bimodal distribution for age of incidence, with increased rates in persons younger than 10 years and older than 60 years. Epilepsy is more common in men and may be more common in black Africans (Sandler and Shorvon 1996).

A specific etiological mechanism is identified in less than one-third of cases. These mechanisms include perinatal disorders, learning disabilities, cerebral palsy, head trauma, CNS infection, cerebrovascular disease, brain tumors, Alzheimer's disease, and substance misuse. In addition, many so-called idiopathic seizures are likely to have a genetic basis.

Estimates of seizure recurrence after a first event are widely varied and depend on the population being studied (Cockerell et al. 1997; Sander 1993). However, if seizures are going to recur, they usually do so within 6 months of

the first event; the prognosis improves as the seizure-free period lengthens. In patients with established epilepsy, the prognosis is extremely variable. In some benign childhood epilepsies, anticonvulsant medication is unnecessary and remission the rule. In the majority of patients with epilepsy, remission occurs with treatment, and it may be possible to withdraw treatment in the long term. In some epilepsy syndromes, such as juvenile myoclonic epilepsy, treatment is effective but must be continued indefinitely. In around one-third of patients with epilepsy, anticonvulsants fail to provide adequate control of seizures. This is particularly likely in patients with aggressive pediatric epilepsy syndromes (e.g., infantile spasms, Lennox-Gastaut syndrome) or in patients whose epilepsy has a defined structural or congenital cause.

## Clinical Features

Epilepsy constitutes a heterogeneous group of disorders with multiple causes, and its clinical features reflect this diversity. The key clinical distinction is between seizures with a focal and seizures with a generalized cerebral origin. The former are more likely to be associated with a detectable and potentially remediable cerebral lesion, whereas the latter are more likely to start in childhood or adolescence and to be familial. Despite the wide variety of possible seizure manifestations, an individual patient's seizures are usually stereotyped. Their clinical features result from a recurrent pattern of cortical hyperactivity during the ictal event followed by hypoactivity in the same area postictally.

Documentation of the clinical features of the seizure is the key to diagnosis. Because firsthand observation is seldom possible unless seizures are very frequent, the history of the episode, including an eyewitness account (or a home video), is of paramount importance.

### *Tonic-Clonic Seizures*

Tonic-clonic seizures are the most dramatic manifestation of epilepsy and are characterized by motor activity and sudden loss of consciousness. In a typical seizure, a patient has no warning (with the possible exception of a couple of myoclonic jerks) of its onset. The seizure begins with sudden loss of consciousness and a tonic phase during which there are sustained muscle contractions lasting 10–20 seconds. This is followed by a clonic phase of repetitive muscle contractions that last approximately 30 seconds. A number of autonomic changes, including increase in blood pressure and pulse rate, apnea, mydriasis, incontinence, piloerection, cyanosis, and perspiration, may also occur. In the postictal period, the patient is drowsy and confused. Abnormal neurological signs are often elicited.

### *Partial Seizures*

Partial seizures are categorized according to whether they are simple (without impairment in consciousness) or complex (with impairment of consciousness). This classification may be difficult to apply in practice, however.

**Simple partial seizures.** The clinical features of simple partial seizures depend on the brain region activated. Although the initial area is relatively localized, it is common for the abnormal activity to spread to adjacent areas, producing a progression of seizure pattern. If the activity originates in the motor cortex, there will be jerking movements in the contralateral body part. This can cause progressive jerking in contiguous regions (known as “Jacksonian march”). Activity in the supplementary motor cortex causes head turning with arm extension on the same side—the classic “fencer’s posture.”

Seizures originating in the *parietal lobe* can cause tingling or numbness in a bodily region or more complex sensory experiences such as a sense of absence on one side of the body, asomatognosia. Seizures in the inferior regions of the parietal lobe can cause severe vertigo and disorientation in space. Dominant-hemisphere parietal lobe seizures can cause language disturbance.

Seizures of the *occipital lobe* are associated with visual symptoms, which are usually elementary (e.g., simple flashing lights). However, if the seizure occurs at the border with the temporal lobe, more complex experiences can occur, including micropsia, macropsia, and metamorphosis, as well as visual hallucinations of previously experienced imagery.

Seizures affecting the *temporal lobe* can be the most difficult to diagnose, but this lobe is also the most common site of onset, accounting for 80% of partial seizures. Symptoms may include auditory hallucinations, ranging from simple sounds to complex language. Olfactory hallucinations, usually involving unpleasant odors, follow discharge in the mesial temporal lobe. Seizures in the Sylvian fissure or operculum will cause gustatory sensations; ictal epigastric sensations such as nausea or emptiness generally have a temporal lobe origin. The well-known emotional and psychic phenomena of temporal lobe seizure activity can occur in simple seizures but are more common in complex partial seizures.

**Complex partial seizures.** In a complex partial seizure, the patient frequently experiences an aura at the onset of the seizure. The aura is a simple partial seizure lasting seconds to minutes. It should be distinguished from a prodrome, which is not an ictal event and which can last for hours or even days before a seizure. Prodromes usually consist of a sense of nervousness or irritability. The

content of the aura will depend on the location of the abnormal discharge within the brain. Thus, it may contain motor, sensory, visceral, or psychic elements. These can include hallucinations; intense affective symptoms such as fear, depression, panic, or depersonalization; and cognitive symptoms such as aphasia. Distortions of memory can include dreamy states, flashbacks, and distortions of familiarity with events (*déjà vu* or *jamais vu*). Occasionally, rapid recollection of episodes from earlier life experiences occurs (panoramic vision). Rage is rare; when it does occur, it is characterized by lack of provocation and abrupt abatement. This phase is followed by impairment of consciousness and a seizure usually lasting 60–90 seconds, which may generalize into a tonic-clonic seizure. Automatism may occur and can involve an extension of the patient's actions prior to seizure onset. Common facial automatisms include chewing or swallowing, lip smacking, and grimacing; automatisms in the extremities include fumbling with objects, walking, or trying to stand up. Postictal confusion is usually significant and typically lasts 10 minutes or longer.

Complex partial seizures of frontal lobe origin tend to begin and end abruptly, with minimal postictal confusion. They often occur in clusters. The attacks are usually bizarre, with motor automatisms such as bicycling or with sexual automatisms and vocalizations.

### ***Absence Seizures***

Absence seizures are well-defined clinical and EEG events. The essential feature is an abrupt, brief episode of decreased awareness that occurs without any warning, aura, or postictal symptoms. At the onset there is a disruption of activity.

A *simple* absence seizure is characterized by only an alteration in consciousness. The patient remains mobile, breathing is unaffected, and there is no cyanosis or pallor and no loss of postural tone or motor activity. The ending is abrupt, and the patient resumes previous activity immediately, often unaware that a seizure has taken place. An attack usually lasts around 15 seconds. A *complex* absence seizure involves additional symptoms such as loss or increase of postural tone, minor clonic movements of the face or extremities, minor automatisms, or autonomic symptoms such as pallor, flushing, tachycardia, piloerection, mydriasis, and urinary incontinence.

### ***Violent Behavior***

Epilepsy, in particular epilepsy involving the temporal lobe, may cause emotional symptoms and very occasionally can result in undirected violent behavior (Kotagal 1997). However, in the majority of cases of epilepsy-related

violence, the behavior occurs in response to being restrained during a seizure. One should be very cautious in attributing other violent assaults to a seizure. This issue is discussed in more detail in Chapter 8, "Aggression and Violence," which includes criteria for determining whether a violent act resulted from an epileptic seizure.

### **Differential Diagnosis**

Differentiating epilepsy from nonepileptic attack disorder (psychogenic epilepsy, or pseudoseizures) and syncope can be difficult (Roberts 1998). Other paroxysmal disorders should also be considered; these include transient ischemic attacks, hypoglycemia, migraine, transient global amnesia, cataplexy, paroxysmal movement disorders, and paroxysmal symptoms in multiple sclerosis. Attacks during sleep can pose particular difficulties, as informant reports are less useful.

### ***Nonepileptic Attack Disorder***

Nonepileptic attack disorder (NEAD), also referred to as "pseudoseizures" or "psychogenic epilepsy," is the most common alternative diagnosis, accounting for about 30% of patients presenting to clinics with suspected epilepsy (Reuber and Elger 2003), and with a reported community prevalence of 33 per 100,000 population (Benbadis and Allen 2000). The terminology is confused, and it is unclear whether NEAD is a specific diagnosis or a collective term for a number of psychiatric diagnoses or symptoms that may cause seizurelike spells, including conversion, panic attacks, hyperventilation syndrome (see Chapter 20, "Lung Disease"), posttraumatic stress disorder (PTSD), and catatonia. We personally favor the view that NEAD is a variant of panic disorder without the expression of fear (Vein et al. 1994). Some patients have both epilepsy and nonepileptic attacks, but probably only around 10% of individuals with NEAD fall into this category (Benbadis et al. 2001; Reuber et al. 2002). Many of these patients are learning disabled and at increased risk of both epilepsy and psychiatric disorders.

The diagnosis of NEAD can often be made on the basis of a careful history and examination. Clinical clues include the presence of prior or current psychiatric disorders, including somatoform disorders; atypical varieties of seizure, especially the occurrence of frequent and prolonged seizures in the face of normal interictal intellectual function and EEG; a preponderance of seizures in public places, especially in clinics and hospitals; and behavior during an apparent generalized seizure that suggests preservation of awareness (e.g., resistance to attempted eye opening, persistent aversion of gaze from the examiner). Previous childhood sexual abuse is very common but not

universal among those with the diagnosis (Binzer et al. 2004). When doubt remains after careful clinical assessment and standard investigations, the gold standard for diagnosis is observation of attacks during videotelemetry. A normal EEG during or immediately following an apparent generalized seizure also provides strong evidence for NEAD.

The diagnosis of NEAD is regarded as distinct from deliberate falsification of attacks (i.e., malingering or factitious disorder). The majority of patients will be cooperative with investigation and diagnosis, even when they know in advance that the purpose is to confirm NEAD and refute epilepsy (McGonigal et al. 2002).

### *Syncope*

Syncope, usually due to temporary interruption of the blood supply to the brain, is often accompanied by myoclonic jerks that are frequently regarded as epileptic by lay and medical onlookers (Lempert et al. 1994). The occurrence of more complex movements, eye deviation, eyelid flicker, or vocalizations can confuse the diagnosis further, as can aura symptoms, which are recalled by the majority of subjects and which include epigastric, vertiginous, visual, and somatosensory experiences (Benke et al. 1997).

### *Sleep Disorders*

Sleep disorders—including sleepwalking, night terrors, and confusional arousals, all of which occur during slow-wave sleep; rapid eye movement (REM) sleep behavior disorder; and a variety of other parasomnias, including bruxism, rhythmic movement disorder, and periodic limb movements—must all be distinguished from epilepsy (see Chapter 16, “Sleep Disorders”).

## Investigation of Seizures

Epilepsy is above all a clinical diagnosis, and the use and interpretation of tests should reflect this. Routine blood tests should include a complete blood count and routine chemistries, including serum calcium and magnesium. An electrocardiogram (ECG) should always be performed. An EEG is helpful in confirming the diagnosis and in clarifying the type of epilepsy (i.e., generalized versus focal, a distinction particularly relevant for children and adolescents). However, the EEG is insensitive: a single interictal EEG will detect clearly epileptiform abnormalities in only about 30% of patients with epilepsy. Therefore, a normal EEG does not exclude epilepsy, just as minor nonspecific abnormalities do not confirm it. Serial recordings, including sleep-deprived recordings, increase the diagnostic yield to around 80% (Chabolla and Cascino 1997). EEG can be supplemented with video recording to allow

examination of the correlation between the clinical symptoms and the EEG abnormalities (videotelemetry). Twenty-four-hour ambulatory monitoring is sometimes helpful.

Some form of neuroimaging should be performed in all patients with epilepsy, unless EEG has clearly demonstrated a syndrome of primary generalized epilepsy in a young patient. CT is adequate to exclude tumors and major structural abnormalities and has the benefit of ease of access in most developed countries; however, CT may miss subtle pathologies. MRI is undoubtedly the imaging modality of choice, capable of detecting pathological abnormalities in up to 90% of patients with intractable epilepsy, including mesial temporal sclerosis (Spencer 1994). It can, however, be difficult to access in some countries.

Measurement of serum prolactin after seizures has a limited role in the diagnosis of NEAD. Prolactin will rise after a generalized seizure but not, as a rule, after a non-epileptic attack. However, interpretation of the test requires knowledge of the basal prolactin and concurrent drug treatment (e.g., antipsychotics). Partial seizures and syncope can also elevate prolactin (Oribe et al. 1996; Pohlmann-Eden et al. 1997).

Additional cardiac investigations that may be helpful in selected cases include 24-hour ambulatory ECG to identify cardiac dysrhythmias; echocardiography, to identify structural cardiac abnormalities; and tilt-table testing, to help confirm orthostatic syncope.

## Psychiatric Complications

Recent record-linkage studies (Bredkjaer et al. 1998; Jalava and Sillanpaa 1996) have reported an increase in psychotic symptoms, particularly schizophreniform and paranoid psychoses, in men but not women with epilepsy. Studies have also shown a fourfold increase in overall rates of psychiatric disorder in both men and woman with epilepsy compared with individuals in the general population, but not compared with patients with other medical diagnoses.

### *Psychosis*

Psychotic symptoms may be categorized as transient postictal psychosis and chronic interictal psychosis. Patients with transient postictal psychosis often present with manic grandiosity with religious and mystical features (Kanemoto et al. 1996a). A number of small studies have suggested that such patients are more likely than other epilepsy patients to have psychic auras, bilateral interictal spikes, and nocturnal secondarily generalized seizures (Devinsky et al. 1995). In general, psychotic episodes do

not start immediately after a seizure, but instead occur after a lucid interval of 2–72 hours. In one study, patients with chronic interictal psychosis had a higher frequency of perceptual delusions and auditory hallucinations than did patients with postictal psychoses (Kanemoto et al. 1996b).

Transient psychosis was reported in 1% of patients following temporal lobectomy for epilepsy. Men with right-sided foci who were not seizure free after surgery appeared to be at particular risk for this symptom (Manchanda et al. 1993). There may be an increased risk of postictal psychoses in patients with temporal lobe epilepsy and hippocampal sclerosis (in comparison with those with temporal lobe epilepsy and no sclerosis) (Kanemoto et al. 1996a). How mesial temporal sclerosis relates to psychosis is unclear.

The work of Landolt in the 1950s drew attention to the occurrence of psychosis in some patients in whom epileptiform EEG abnormalities were normalized by treatment (“forced normalization”) (Krishnamoorthy and Trimble 1999; Landolt 1958). The concept remains controversial.

Antiepileptic drugs may contribute to the development of psychotic symptoms. Several of the newer drugs have significant psychiatric side effects. Vigabatrin, an irreversible inhibitor of gamma-aminobutyric acid (GABA) transaminase, has been shown to precipitate psychotic and affective symptoms in 3%–10% of patients (Levinson and Devinsky 1999). This effect occurs more commonly in patients with a history of psychiatric illness.

### *Depressive and Anxiety Disorders*

Depressive and anxiety disorders affect approximately one-third of patients with epilepsy (Jalava and Sillanpaa 1996; Kanner and Balabanov 2002; Stefansson et al. 1998). Neurobiological, psychological, social, and iatrogenic factors have all been proposed and probably all are relevant (Lambert and Robertson 1999; Weigartz et al. 1999). Links have been suggested between complex partial seizures and concomitant frontal lobe dysregulation in the genesis of depression; however, study samples have been small and the possibility of confounding variables large (Weigartz et al. 1999). Depression arising from learned helplessness may occur in patients with epilepsy as a consequence of repeatedly experiencing unpredictable and unavoidable seizures (Weigartz et al. 1999). The stress of having to live with a stigmatized chronic illness may also be relevant. Finally, the antiepileptic drugs used in the treatment of epilepsy can themselves be a cause of depression. The relationship between depression and epilepsy is bidirectional (i.e., each is a risk factor for the

other). Depression is an independent risk factor for unprovoked seizures (Hesdorffer et al. 2000). This effect seems to be particularly marked for partial seizures.

Similarly, anxiety in epilepsy may have a complex etiology (Goldstein and Harden 2000). Anticipatory anxiety about having a seizure without warning can lead to agoraphobic-like symptoms and behavior.

The treatment of depressive and anxiety disorders in epilepsy is the same as that of anxiety and depression in the medically ill (Hermann et al. 2000; see also Chapter 9, “Depression,” and Chapter 12, “Anxiety Disorders”). Increased seizure risks associated with specific psychiatric drugs are reviewed in Chapter 37, “Psychopharmacology.”

### Treatment

The basic principles of epilepsy treatment are as follows:

1. Use a single drug whenever possible.
2. Increase the dose slowly until either the seizures are controlled or toxicity occurs.
3. If a single drug does not control seizures without toxicity, then switch initially to another drug used alone.
4. Drug-level monitoring is generally unnecessary except in the case of phenytoin and is sometimes misleading: some patients do well with drug levels below or above the “therapeutic range.”
5. Consider using two drugs only when monotherapy is unsuccessful.
6. Be aware that the metabolism of drugs may be different in the young, the elderly, pregnant women, and patients with chronic disease, particularly hepatic and renal chronic disease, and be on the lookout for drug interactions.

Approximately 20%–30% of patients do not achieve seizure control with drug therapy. In carefully selected cases, surgery can be effective (Engel 1993; Vickrey et al. 1993). The criteria for selection generally include the presence of a focal lesion on neuroimaging, evidence from videotelemetry that the lesion is the source of the habitual seizures, and neuropsychological evidence that resection of the lesion should not cause major cognitive deficits (Sperling 1994). Psychological factors are also often relevant to the decision to perform surgery (see section “Neurosurgical Issues” later in this chapter).

Vagal nerve stimulation has been shown to reduce seizure frequency in some patients with refractory epilepsy (Schachter 2002), but it probably is no more effective than the addition of the newer anticonvulsants to established therapy.

## Tic Disorders

---

Tics are habitual spasmodic muscular movements or contractions, usually of the face or extremities that are associated with a variety of disorders.

Gilles de la Tourette's syndrome (GTS) is characterized by a combination of multiple waxing and waning motor and vocal tics. These vary from simple twitches and grunts to complex stereotypies. Premonitory sensory sensations in body parts that "need to tic" are a common feature and complicate the picture, because their temporary suppressibility lends them a voluntary component. Other features are echolalia and coprolalia, particularly in severe cases. GTS is strongly associated with obsessive-compulsive disorder (OCD) (Eapen et al. 1997; Miguel et al. 1997; Muller et al. 1997; Zohar et al. 1997), but many claim that it is qualitatively different from pure OCD, with greater concern with symmetry, aggressive thoughts, forced touching, and fear of harming oneself in OCD-GTS compared with a more frequent focus on hygiene and cleanliness in pure OCD. Depressive symptoms are common (Wodrich et al. 1997). The prevalence of GTS is about 5 per 10 000 population, with a male:female ratio of 4:1 (Staley et al. 1997). A debate exists as to whether OCD in itself constitutes a specific psychopathological entity comorbid with GTS or whether diverse pathological disorders—including attention-deficit/hyperactivity disorder (ADHD), eating disorders, anxiety, and substance misuse—should also be considered part of the phenotype (Blum et al. 1997; Pauls et al. 1994). This issue clearly has implications for genetic studies, which have suggested a strong hereditary component in the disorder. Similarly, the neurobiology of GTS remains elusive, with evidence supporting dysfunctions in dopaminergic basal ganglia circuitry receiving the most attention. Structural imaging findings in GTS are usually normal; functional imaging data are contradictory at present (Robertson and Stern 1998).

A syndrome known as pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) has been defined, consisting of OCD accompanied by tics with abrupt onset or exacerbation associated with beta-hemolytic streptococcal infection (see Chapter 27, "Infectious Diseases"). PANDAS may lie on the same clinical spectrum as Sydenham's chorea, in which OCD and vocal tics have also been reported (Mercadante et al. 1997; Swedo et al. 1998), and may cast light on the etiology of GTS. Some preliminary studies have suggested that B-cell antigen D8/17, an immunological marker of susceptibility to rheumatic fever, may be associated with both PANDAS and GTS (Murphy et al. 1997; Swedo et al. 1997). This offers the attractive possibility of

immune-mediated treatments as well as an explanation for the occurrence and subsequent successful treatment of GTS as a complication of both Lyme disease (Riedel et al. 1998) and oral herpes simplex (Budman et al. 1997).

Management of GTS is multidisciplinary, with clear need to address the educational, social, and family consequences of the disorder. Dopamine antagonists remain the mainstay of pharmacological management. Haloperidol has been the most widely used antipsychotic, but many authors advocate use of newer antipsychotic agents on the basis of fewer side effects (Jimenez-Jimenez and Garcia Ruiz 2001; Robertson and Stern 2000). Pimozide was shown to be superior to haloperidol in one of the few randomized, controlled trials conducted, but potential cardiac side effects generally prohibit its use (Sallee et al. 1997). The dopamine D<sub>2</sub> selective agent sulpiride (not available in the United States) is potentially useful. Of the newer antipsychotic agents, risperidone has attracted interest but thus far has appeared to be more effective in the treatment of related OCD phenomena than in the treatment of the tics themselves (Robertson et al. 1996; Stein et al. 1997). Tetrabenazine, a presynaptic monoamine depletor with postsynaptic blockade, has shown considerable efficacy in case series studies (Jankovic and Beach 1997), without a risk of dystonia or tardive dyskinesia but with a high risk of depression. In patients with comorbid restless legs syndrome, the dopamine agonist pergolide was effective in alleviating Tourette's symptoms, despite the fact that one might have predicted the opposite effect (Lipinski et al. 1997). Clonidine is used widely in the United States, but in the United Kingdom its use is generally restricted to patients with comorbid ADHD symptoms (Leckman et al. 1991). In establishing treatment priorities, one should bear in mind that the associated OCD and ADHD symptoms probably cause more functional and educational disability than the tics themselves (Abwender et al. 1996; De Groot et al. 1997).

## Dystonias

---

The dystonias are a group of disorders characterized by involuntary twisting and repetitive movements and abnormal postures. The traditional clinical categorization is based on age at onset, distribution of symptoms, and site. Early-onset dystonia often starts in one limb, tends to generalize, and frequently has a genetic origin. By contrast, adult-onset dystonias usually spare the lower limbs, frequently involve the cervical or cranial muscles, and have a tendency to remain focal. They appear sporadic in most cases. Dystonias tend to improve with relaxation, hypnosis, and sleep. With the exception of cervical dysto-

nia, pain is uncommon. Erroneous attribution of dystonia to a psychogenic cause is common because of the fluctuating nature of the symptoms, their often dramatic appearance, the ability of patients to use “tricks” to suppress them, and their association with task-specific symptoms (e.g., writer’s cramp) (Eldridge et al. 1969). Dystonia may, however, occur as the presentation of a conversion disorder, although this is rare (Marjama et al. 1995; Verdugo and Ochoa 2000).

*Primary torsion dystonia* has autosomal dominant inheritance with reduced penetrance. It usually begins in childhood in one limb and then generalizes to other body parts.

*Focal dystonia* is the most prevalent form. It starts in adulthood and usually remains localized (e.g., as an isolated torticollis). The majority of cases are sporadic, although some family pedigree studies have shown an increased risk of focal dystonias in other family members (Waddy et al. 1991).

*Dopa-responsive dystonia* is characterized by childhood onset, diurnal fluctuation of symptoms, and a dramatic response to L-dopa therapy. It generally has autosomal dominant inheritance, although recessive forms associated with mutations in the tyrosine hydroxylase gene have been described (Knappskog et al. 1995).

It is important to remember the role of exposure to medications (antipsychotics, antiemetics) in the development of both acute and tardive dystonias (Sweet et al. 1995).

Medical treatment involves oral drugs and botulinum injections (Bentivoglio and Albanese 1999; Klein and Ozelius 2002). Botulinum therapy is the most effective treatment for focal dystonias such as torticollis. In generalized dystonia, a trial of L-dopa should be considered in all early-onset cases, given the possibility of dopa-responsive dystonia. Thereafter, the first-line treatment is usually anticholinergics, followed by baclofen and possibly benzodiazepines and dopamine depletors such as tetrabenazine. Surgical treatment can involve selective peripheral denervation or functional brain surgery. Comorbid psychiatric disorders are commonly associated with dystonias, particularly OCD, panic disorder, and depression (Wenzel et al. 1997). Their presence does not necessarily indicate that the dystonia is psychogenic, and they should be actively treated in their own right (Muller et al. 2002).

## Headache

---

### Acute Headache

Headache of abrupt onset that is very severe and prolonged can be due to *subarachnoid hemorrhage*, usually

from a ruptured aneurysm, or to migraine, meningitis, or other cranial infection such as otitis media or sinusitis. The diagnosis of subarachnoid hemorrhage is suggested by the rapidity of onset (“thunderclap” headache, at its worst within 1 minute or so) and associated loss of consciousness, photophobia, vomiting, and neck stiffness. A headache with these features requires immediate neurological referral for assessment with CT scan (which reveals subarachnoid blood in the majority of cases) and lumbar puncture, when CT is negative, to examine for xanthochromia (which is present reliably from 12 hours after subarachnoid hemorrhage). Psychiatrists are predominantly involved in the management of the associated brain injury following subarachnoid hemorrhage. (For a further discussion of these management principles, see the section “Stroke” earlier in this chapter and Chapter 35, “Physical Medicine and Rehabilitation.”)

*Migraine* can mimic subarachnoid hemorrhage. The diagnosis is usually suggested by a history of more typical migrainous headaches with prodromal visual (or other focal neurologic) disturbance and a gradually evolving hemicranial throbbing headache with photophobia and nausea or vomiting. *Meningitis* is suggested by a severe headache, usually worsening over hours, with photophobia, nausea, and neck stiffness in association with fever and other features of infection.

### Chronic Headache

Headache is common. *Tension-type headache* is familiar to most of us as a global headache, usually of mild to moderate severity, sometimes with a “bandlike” or pressing quality. It often worsens as the day goes on or following stress and has few associated symptoms. *Chronic daily headache* (CDH) is usually of the tension type (Welch and Goadsby 2002) and has been associated with depression and persisting stressors (Holroyd et al. 1993; Mitsikostas and Thomas 1999; Rasmussen 1992), although this association does not necessarily indicate the causal mechanism. CDH is indicative of the need for more sophistication in our approach to understanding the complex interactions between brain biology, psychological processes, and behavioral responses. The majority of cases of CDH involve a prior history of migraine (Bahra et al. 2000; Lance et al. 1988). It appears that prolonged exposure to analgesics (e.g., opiates, ergotamine derivatives, nonsteroidal anti-inflammatory drugs) may be necessary for transformation to CDH to take place. Certainly, failure to withdraw from such analgesics usually results in failed treatment (Kudrow 1982). Treatment of comorbid mood disorders (Gill and Hatcher 1999) and CBT can also be helpful (Kroenke and Swindle 2000).

Classical *migraine* has the features described above; common migraine causes “migrainous” throbbing hemispherical headache, nausea, and photophobia in the absence of focal neurological symptoms such as visual disturbance (Cutrer 2003). Patients with chronic migraine headaches have often been described as having a “typical” personality characterized by conscientiousness, perfectionism, ambitiousness, rigidity, tenseness, and resentfulness; however, controlled studies have not consistently supported this profile. Specific personality traits in migraine appear more likely to be a consequence rather than a cause of suffering from recurrent headaches (Stronks et al. 1999). A community-based survey found more personality disturbance and 2.5 times more psychological distress in migraine sufferers than in matched control subjects, but there was no relationship between headache frequency and the severity of psychological distress or personality abnormality (Brandt et al. 1990; Breslau et al. 2003; Glover et al. 1993). An association with both depression and bipolar disorder is recognized (Lipton et al. 2000; Merikangas 1994), and there are interesting genetic studies linking migraine with the dopamine *DRD2* gene (Peroutka et al. 1997). Psychiatric management is as for CDH.

*Cervicogenic headache* is headache originating in the neck, usually associated with neck pain and limitation of movement, radiating forward from the neck or occiput. *Temporal arteritis* is a disorder of older people (it is very rare in persons younger than 55 years) that causes scalp pain and tenderness, jaw claudication, malaise, and an elevated erythrocyte sedimentation rate (usually of more than 50 mm/hour). Treatment with corticosteroids should be started immediately and arrangements made for confirmatory temporal artery biopsy. *Raised intracranial pressure* typically causes a headache that is worse on lying down (and can be relieved by standing), disturbing sleep and present in the mornings. The pressure eventually causes nausea and vomiting and, if brain stem compression occurs, a progressive reduction of consciousness. The raised pressure can result from space-occupying lesions (e.g., tumors, subdural hematomas), hydrocephalus, or idiopathic intracranial hypertension. The typical features of raised intracranial pressure (i.e., headache, ataxia, drowsiness, confusion, coma) are not always present. If they are, or if headache is associated with papilledema or focal neurological signs, a CT scan should be obtained urgently. *Low CSF volume headache* is an increasingly well-recognized syndrome with features inverse to those of the headache of raised intracranial pressure: the headache comes on after getting up and is relieved by lying down. This type of headache is often iatrogenic (e.g., following lumbar puncture), but it can also occur as a result of spontaneous CSF leaks.

Certain “headaches” are felt mainly in the face. *Cluster headache*, a rare type of headache that is more common in young men, gives rise to severe retro-orbital pain occurring in bursts lasting an hour or so that recur over a period of days to weeks (the “cluster”). The headache often wakes the sufferer in the middle of the night and usually makes him or her extremely restless (in contrast to migraine, which sends sufferers to their beds) (May and Goadsby 1998). *Trigeminal neuralgia* causes stabs of lancinating pain in the one of the three divisions of the trigeminal nerve (Graff-Radford 2000). *Atypical facial pain* is a diagnosis of exclusion, the facial equivalent of chronic daily headache.

## Somatoform and Conversion Disorders in Neurology

---

Somatic symptoms unexplained by neurological disease are commonly encountered in neurological practice and may be diagnosed as somatoform disorders. Other names include medically unexplained symptoms, psychogenic disorders, and functional disorders. DSM-IV, and its text revision, DSM-IV-TR, use the term *somatoform disorders*, although patients may prefer the term “functional disorders” (Stone et al. 2002).

*Conversion disorder* is regarded as a subgroup of somatoform disorders. The term is reserved to describe patients with motor or sensory symptoms or deficits that suggest a neurological or other general medical condition but in whom no such condition is found by appropriate examination and investigation. DSM-IV-TR also requires that the psychological factors be judged to be associated with the symptoms because their initiation or exacerbation is *preceded by* conflicts or other stressors. This requirement is controversial, as its theoretical basis is unconfirmed. Furthermore, because psychological factors are common in all neurological presentations, the requirement is nonspecific and likely to be unreliable. Common conversion symptoms include paralysis, weakness, seizures, anesthesia, aphonia, blindness, amnesia, and stupor. Conversion disorder is also discussed in Chapter 13, “Somatization and Somatoform Disorders.”

### Epidemiology

Neurological symptoms in the absence of neurological disease or grossly disproportionate to disease are observed in approximately one-third of patients attending neurological clinics (Carson et al. 2000b). Functional weakness and paralysis, a subgroup of neurological symptoms occurring in the absence of disease, have an incidence of at least 4

per 100,000 (Binzer and Kullgren 1998), a rate similar to that of multiple sclerosis. In less than half of patients do the symptoms remit spontaneously (Carson et al. 2003).

## Clinical Features

A careful history is essential to diagnosis, first concentrating on the somatic symptoms, and only then exploring psychological and social factors. Pain is the most common symptom (Carson et al. 2000b). In considering the diagnosis, particular attention should be paid to the presence of multiple somatic symptoms (multiple symptoms make a somatoform disorder more likely), depression or anxiety (particularly panic), and a history of previous functional symptoms or of multiple surgical operations in the absence of organic pathology (Barsky and Borus 1999). Childhood abuse and neglect, personality factors, recent stressful life events, secondary gain (financial or otherwise), and illness beliefs may all be relevant to management, but their presence does not allow one to infer a diagnosis of conversion disorder (Stone et al. 2002).

The history of the onset of the symptoms can be particularly useful in diagnosis. Patients with conversion weakness will often describe symptoms suggestive of depersonalization or derealization at the time of onset. These symptoms may have been associated with a panic attack, physical trauma (often minor), or unexpected physiological events (e.g., postmicturitional syncope, sleep paralysis). In this context, a patient might report that “the leg felt as if it was not connected to me,” “I felt far away,” or “I was in a place of my own” (Stone et al. 2002).

The neurological examination has an important role in diagnosis of conversion disorder. Helpful signs include inconsistency, Hoover’s sign (Ziv et al. 1998), collapsing (“giveaway”) weakness (Gould et al. 1986), and co-contraction (Knutsson and Martensson 1985). Muscle tone and reflexes should be normal but may be mildly asymmetrical. Mild temperature and color changes in the affected limb are common in conversion disorder (Stone et al. 2002). These signs should be demonstrated to patients in a collaborative, rather than confrontational, manner.

## Pathology and Etiology

The etiology of conversion disorder remains unknown, and there is value in remaining neutral about the relative contributions of biological, psychological, and social factors (Kroenke 2002). In particular, one should be aware that although Freudian theory portrays conversion disorder as a mechanism for dealing with unconscious conflict and traumatic experience, this model fits only some pa-

tients. Early functional imaging studies have yielded intriguing results (Vuilleumier et al. 2001), and numerous, although often inconsistent, biochemical abnormalities have been described (Clauw and Chrousos 1997). The psychological and social risk factors for conversion disorder are similar to those for other somatoform disorders, as described in Chapter 13, “Somatization and Somatoform Disorders.”

## Investigation and Differential Diagnosis

Diagnostic accuracy is high, with an error rate between 5% and 10%, which compares favorably with diagnostic error rates for most common neurological conditions (Carson et al. 2003). Misdiagnosis may be more common in the presence of known psychiatric comorbidity such as schizophrenia or learning disability, particularly when the illness interferes with history taking. Further imaging or neurophysiological testing may be required, depending on the symptoms present. As a general rule, further investigations tend to rule out putative “organic” diagnoses rather than overturn the diagnosis of conversion disorder (Crimlisk et al. 1998). Although clinicians tend to worry about missing “organic” disease and therefore are often very conservative in making a diagnosis of conversion disorder, available evidence suggests that the reverse is more of a problem, leading to iatrogenic complications of unneeded treatment and invalidism (Fink 1992; Nimnuan et al. 2000).

## Management

Patients are best managed by a psychologically sophisticated medical approach (Sharpe and Carson 2000). Key steps are first, an explicit acceptance of the reality of the symptoms; second, a nonstigmatizing, positive explanation of the diagnosis; and third, appropriate reassurance (Thomas 1987). Such reassurance communicates to the patient that a full, but gradual, recovery may be possible and that dreaded diseases, such as stroke and multiple sclerosis, have been ruled out. Dismissing the symptoms as “nothing wrong” risks antagonizing or humiliating the patient and is rarely a good basis for collaborative management.

There is evidence for moderate effectiveness of antidepressant drugs, particularly TCAs, in conversion disorder, with an odds ratio for improvement of 3.4 compared with placebo (O’Malley et al. 1999). Interestingly, this effectiveness does not depend on the presence of depressive symptoms. Clinical experience suggests a role for gabapentin, particularly when pain symptoms are prominent; however, controlled trials are lacking. CBT may be effec-

tive in up to 70% of cases (Kroenke and Swindle 2000). We have found that physical therapy, especially physiotherapy, can be helpful in aiding a return to full function, and in some patients with long-standing disuse due to conversion disorder, physical therapy is necessary to restore normal function (see Chapter 13, “Somatization and Somatoform Disorders,” for further discussion).

## Neurosurgical Issues

---

Many of the psychiatric issues arising in neurosurgical settings are described in other chapters in this book. Of particular relevance are Chapter 6, “Delirium”; Chapter 35, “Physical Medicine and Rehabilitation”; and Chapter 36, “Pain.” High doses of corticosteroids are used by neurosurgeons to reduce elevated intracranial pressure; the psychiatric adverse effects of corticosteroids are reviewed in Chapter 25, “Rheumatology.” Mood disorders are frequent after neurosurgery, and their assessment should be guided by the discussion in the earlier sections of this chapter, particularly the section on stroke.

### Central Nervous System Tumors

Psychiatric aspects of cancer are reviewed in Chapter 24, “Oncology.” Psychiatrists generally become involved in neuro-oncology cases after tumor diagnosis, when the clinical issues are adjustment, mood disorder, or cognitive impairment. Patients with primary and metastatic CNS tumors typically present with headache, focal neurological signs, or seizures, but these tumors can also cause cognitive impairment, and occasionally their presentation mimics a dementing illness (Lishman 1997). Some brain tumors present with predominantly psychiatric symptoms. CT scanning should reveal their presence, although diffusely infiltrating tumors are sometimes missed in the early stages.

### Hydrocephalus

Hydrocephalus is caused by dilatation of the ventricles within the brain resulting from elevation of CSF pressure. Hydrocephalus is termed *communicating* when the blockage to CSF flow is outside the ventricular system, *noncommunicating* when the blockage is within the ventricles. In “compensated” hydrocephalus, the clinical signs and CSF dynamics stabilize at an elevated level of CSF pressure. In normal-pressure hydrocephalus (NPH), the ventricles enlarge despite apparently normal CSF pressure, possibly as the result of persistent elevation or intermittent surges of high pressure.

### Clinical Features

Hydrocephalus can cause a wide range of psychiatric symptoms and signs. These include enlargement of the head (if present in infancy), depression, headache, sudden death due to “hydrocephalic attacks” with acute elevation of intracranial pressure, progressive visual failure, gait disturbance (often “gait apraxia”), incontinence, and subcortical cognitive impairment progressing to dementia (Hebb and Cusimano 2001). NPH in older individuals is classically associated with the triad of gait apraxia, incontinence, and cognitive decline (Hebb and Cusimano 2001).

### Diagnosis

In younger persons, the radiological signs of hydrocephalus are usually clear-cut on CT scanning. This may also be the case in some elderly patients, but in other older patients apparent hydrocephalus is sometimes due to atrophy of the brain. When enlargement of the ventricles raises a suspicion of communicating hydrocephalus in an older person, determination of whether the scan appearance is relevant to the clinical problem requires specialized studies—usually either serial lumbar punctures with observation of the clinical effects or neurosurgical studies of CSF pressure (Hebb and Cusimano 2001).

### Management

*Shunting* of hydrocephalus—diversion of CSF from a CSF space to the venous system or peritoneum—can be beneficial or even lifesaving. However, the procedure is prone to complications, including subdural hematoma and shunt infection, and should not be undertaken lightly (Hebb and Cusimano 2001).

### Subdural Hematoma

Subdural hematoma is caused by accumulations of blood and blood products in the space between the fibrous dura mater and the more delicate arachnoid membrane that encloses the brain. Acute subdural hematomas accumulate rapidly following head injury; chronic hematomas can often (although not always) be traced back to a head injury.

### Clinical Features

Acute subdural hematomas are, by definition, diagnosed close to the time of trauma, as a result of symptoms present at the time—headache, depressed level of consciousness, focal neurological signs—or seen on CT scan. Chronic subdural hematomas give rise to more gradually evolving symptoms and signs. Although they also can cause headache, depressed consciousness, and focal signs, chronic subdural hematomas sometimes result in pre-

dominantly cognitive features, including confusion and dementia (Black 1984; Lishman 1997). Marked variability of the mental state, and sometimes also of the neurological features, is often a clue to the diagnosis. Seizures can occur. Both acute and chronic subdural hematomas are especially common in alcoholic individuals, who frequently do not recall having experienced head trauma (Selecki 1965).

### *Pathology*

The variability of the clinical features is explained by the tendency of the size of a chronic subdural hematoma to wax and wane as a result of alternating phases of bleeding and of breakdown of the contents of the hematoma (McIntosh et al. 1996). Subdural hematomas exert their effects both by local compression and irritation of adjacent cortical tissue and by global “brain shift” (with the risk of brain herniation and secondary brain stem compression).

### *Investigation and Differential Diagnosis*

Subdural hematomas can generally be diagnosed on CT scanning. They are occasionally “isodense” with brain and therefore easily missed, especially if bilateral (Davenport et al. 1994). It is important to recognize that a small subdural hematoma can be an incidental finding; for example, cerebral atrophy occurring in the course of a dementing illness predisposes to subdural hematoma as vulnerable bridging veins are stretched between the dura and the arachnoid. In these circumstances, treatment of the subdural hematoma is unlikely to be helpful.

### *Management*

Management requires liaison with a neurosurgical team. Small subdural hematomas often resorb spontaneously. If a subdural hematoma is considered to be relevant to a patient's problems and drainage is required, several surgical approaches are available. However, there is always a risk that the hematoma will reaccumulate after surgery (Bullock and Teasdale 1990).

## Subarachnoid Hemorrhage

Severe, prolonged headache of abrupt onset can be due to a subarachnoid hemorrhage, usually arising from a ruptured Berry aneurysm. A diagnosis of subarachnoid hemorrhage is suggested by the rapidity of onset (“thunderclap” headache, at its worst within a minute or so) and associated loss of consciousness, photophobia, vomiting, and neck stiffness. Psychiatrists are rarely involved in the diagnosis of subarachnoid hemorrhage but are frequently asked to evaluate patients in the postacute phase, as for

stroke (symptoms of irritability and anxiety may be more common after subarachnoid hemorrhage than after stroke) (Lishman 1997).

## Fitness for Surgery

Psychiatrists may be requested to assess patients for fitness for neurosurgery. Such requests occur most commonly for patients with epilepsy and with Parkinson's disease. A general assessment of capacity (see Chapter 3, “Legal Issues”) and consideration of specific issues relevant to the operation in question are required, necessitating special attention when the operation is considered investigational.

### *Epilepsy Surgery*

A psychiatric opinion should be sought prior to surgery if there are significant associated behavioral or social problems. Such problems include anticipated noncompliance with medication, severe personality disturbance, psychosis, mood disorder, unrealistic expectations of surgery, and an absence of social support. The presence of mental retardation is not an absolute contraindication to surgery but can complicate postsurgical care (Sperling 1994). The most commonly performed procedures are temporal lobectomy and amygdalohippocampectomy. Other procedures include extratemporal cortical resections, hemispherectomy, and white matter transactions, including corpus callosotomy (Engel 1993). It is noteworthy that poor psychological outcomes occasionally accompany good postoperative seizure control, and some patients need considerable psychological help in adjusting to life without seizures (Vickrey 1993).

### *Parkinson's Disease Surgery*

Neurosurgery for Parkinson's disease is an evolving field in which a number of different surgical interventions have been suggested (Olanow 2002). Psychiatric complications can follow surgery (e.g., corticobulbar syndromes and psychic akinesia after bilateral pallidotomy) (de Bie et al. 2002; Merello et al. 2001). However, there is little in the way of guidance available for the psychiatrist asked to assess a patient's fitness for neurosurgery. It is generally agreed that patients with dementia tend to have poor outcomes; otherwise, the same principles would apply as for epilepsy surgery.

## Conclusion

The practice of psychiatry in a neurological or neurosurgical setting is both challenging and rewarding. One of

the challenges is the often complex task of determining the relationship between comorbid neurological and psychiatric symptoms. In this chapter we have outlined general principles of assessment and management in relation to the more commonly encountered conditions. These same principles apply to the more rarely encountered problems. Working closely with colleagues who share an interest in disorders of the brain can be very rewarding, and new developments in neuroscience are providing a greater understanding of the mechanisms by which biological, psychological, and social factors interact to cause both neurological and psychiatric illness. Consequently, the interface between these specialties is rapidly becoming one of the most intellectually fascinating areas of work for the specialist in psychosomatic medicine.

## Obstetrics and Gynecology

---

Nada L. Stotland, M.D., M.P.H.

Donna E. Stewart, M.D., F.R.C.P.C.

Sarah E. Munce, B.Sc.

Danielle E. Rolfe, B.P.H.E.

**REPRODUCTIVE EXPERIENCES AND** behavior are fraught with intense feelings: joy, pride, and passion, as well as shame, guilt, and fear. The ability to reproduce can be, or be perceived as, a requisite for a permanent relationship, a family, a place in society, or admission to the eternal afterlife. Therefore, interactions between obstetrics and gynecology and psychiatry are particularly important. Up-to-date information about obstetrics and gynecology is essential for the psychiatrist, and information about psychiatric issues is essential for the obstetrician/gynecologist. Each also needs to know something about the realities of practice for the other.

Tradition or regulations sometimes separate a patient's obstetrics and gynecology care from her mental health care and may divide her mental health care among two or more practitioners (Fugh-Berman and Kronenberg 2003). Obstetricians and gynecologists must master new technical developments, may provide primary care, and usually have little training in mental health. The fear of malpractice claims is especially onerous for obstetricians and gynecologists.

Since Hippocrates and the notion of the unmoored uterus causing "hysteria," physicians have linked women's reproductive functions to mental illness (Hirshbein 2003). The care of female patients requires an understanding of the anatomical and physiological substrates of reproduction, its social contexts, and the nature of obstetric and gynecological diseases and treatments. This understanding is also valuable in the care of male patients, whose mothers, sisters, (most) intimate partners, and daughters are female.

In this chapter, we cover gender identity, infertility, contraception, sterilization, hysterectomy, abortion (both spontaneous and induced), chronic pelvic pain, psychiatric disorders during pregnancy and postpartum and their treatment, menopause, and urinary incontinence. Eating disorders are covered in Chapter 15, "Eating Disorders," and female oncology is discussed in Chapter 24, "Oncology."

Note that some of the phenomena described in this chapter vary by culture and sexual orientation and that most findings are generally derived from research on presumably heterosexual women in North America and Europe. An often-overlooked minority group is lesbian women. Many lesbians experience or fear disapprobation and misunderstanding in most health care settings, are reluctant to seek care, and therefore experience adverse health outcomes. Psychiatrists can help gynecologists and other primary care physicians to phrase questions about sexual orientation and activity in nonjudgmental terms and become familiar with the range of lesbian sexual practices.

### Gender Identity

---

The first question about a newborn (or fetus) is whether it is a boy or girl, a determination made on the basis of the external genitalia. Ambiguous genitalia cause consternation; physicians and parents must decide whether to live with the ambiguity or assign the child to one gender or the other. Some believe that gender assignment should be

made and carried out as early as possible, so that the child can grow up with a clear gender, and others think that the child should be left as nature intended and allowed to make a personal gender assignment when of age. (Gender identity disorders are discussed in Chapter 17, "Sexual Disorders.") Reproductive organs are the first defining feature of each human being, and gender remains a core aspect of identity throughout life. Sex hormones influence not only physical development and a host of physiological functions but also brain structure and activity. Environmental factors influence developing anatomy and ongoing physiology. A lifelong, active interplay occurs among anatomy, physiology, social influences, and individual psychology.

The term *sex* refers to narrowly defined biological characteristics. The term *gender* includes social roles and an individual's sense of femininity or masculinity. Some evidence indicates that girls are aware of their sexual organs and identity as early as toddlerhood. As puberty approaches in females, the sense of gender identity is powerfully reinforced and reshaped by physical changes: the development of breasts and pubic hair and the onset of menstruation. In some cultures, girls are told at menarche that they are now women. With menarche come fertility and the possibility that sexual activity will lead to pregnancy. Although girls can be sexually abused at any age, the possibility of rape is more overt after puberty, and vulnerability to attack becomes part of gender identity. The possibility of pregnancy can be at once a worry and a wish. A young woman may feel that she is not truly a woman until she has had heterosexual intercourse or until she has borne a child. Girls who feel sexual attraction for other girls face a crisis in gender identity because society increasingly expects them to date, form relationships, and engage in sexual activity with males. Medical problems that interfere with any of these functions threaten core gender identity.

## Infertility

---

*Infertility* is commonly defined as 12 months of appropriately timed unprotected intercourse that does not result in conception. Approximately 40% of infertility problems are attributable to the female, and 60% are attributable to the male or are of unknown etiology (Klock 1998). The World Health Organization has reported that between 8% and 12% of couples, or approximately 50–80 million people worldwide, experience some type of fertility problem during their reproductive lives (World Health Organization Programme of Maternal and Child Health and Family Planning Unit 1991). Within the United States, it

has been estimated that 7.1% of married couples, or 2.3 million married women of childbearing age, have a fertility problem (Abma et al. 1997). Although the popular impression is that the prevalence of infertility has risen over the past few decades, the rate of infertility has remained relatively stable since 1965 (Keye 1999). Rather, the use and availability of medical services, as well as willingness to disclose and public awareness of infertility treatment options, have increased (Burns and Covington 1999; Keye 1999). Although much of the public attention has centered on advances in medical treatment and technology, both organic and psychological factors may be involved in infertility (American Psychological Association 1996; Kainz 2001).

## Psychological Factors Associated With Infertility

There has been increasing understanding of the psychosocial aspects of infertility. Early publications suggested that infertility without a detectable organic cause was "psychogenic." More recent studies have used a biopsychosocial approach and have examined the stresses of investigation and treatment, as well as psychiatric morbidity, influencing fertility and the outcomes of infertility treatments (Burns and Greenfield 1991). For example, in a study that used a nationally representative sample of 11,000 American women, generalized anxiety disorder was associated with lower fecundity, independent of treatment status (King 2003). A prospective study that investigated the effect of chronic stress levels (trait anxiety) on conception rates in normally fertile women found that a higher initial trait anxiety level significantly predicted a lower pregnancy rate (Demyttenaere et al. 1988). Similarly, these investigators found that increased depressive symptoms were associated with lower pregnancy rates after in vitro fertilization in infertile women (Demyttenaere et al. 1998). Eating disorders (anorexia nervosa, bulimia nervosa, and obesity) are all associated with infertility (Stewart et al. 1990). Restrictive or purging eating behaviors are often undisclosed and result in both subfecundity and poor pregnancy outcomes (Stewart and Robinson 2001a).

Studies on gender differences in psychological reactions to infertility have shown that women report a higher degree of anxiety, depression, and loss of self-esteem compared with their partners. What is unclear is whether this plays an etiological role or is reactive to infertility labeling, investigation, or treatment. Infertile women are also significantly more depressed than their fertile counterparts, with depression and anxiety levels equivalent to those in women with heart disease, cancer, or HIV-positive

status (Kainz 2001). Women tend to report that the diagnosis and treatment of infertility are the most psychologically painful and challenging experiences they have ever had. Furthermore, infertile women report poorer sexual and marital adjustment; more sexual dysfunction; and more feelings of guilt, inferiority, and isolation compared with infertile men (Weaver et al. 1997). Finally, the negative effects of infertility on quality of life have been shown to be stronger for infertile women compared with infertile men (Hjelmstedt et al. 1999; Kainz 2001).

## Psychosocial Assessment in Infertility Patients

Some have suggested that current levels of distress and coping strategies should be assessed in couples before initiating infertility treatment to provide the opportunity to learn and practice new adaptive behaviors that could enhance their ability to cope with infertility and the associated medical investigations and procedures (Lukse and Vacc 1999). Counseling is sometimes recommended in couples considering donor eggs or sperm or surrogacy.

The process of infertility diagnosis and treatment is grueling. Normally intimate and private behaviors are asked about, subjected to strict timing, and brought into the clinical situation. The psychological effects, particularly mood alterations, of fertility-enhancing drugs are underappreciated. Careful attention should be paid to recent changes in drug regimens and their potential contribution to recent-onset psychiatric symptoms such as depression, anxiety, mania, or psychosis (Lukse and Vacc 1999).

The goal of mental health evaluation is to identify and treat any comorbid psychiatric disorders, to prepare the couple for infertility treatments, to raise emotional and ethical treatment issues that the couple may not have considered, and to offer support and coping strategies. Group interventions are often helpful in providing mutual support, information, and coping techniques (Kainz 2001).

## Contraception

---

Contraceptive information and care are widely available in the Western world. Nevertheless, half of the pregnancies in North America each year are unintended. Contraceptive choices and use are affected by knowledge and misinformation, by women's comfort with their own genitalia, by the preferences of sexual partners, by social custom, and by access to physicians for hormonal methods. Many women are ill-informed about the advantages of hormonal contraception (Picardo et al. 2003).

Gender and relationship power differentials play major roles in the use of contraception (Harvey et al. 2002). A psychological study of 132 heterosexual college men reported that condom users were more independent, clever, and uninhibited. Those who had not used condoms at last intercourse stated that they had not planned on sex and had no condoms available (Franzini and Sideman 1994). In another study of students, the attitudes of men and women toward male and female contraceptive pills were compared. Of the women, 71% expressed willingness to take an oral contraceptive; for men, the figure was 20%. Hesitancy about female pill use among women centered on "bother"; men were concerned about the safety of the female pill. Men thought that a male oral contraceptive would be more unnatural, bothersome, harmful, and opposed to their beliefs than would a female oral contraceptive. The authors concluded that, despite their level of education, these men were not willing to assume responsibility for contraception (Laird 1994). Women who do not discuss sexual decisions with their male partners are at increased risk for contraceptive failure (Zlokovich and Snell 1997). Ethnicity plays a role as well; Hispanic women may be less likely, and African American women more likely, to use condoms than are white women (Castaneda and Collins 1998; Upchurch et al. 2003).

Psychodynamics and psychiatric conditions can interfere with a woman's use of a contraceptive technique. Pregnancy may be sought, consciously or unconsciously, as proof of fertility and womanhood. Contraception requires the acknowledgment of future sexual activity. Unmarried women who do not approve of extramarital sexual intercourse may be able to engage in it only when "swept away" by a romantic situation and thus be unprepared to prevent pregnancy. Some women feel uncomfortable touching their own genitalia, as some contraceptive methods require. Many women have limited knowledge about their own anatomy, are too anxious to absorb the information in a hurried office or clinic visit, and are too embarrassed to ask that information be repeated (Sanders et al. 2003). Homeless women, among whom are many with psychiatric illnesses, have little access to information or care (Gelberg et al. 2002). Women who grow up in foster care are at increased risk for early coitus and unprotected sexual intercourse (Crocker and Carlin 2002; Koniak-Griffin et al. 2003).

Unplanned pregnancy is by no means always the result of unconscious conflict. Contraceptives do fail. Some women are sexually assaulted, bullied, and cajoled into unprotected sexual intercourse (Rickert et al. 2002). Some are threatened with abandonment if they do not keep their male partners sexually satisfied. Some trade sex for drugs. Some are members of religious groups requir-

ing that they obey their husbands. However, the myth of female control over sexuality and female seduction, as reflected in the biblical story of Adam and Eve, persists. Women are blamed and looked down on, in general and in the medical context, for becoming pregnant at the wrong time or with the wrong partner. Their sense of shame can exacerbate whatever psychiatric symptoms they have and, paradoxically, leave them more vulnerable to future unplanned pregnancies.

New developments in contraception have important psychosocial implications (Fraser and Kovacs 2003). Emergency contraception consists of doses of oral contraceptives taken after unprotected intercourse. Although it was believed at first that the hormones had to be ingested within 24 hours, it now appears that they can be effective within at least 3, and possibly 5, days. In England, some parts of the United States and Canada, and some other countries, emergency contraceptives can be obtained without a prescription. In other areas, they can be obtained at family planning clinics, hospital emergency departments, or pharmacies by prescription. However, several barriers exist to the use of this highly effective contraceptive technique (DelBanco et al. 1997). Women who are young, especially those who are poor, may be uninformed, embarrassed, unaware of their level of risk for pregnancy, worried about side effects, and concerned about negative responses from others (Free et al. 2002). Pharmacies may decline to stock the medication, because of either moral objections, lack of demand, or disagreement over patient access without a physician prescription (N. Cooper et al. 2000).

Another new development is the use of hormonal contraceptives on a continuous, rather than intermittent, basis. Women can receive long-lasting hormone implants, use a contraceptive patch, or take contraceptive pills every day with breaks for withdrawal bleeding, which is easier to remember than the usual regimen. Continuous hormonal contraception causes months of amenorrhea. Women who experience menstrual periods as painful and inconvenient welcome amenorrhea, whereas others hold personal or cultural beliefs that bleeding is necessary to clean the uterus or confirm femininity (Glasier et al. 2003). Clinicians need to elicit and deal with patients' feelings and preferences.

Patients may be so accustomed to their birth control pills or injections that they fail to report them when asked what medications they are taking. Clinicians must ask about these contraceptives specifically. Hormonal contraceptives interact with some psychotropic medications. Implanted levonorgestrel metabolism is enhanced by phenobarbital, possibly resulting in a pregnancy (Shane-McWhorter et al. 1998). Modafinil, carbamazepine, and

oxcarbazepine enhance the metabolism of oral contraceptives, decreasing their effectiveness; the oxidation of benzodiazepines and tricyclic antidepressants (TCAs) in the liver is inhibited, and their blood levels increased, by oral contraceptives (Schatzberg et al. 2003).

Inquiries about sexual behavior and protection from unwanted consequences should be part of every medical, including psychiatric, history and treatment. Some physicians ensure that all their female patients of reproductive age who are not intending to become pregnant are supplied with either emergency contraceptive prescriptions or the pills themselves. Because some psychiatric illnesses increase vulnerability to unprotected sexual intercourse, psychiatrists should be prepared to provide relevant information.

## Sterilization

---

Sterilization is a permanent solution to unwanted fertility. A psychiatrist may be asked to consult when a young, nulliparous woman, or a patient with a mental illness, desires to be sterilized. The question of informed consent in the latter circumstance has been highlighted by state laws enacted in the wake of the involuntary sterilization of mental "defectives" in the past. The situation is paradoxical. Guardians may have difficulty obtaining sterilization procedures for severely cognitively impaired or developmentally delayed adult women who are unable to cope with the hygienic aspects of menstruation, are victimized by male predators, become pregnant, and are entirely unable to cope with the stresses of birth and parenting. Women may have psychotic symptoms, or a history of them, that interfere with capacity, but they also may make well-informed decisions not to have children, or more children, precisely because they recognize that their illness would interfere with their parenting. One way to approach this situation is to ask the patient to return in 3–6 months. If she is mature, not acutely psychotic, and persistent in her desire for sterilization, she may be as appropriate a candidate for the procedure as a woman without diagnosed psychiatric illness.

Recent studies of psychological aspects of sterilization in North America have focused almost entirely on the incidence of postsurgical regret. The occurrence of regret ranges from 5% to 20% (Hillis et al. 1999; Newton and McCormack 1990). Risk factors include youth, marital conflict over the procedure, and subsequent changes in marital partnerships (Jamieson et al. 2002). Studies of the effect of parity on postsurgical regret have been inconclusive. Sexual satisfaction does not appear to be affected (Pati and Cullins 2000). The provision of clear

information about the nature, effectiveness, risks, and benefits of the procedure is a crucial factor in patient satisfaction.

## Hysterectomy

---

### Epidemiology and Indications

Hysterectomy (the surgical removal of the uterus) is one of the most common surgical procedures performed on North American women, with rates of approximately 500 of every 100,000 women (Farquhar and Steiner 2002; Stewart et al. 2002) (see also the "Pelvic Surgery" section in Chapter 30, "Surgery"). Hysterectomy rates in the United States and Canada are more than double those in many European countries, but small area rate variations are widespread in most countries and appear to depend on women's socioeconomic class, race/ethnicity, education level, religion, physician practice, reimbursement schedules, and availability of new technology (Stewart et al. 2002). Hysterectomy may be complete or incomplete (the cervix is left intact) and also may be combined with removal of the fallopian tubes and ovaries (salpingo-oophorectomy). Although vaginal hysterectomy is associated with lower mortality and shorter length of stay, abdominal hysterectomy remains the most common hysterectomy procedure.

A small proportion of hysterectomies are performed to treat malignancies or catastrophic hemorrhage, but the vast majority are elective procedures performed primarily to improve quality of life in women with abnormal uterine bleeding, fibroids, uterine prolapse, chronic pelvic pain, or endometriosis. The mean age of most women undergoing hysterectomy is the mid-40s, or an average of 6–7 years before the mean age of natural menopause, when some of these problems (abnormal uterine bleeding, fibroids) spontaneously resolve. However, hysterectomy is the treatment of choice for certain gynecological conditions, and the predicted advantage must be carefully weighed against the risks of surgery and other treatment alternatives such as hormonal therapy, and endometrial ablation (Lefebvre et al. 2002).

### Psychosocial Issues

#### *Information Needs and Decision-Making Preferences*

Well-informed women who have been involved in decision making about hysterectomy have the best outcomes (Stewart et al. 2002). Various studies and expert panels

have concluded that women and their family physicians should be provided with an adequate level of knowledge to make a fully informed decision of whether hysterectomy, less invasive procedures, medical management, or watchful waiting is the best option (Galavotti and Richter 2000; Mingo et al. 2000; Stewart et al. 2002; Uskul et al. 2003; Vigod and Stewart 2002; Williams and Clark 2000). Similarly, the options for retention or removal of the cervix and ovaries and route of hysterectomy (vaginal vs. abdominal) should be discussed. Women's decision making regarding, and response to, hysterectomy is influenced by their age, socioeconomic status, education, desire for fertility, sexual orientation, and ethnicity and by the role of their family, friends, and partners (Galavotti and Richter 2000; Groff et al. 2000; Richter et al. 2000) and the severity of their symptoms. Women who require hysterectomy for the treatment of malignancies are understandably focused more on the cancer, its treatment, and its outcome.

#### *Variations With Ethnic, Socioeconomic, and Sexual Diversity*

Several articles have explored ethnic differences and indications for hysterectomy (Farquhar and Steiner 2002; Groff et al. 2000; Lewis et al. 2000). Qualitative analyses with Hispanic, African American, and lesbian women (Groff et al. 2000) have explored their capacity to acquire a second opinion about hysterectomy and available alternatives that may be limited by education, ethnicity, economics, and access. African American women undergo hysterectomy at a younger age for most diagnostic categories, including leiomyomas, genital prolapse, and endometriosis. They are also more likely to have an abdominal hysterectomy, extended hospital stays, and higher in-hospital mortality (Lewis et al. 2000).

#### *Psychological and Sexual Outcomes of Hysterectomy*

Women with substantiated diagnoses and clear indication for hysterectomy have better physical and psychological outcomes than do women with less-defined symptoms and indicators such as chronic pelvic pain. A recent prospective study (Kjerulff et al. 2000) in more than 1,000 women with benign conditions at 28 Maryland hospitals collected and reported data for 2 years after hysterectomy. Although symptom severity, depression, and anxiety decreased significantly after hysterectomy and quality of life improved for most women, 8% of the women reported symptoms that were at least as severe 1–2 years after hysterectomy as before. Presurgical characteristics that predicted lack of symptom relief included previous therapy

for psychological problems, history of depression, and household income less than \$35,000. Bilateral oophorectomy also predicted lack of symptom relief at 2 years after hysterectomy (Kjerulff et al. 2000). A small study of 48 Chinese women undergoing elective hysterectomy found that a psychoeducational intervention resulted in lower postoperative anxiety, less pain, and higher levels of satisfaction than in women in the control group (Cheung et al. 2003).

A systematic review of English- and German-language literature on sexual outcomes after hysterectomy located 18 studies, 8 of which were prospective. The methodological quality of all the studies was poor, but most studies found no change in or an enhancement of sexuality in the women after hysterectomy (Farrell and Kieser 2000). The Maryland study discussed in the previous paragraph reported increased rates of sexual intercourse and decreased rates of dyspareunia, anorgasmia, low libido, and vaginal dryness at 1 and 2 years after hysterectomy. Pre-hysterectomy depression was notably associated with continuing dyspareunia, vaginal dryness, low libido, and anorgasmia after hysterectomy (Rhodes et al. 1999). Similar negative outcomes have been described in women seeking hysterectomy for poorly defined chronic pelvic pain. Studies exploring psychological outcomes of hysterectomy in diverse groups of women are rare (Galavotti and Richter 2000; Mingo et al. 2000).

Women undergoing hysterectomy with oophorectomy have to confront the onset of sudden surgical menopause if estrogen therapy is not begun shortly after surgery. This sudden hormonal change may result in vasomotor symptoms, sleep loss, and depression, especially in vulnerable women with a history of depression associated with reproductive events (Stewart and Boydell 1993). Even women whose ovaries were left intact sometimes enter premature menopause if the blood supply to the ovaries has been disrupted.

## Role of the Psychiatrist

There may be a role for psychiatrists in assessing mood, anxiety, understanding, and feelings about sexuality and fertility in vulnerable women undergoing hysterectomy. For the informed, psychologically healthy woman who has failed to respond to other treatment options and who has a significantly impaired quality of life because of a specific gynecological condition, hysterectomy may offer an improved quality of life. However, for women with premonitory depression, anxiety, or personality disorders, especially if accompanied by ambivalence about sexuality, fertility, or the procedure, hysterectomy may fail to ameliorate, or may even exacerbate, preexisting symptoms

(Stoppe and Doren 2002). Psychiatrists should ascertain the hormonal status of women with sudden mood changes following hysterectomy and consider short-term hormonal treatment as well as antidepressants.

Psychiatrists who assess women after hysterectomy should evaluate their understanding of the procedure, attitudes toward fertility and sexuality, and experience and expectations of surgery, as well as psychiatric history. The appropriate treatment, whether psychotherapy, hormones, or psychotropics, will, as always, depend on the individual woman.

## Abortion

---

### Spontaneous Abortion

Abortion can be spontaneous (miscarriage) or induced (usually just termed *abortion*). Spontaneous abortion generally evokes feelings of failure and loss. A woman's body has failed to perform one of its basic functions; she has failed to produce a child for her partner and parents; she has expelled her own potential child; and she may have conceived an embryo with genetic anomalies (Friedman and Gath 1989). Decades ago, miscarriage was sometimes attributed to the woman's unconscious rejection of motherhood, but this theory has never been validated by empirical research. Spontaneous abortion, like a stillbirth or neonatal death, may precipitate pathological grief, postpartum depression, or posttraumatic stress (Beutel et al. 1995; Engelhard et al. 2003). Women report that the failure of society in general and of friends and family to acknowledge the loss is painful and complicates the grieving process. People often say, "There must have been something wrong with the baby," "This is God's way of correcting mistakes," or "You can just get pregnant again." There are no ceremonies to mark the occasion. Friends and co-workers tend to avoid the subject and to expect the woman to recover within days or weeks, but grief may last for months.

Health care providers also may fail to recognize the emotional effect of spontaneous abortion. They feel helpless to prevent it, and it is generally not associated with serious medical or obstetrical complications. Psychiatrists can help them to understand and tolerate how their patients are feeling and to appreciate the benefits of simply allowing patients to express those feelings. Health care providers should be aware that emotional recovery, depending on the circumstances, can take months, and they need to know when and how to make the diagnosis of pathological grief. It is often helpful for them to meet with the patient some weeks after the event to go over the

medical findings, if any; the prognosis; and the state of the woman's recovery.

The loss of pregnancy through miscarriage or stillbirth is associated with an increase in anxiety during a subsequent pregnancy and sometimes with overprotectiveness toward children subsequently born (Bourne and Lewis 1984). Although patients are frequently counseled to wait 6 months or a year after such a loss, they often conceive as soon as possible, especially if they feel that the clock is ticking. The obstetrician must be prepared to offer them enhanced support.

## Induced Abortion

### *Psychiatric Sequelae*

Approximately 1 million abortions are performed every year in the United States; approximately one in four women will have an abortion in her lifetime (Ventura et al. 2000). Psychiatrists are seldom consulted about abortion and abortion decisions, and no evidence shows that formal mental health consultation is routinely necessary. The psychiatric ramifications of abortion are a matter of some debate, but the findings are clear once methodological confounds are taken into account. Unbiased reviews of the literature indicate that self-limited feelings of guilt and sadness are common after abortion, although the predominant reaction is one of relief, and new episodes of psychiatric illness are rare (Adler et al. 1990; Dagg 1991; Koop 1989; Torres and Forrest 1988). A recent study corroborated findings that women's quality of life improves in the period from before to after an early abortion (Garg et al. 2001; Westhoff et al. 2003). The best outcomes prevail when women are able to make autonomous, supported choices about their pregnancies. When women seek, but are denied, abortion, the resulting children have significantly poorer mental health than their siblings or matched control subjects (Kubicka et al. 2002).

Antiabortion groups and writers claim that abortion is associated with a higher risk of serious psychiatric disorders and suicide than is childbirth (Pro-Life Action Ministries, undated; Reardon et al. 2003; Thorp et al. 2003). These publications fail to address the circumstances of and reasons for abortion. Sometimes they confound common, self-limited feelings of loss and guilt with diagnosable depression (Dagg 1991). Women have abortions because they have been abandoned by the men who impregnated them, because those men threaten to leave if they continue the pregnancy, because the pregnancy is the result of rape or incest, because they are poor and overburdened with other responsibilities, or because they do not have the resources—educational, financial, emotional, or social—to provide adequate parenting. They may sim-

ply not want to be a parent. Preexisting serious psychiatric illness makes some women more vulnerable to unwanted pregnancy and less able to parent.

### *Risk Factors*

Not surprisingly, coercion, lack of social support, poverty, rape, incest, and preexisting psychiatric illness are associated with increased risk for psychological difficulties following, but not causally related to, abortion. Women who belong to religious faiths opposed to abortion choose abortion as often as or more often than those who do not. Efforts have been made to reach out to this population, both to enlist them in antiabortion advocacy and to offer them spiritual support (Gay and Lynxwiler 1999; Jeal and West 2003; Ventura et al. 2000). Demonstrators or fear of terrorism at an abortion facility may exacerbate stress, and the attitudes and behaviors of medical personnel during the abortion procedure have a significant influence on patients' experience (Slade et al. 2001).

The delay of abortion into the second trimester, or later, is most often secondary to denial of pregnancy, difficulties with access, or diagnosis of a serious fetal defect, each of which increases the risk for postabortion reactions. The discovery of a fetal defect in a wanted pregnancy, or the need to abort because of serious illness in the mother, arouses the same sense of failure and loss as a miscarriage, with the added concern that one is carrying a genetic anomaly or is physically unable to bear a child. Consultation may be sought when a woman or family cannot decide, or manifests overwhelming anxiety, when making an abortion decision under these circumstances (Zlotogora 2002). Continuing a pregnancy and relinquishing the child for adoption pose a psychological burden as well (Cushman et al. 1993; Deykin et al. 1984; Rynearson 1982).

## Minors and Abortion

The effect of abortion on minors, and their ability to make decisions about abortion, is another area of controversy. The vast majority of pregnant minors choose to involve their parents in the abortion decision. No evidence shows that those who think it is not safe or wise to inform their parents derive benefit from being forced to do so. Term pregnancy and delivery pose greater medical and psychological risks for adolescents than does abortion. Arguments that minors are too immature to elect abortion overlook the fact that these same minors, if their pregnancies are not terminated, will soon be mothers with responsibility for infants. In Zabin's classic study of inner-city girls who obtained pregnancy tests at a school clinic, those who had abortions had better outcomes than

did those who carried to term and even than did those whose pregnancy test results were negative. This does not imply that the abortion improved their mental health; it may imply that the inability to tell whether one is pregnant is associated with other psychosocial problems. Marriage of the pregnant teenager to the father of the baby does not improve outcome and may worsen it (Zabin et al. 1989).

## Chronic Pelvic Pain

---

Chronic pelvic pain is nonmenstrual pelvic pain of 6 or more months' duration that is severe enough to cause functional disability or require medical or surgical treatment (Howard 2003). It is a relatively common and significant disorder of women, with an estimated prevalence of 3.8% in adult women, similar to that of asthma or back pain (Zondervan et al. 1999). Chronic pelvic pain is one of the most common gynecological complaints and accounts for 2%–10% of outpatient gynecological referrals (Howard 2003; Savidge and Slade 1997). In the United States, indirect total costs for chronic pelvic pain may be more than \$2 billion per year (Mathias et al. 1996). At the individual level, chronic pelvic pain may lead to disability and suffering, with loss of employment, marital discord and divorce, and an overall decline in quality of life (Howard 2003).

### Etiology of Chronic Pelvic Pain

Despite the severity and frequency of chronic pelvic pain, its etiology is often difficult to discern. Disorders of the reproductive, gastrointestinal, urological, musculoskeletal, and neurological systems may be associated with chronic pelvic pain. In many cases, however, the pain is related to a combination of physical and psychological factors, such as endometriosis, adhesions, urological problems, irritable bowel syndrome, myofascial pain, depression, anxiety, somatization, and past abusive experiences (Howard 2003; Moore and Kennedy 2001). Endometriosis and pelvic adhesive disease are responsible for most cases of chronic pelvic pain with organic findings, but a significant number of patients have no obvious etiology for their pain at the time of laparoscopy (Gelbaya and El-Halwagy 2001; Savidge and Slade 1997). As with other chronic syndromes, especially those with ambiguous etiology, the biopsychosocial model offers the best way of integrating physical causes of pain with psychological and social factors. One model, the gate-control theory of pain, proposes that peripheral nociceptive signals can be modified by neurotransmitters, such as serotonin and endorphins, that

control mood states, and accordingly, the gateway to chronic pain can be opened by depression and by direct tissue irritation. Because interacting psychological and physical factors are likely to be present early in the course of pain, attempts to separate chronic pain into a simple cause-and-effect relation are usually unrewarding. An alternative theory, the diathesis stress model, proposes that some patients are at increased risk for chronic pain because of preexisting acquired vulnerability. This might explain why a disproportionate number of patients with chronic pelvic pain report histories of physical and sexual abuse (Gelbaya and El-Halwagy 2001).

### Psychological Factors Associated With Chronic Pelvic Pain

The relation of chronic pelvic pain to psychological state or personality style has received great attention. A comprehensive review in *PsychLit* and *MEDLINE* (1966–1997) of psychosocial factors in chronic pelvic pain identified 43 articles considered to be salient in exploring this link. Early studies tried to separate the pain into psychogenic and organic etiologies, but this has been largely unhelpful. Most studies have reported more depression, somatic symptoms, substance abuse, sexual dysfunction, and physical and sexual abuse in patients with chronic pelvic pain than in comparison groups (Fry et al. 1997). The reviewers, however, pointed out the numerous limitations in sample size, methodology, and comparison groups inherent in most of these studies. In general, the concept of psychogenic pain (emotional pain displaced onto the body) has been largely superseded. Cognitive-behavioral and psychophysiological theories have moved increasingly toward supporting more complex, multicausal views of chronic pelvic pain. Chronic pelvic pain is likely to be the outcome of several somatic, social, and psychological influences acting together in varying degrees, but more recent work has questioned the specificity of some of these, such as child sexual abuse.

A subsequent review of chronic pelvic pain (Reiter 1998) described predisposing psychosocial variables in chronic pelvic pain to be familial pain models, mood and anxiety disorders, marital adjustment problems, spousal responses, abuse history, and somatization. The author reported that psychological diagnoses were apparent in 60% of the women referred for chronic pelvic pain, with major depressive disorder the most common.

### Management of Chronic Pelvic Pain

A comprehensive evidence-based management review of chronic pelvic pain (Reiter 1998) recommended a multi-

disciplinary, multifocal approach to chronic pelvic pain, individualized for each woman. Management might include medical therapies (oral analgesics, antidepressants, drugs for dysmotility disorders, management of musculoskeletal pain, ovarian cycle suppression, and antibiotics) and cognitive-behavioral or other psychotherapeutic approaches. Focused psychotherapy may be useful to address issues such as pain management, current conflicts, past sexual and physical abuse, current domestic violence, substance abuse problems, and sexual and marital dysfunction. Phases of treatment include education, skills acquisition, behavior modification, and maintenance. Special techniques may increase the patient's coping ability and sense of control; such techniques include muscle relaxation, deep breathing and imagery, and cognitive-behavioral techniques to identify and address maladaptive thoughts. Because patients with chronic pelvic pain frequently limit their activity to avoid possible pain, activity programs can be initiated to decrease disability behaviors. Several studies have reported that multidisciplinary management of chronic pelvic pain has significantly better outcomes than does traditional medical management (Price and Blake 1999; Reiter 1998; Savidge and Slade 1997).

## Endometriosis

Endometriosis is a common gynecological complaint caused by the presence of hormonally responsive endometrial tissue outside the uterine cavity. The precise pathogenesis is not clearly established but likely involves retrograde menstruation with seeding of endometrial glands in the dependent part of the pelvis and in or on the ovary, posterior cul-de-sac, broad ligament, uterosacral ligament, rectosigmoidal colon, bladder, and distal ureter. It has been proposed that retrograde menstruation occurs to some degree in all women, but that only those who are unable to clear the menstrual debris because of immune dysfunction will go on to develop endometriosis (Cramer and Missmer 2002). Family history is a risk factor for endometriosis, and current efforts are being made to investigate genetic factors. The mean age of women at diagnosis of endometriosis ranges from 25 to 30 years. This condition is often asymptomatic but is also found in association with dysmenorrhea, dyspareunia, infertility, chronic pelvic or back pain, and rectal discomfort. The pain from the disorder is often cyclic, although it can be constant. The gold standard for diagnosis and staging of endometriosis depends on laparoscopy; however, the intensity of pain and discomfort does not correlate well with the severity of the disease at laparoscopy (Lu and Ory 1995).

## Management

Endometriosis can be treated by watchful waiting or medical or surgical management. Current medical regimens to treat this condition with gonadotropin-releasing hormone agonists and other drugs attempt to create states of pseudopregnancy, pseudomenopause, or chronic anovulation. Surgical treatments vary from conservative removal and destroying of endometrial implants by excision, electrocautery, or laser. However, implants have been shown to recur in up to 28% of patients within 18 months and 40% after 9 years of follow-up. Although surgical conservative treatment is widely used to enhance fertility, its efficacy for endometriosis-associated infertility has not yet been shown. The definitive treatment for endometriosis is total abdominal hysterectomy with bilateral salpingo-oophorectomy, although an ovarian-sparing procedure is reasonable for mild to moderate endometriosis in young women who wish to retain their fertility (Lu and Ory 1995).

## Role of the Psychiatrist

Because endometriosis is often chronic, and its contribution to chronic pelvic pain is sometimes uncertain, psychiatric opinion may be sought. Women with endometriosis also experience a range of problems for which they may not be adequately supported. In fact, some women report that their worst experience is their encounter with health professionals and the way in which their symptoms are trivialized and dismissed (Cox et al. 2003). Depression is a common accompaniment of endometriosis that is accompanied by chronic pain, dyspareunia, or infertility. In addition, gonadotropin-releasing hormone agonists are often used to treat endometriosis, and depressive symptoms may be associated with this treatment. Selective serotonin reuptake inhibitor (SSRI) antidepressants appear to be significantly helpful in the treatment of mood symptoms during the course of gonadotropin-releasing hormone agonists (Warnock et al. 1998). Psychotherapy and antidepressants also may be helpful in addressing other psychological issues and symptoms in women with endometriosis.

## Vulvodynia

Vulvodynia is chronic burning, stinging, or pain in the vulva in the absence of objective clinical or laboratory findings. Vulvodynia is divided into two classes: 1) vulvar vestibulitis, which is restricted burning and pain in the vestibular region that is solicited by touch, and 2) dysesthetic vulvodynia, which is burning or pain not limited to the vestibule, which may occur without touch or pressure. A population-based National Institutes of Health study

found that approximately 16% of women reported lower genital tract discomfort persisting for 3 months or longer (Edwards 2003).

The etiology of vulvodynia is unknown, and previously suspect agents such as subclinical yeast infections and human papillomavirus have largely been discounted.

More recently, neuropathic pain has been invoked, particularly because TCAs, SSRIs, and gabapentin have shown some promise in treating this disorder. Many women with vulvodynia also have comorbid disorders, such as interstitial cystitis, headaches, fibromyalgia, and irritable bowel syndrome, as well as clinical depression. Depression and anxiety are common accompaniments to vulvodynia (Stewart et al. 1994).

Psychiatrists may be asked to assess the role of psychosexual factors and depression in women with vulvodynia. Given the efficacy recently shown by dual-action antidepressants (serotonin and norepinephrine reuptake inhibitors) in treating depression and chronic painful conditions, these antidepressants may be a promising treatment for vulvodynia. However, to date, no randomized, controlled trials with these medications have been published.

## Pregnancy

---

The entire range of psychiatric disorders occurs during pregnancy, and some conditions are unique to pregnancy. Treatment of these disorders is discussed later in this chapter.

### Psychiatric Disorders Occurring During Pregnancy

#### *Depression*

The incidence of depression during pregnancy is approximately the same as that for matched populations who are not pregnant. The signs and symptoms of depression must be carefully distinguished from the sleep, appetite, and energy changes often characteristic of pregnancy and from the signs and symptoms of thyroid dysfunction, anemia, or other diseases of pregnancy. Discontinuation of maintenance medication for women who have had recurrent depressions carries a high risk of relapse. Mild cases can be effectively treated with interpersonal or cognitive-behavioral psychotherapy (Grote and Frank 2003; Spinelli and Endicott 2003).

#### *Bipolar Disorder*

There is a growing literature on bipolar disorders during pregnancy (Cohen et al. 1995; Viguera et al. 2002). Some

pregnant patients can forgo mood stabilizers, but a substantial proportion (up to 50%) may relapse. Serious episodes of mania pose a threat to the pregnancy, necessitating especially careful risk-benefit analysis with regard to psychotropic medication.

#### *Anxiety Disorders*

Panic disorder may remit or recur during pregnancy. Patients with panic disorder who wish to discontinue medication should be tapered off gradually and treated with cognitive-behavioral therapy. More than 10% of female patients with panic disorder report that their first episode occurred postpartum. Panic disorder during pregnancy may recur with subsequent pregnancies. Obsessive-compulsive disorder is likely to worsen pre- and postpartum, and withdrawal of medication is very likely to result in recurrence. Some centers report that as many as 50% of cases of obsessive-compulsive disorder in women begin during their first pregnancy; others disagree (Neziroglu et al. 1992). Patients with moderate to severe symptoms may require maintenance medication during pregnancy; patients with milder cases can be treated with cognitive-behavioral therapy.

#### *Psychotic Disorders*

Because almost all women with psychotic disorders have been deinstitutionalized, their rate of fertility approximates that of the general population. Pregnancy does not ameliorate, and may exacerbate, psychotic symptoms (Davies et al. 1995). Psychotic episodes during pregnancy may be characterized by delusions that the fetus is evil or dangerous, leading the pregnant woman to stab herself in the abdomen or engage in other self-destructive behaviors. Electroconvulsive therapy (ECT) for acute affective psychotic episodes can be effective and is relatively safe for the fetus. Psychotic illness can impair a woman's ability to recognize and react appropriately to the signs and symptoms of labor (L.J. Miller and Finnerty 1996). Hospitalization toward the end of pregnancy is not completely protective against these concerns. Psychiatric inpatient staff are not obstetrically trained and are often uncomfortable assuming responsibility for the safety of mother and child. Obstetrical staff are not comfortable with psychotic patients. The consulting psychiatrist can facilitate collaboration between the departments in these difficult cases (Muqtadar et al. 1986).

Prenatal assessment and treatment can mitigate wrenching custody disputes after the infant is born. Serious psychiatric illness, if treated, is not always incompatible with successful mothering. The psychiatrist and obstetrician, working together with the patient and family, can plan

and make provision for the infant's needs. Psychiatrists may be called on to assist in the assessment of competency to parent an infant. When it is clear that the mother will not be able to care for the child, such as when her other children have been taken into state custody for their protection, the psychiatrist can help her come to terms with the painful separation that will occur.

### *Alcohol and Substance Abuse*

Alcohol and substance abuse arouse heightened concern in a pregnant patient. Standing by while a woman's behavior puts her fetus at risk is a painful situation for prenatal care professionals. The most serious and well-documented result of alcohol abuse during pregnancy is fetal alcohol syndrome. A pregnant woman who drinks the equivalent of 10 beers per day has a one-third risk of delivering a child with fetal alcohol syndrome and a similar risk of delivering a child who is retarded but does not have the full syndrome. The perinatal mortality in these circumstances is 17% (Greenfield and Sugarman 2001). More recent studies have not substantiated early fears of an epidemic of "crack babies." It appears that most or all of the negative cognitive and behavioral findings in these children are a result of the environment in which they grow up rather than intrauterine exposure to cocaine (Chiriboga 1998). However, misinformation and rage at pregnant women who abuse substances has led to instances in which women have been imprisoned, either for the protection of the fetus or as punishment for harming the fetus. Many or most pregnant women who abuse drugs or alcohol will accept treatment if it is practical (e.g., providing child care) and humane. Evidence indicates that the threat of coercion and punishment leads women to avoid seeking prenatal care altogether, obviating any opportunity to treat her and improve the fetus's intrauterine environment (see also Chapter 3, "Legal Issues," for discussion of legal aspects).

### *Situational Anxiety*

Some pregnant patients are referred for psychiatric consultation for evaluation of what seems to the primary care clinician to be an inordinate level of anxiety. A careful history often shows that the patient either has been frightened by the experiences of a close family member or has had a traumatic obstetrical or general medical care experience herself (Saisto and Halmesmaki 2003). The degree of pain a woman experiences in labor is related to many factors, including her expectations of pain (Chang et al. 2002). When the source of the anxiety is identified, it can be addressed by reviewing the past experience and making plans to avoid the frightening aspects of care in the com-

ing delivery, providing prenatal education about delivery, or using relaxation techniques or hypnosis. Domestic violence is another cause of prenatal anxiety. Literature about the effect of pregnancy on domestic violence is contradictory; in some reports, violence is increased, and in others, it is not (Johnson et al. 2003; Saltzman et al. 2003).

## Issues Unique to Pregnancy

### *Denial of Pregnancy*

Some women go into full-term labor without having recognized, or their families having recognized, that they are pregnant. Many such patients are not psychotic, but some are women with schizophrenia who are delusional in denying pregnancy (L.J. Miller 1990). Older patients may report that they thought pregnancy was impossible at their age and attributed their amenorrhea to menopause and the sensations of fetal movement to digestive problems. Younger patients in this situation are typically passive daughters isolated in very strict families without much knowledge about reproduction. Their preconscious or unconscious fears of the consequences of pregnancy are so terrifying that they keep its signs and symptoms out of awareness (Spielvogel and Hohener 1995). They wear loose-fitting clothing and go about their usual activities (Finnegan et al. 1982). These cases generally come to psychiatric attention only when the new mother kills the infant after birth (Brozovsky and Falit 1971). Therefore, these young women end up in the penal—rather than the mental health care—system, and there has been relatively little opportunity to work with them and their families to learn more about the dynamics of these situations. A recent epidemiological study in Germany, perhaps the first of its kind, reported an incidence of up to 1 case of pregnancy denial per 475 births (Wessel et al. 2002).

### *Pseudocyesis*

At the other end of the spectrum from the patient who does not realize she is pregnant is the patient who is convinced she is pregnant when she is not. This condition, referred to as *pseudocyesis*, is a fascinating example of psychobiological interplay. The patient ceases to have menstrual periods. Her abdomen grows, and her cervix may show signs of pregnancy. Some patients with the delusion that they are pregnant are psychotic, but that is not the case in classical pseudocyesis. Patients with pseudocyesis are a heterogeneous group, and they have no other signs or symptoms of frank psychiatric disorder (Rosch et al. 2002). They declare an expected date of delivery and move the date forward when delivery does not ensue. Their conviction may or may not be swayed by ultrasono-

graphic evidence or physical examination. For unknown reasons, the incidence of this condition is decreasing. Frequent antecedents are pregnancy loss, infertility, isolation, naiveté, and a belief that childbearing is a woman's crucial role. These individuals have no interest in psychiatric care, and little is known about how the condition eventually resolves (Whelan and Stewart 1990).

### ***Hyperemesis***

Pernicious vomiting in pregnancy was once thought to be the result of unconscious rejection of the pregnancy (Majerus et al. 1960). Hyperemesis, which can result in dehydration and electrolyte imbalance and may require hospitalization and intravenous treatment, certainly could induce ambivalence about a pregnancy in a woman who had been very pleased at the prospect of becoming a mother, but no scientific evidence indicates that ambivalence induces the vomiting (O'Brien and Newton 1991). Hyperemesis is no longer considered a psychiatric disorder. Mental health intervention can, however, help the patient and family cope until the condition resolves (Deuchar 1995).

### ***Routine Psychiatric Screening***

Psychiatrists may advise obstetricians that including psychiatric screening in routine antenatal care will decrease the frequency and intensity of noncompliance with antenatal care and of psychiatric emergencies during pregnancy and labor. Psychiatric illnesses can be identified and treated. Patients who might not otherwise recognize that they are in labor, and their families, can receive special education so that infants are not delivered into the toilet or in some other less-than-ideal environment. Prenatal education can prepare them for labor and delivery, so that they can best cooperate and communicate with medical staff when the time comes.

## **Postpartum Psychiatric Issues**

---

### **Perinatal Death**

Stillbirth and neonatal death provoke much the same reactions as do losses earlier in pregnancy, which are discussed earlier in this chapter, with the added stresses of full-term labor and delivery and the probability that many practical provisions for the expected infant have been made. Clinical practice in dealing with the bereaved and disappointed parents has varied over time. It is probably best to offer parents the opportunity to see or not to see the stillborn infant and to allow them to decide. Many bereaved parents report that their grief is exacerbated by the

failure of friends and relatives to acknowledge the loss. For some, naming the baby and having a funeral service, with or without a burial, is a helpful ritual. A religious leader of the parents' choice also can help them reconcile their rage at God for depriving them of their child with their need to derive support from their faith in God.

When the cause of fetal or neonatal death is not clear, an autopsy or other tests may be performed. The results will not be immediately available. The obstetrician, pathologist, geneticist, and psychiatrist may want to meet with the parents some weeks later to convey the results, answer questions, observe the grieving process, and determine whether additional supports are necessary. As with miscarriage, stillbirth increases the risk of posttraumatic stress, anxiety, and depression in a subsequent pregnancy (Bourne and Lewis 1984; Hughes et al. 1999). These sequelae generally resolve within 1 year after the birth of a subsequent healthy child (Turton et al. 2001). Premature birth or the stress of complicated, or even normal, labor can precipitate posttraumatic stress symptoms as well, especially in women with preexisting psychiatric symptoms and poor social supports (Czarnocka and Slade 2000; Holditch-Davis et al. 2003).

### **Postpartum Psychiatric Disorders**

#### ***"Baby Blues"***

Within days after birth, 25%–75% of newly delivered women experience significantly heightened emotional lability. After a few days, the symptoms abate. The phenomenon has been reported in a wide variety of cultures and is not related to demographic variables (Sakumoto et al. 2002). Although the patient may be moved to tears from time to time, none of the other signs or symptoms of depression are present nor do they develop as an exacerbation of this condition. The mother also experiences moments of joy. This self-limited state may be caused by prolactin or other hormones. An interesting hypothesis is that "baby blues" may be related to the effects of oxytocin and other hormones involved in the initiation of mother-infant attachment and maternal behavior (L.J. Miller and Rukstalis 1999). Clinicians should offer reassurance. This is especially important because media reports of postpartum depression leading to the murder of children have frightened so many families.

#### ***Postpartum Depression***

Postpartum depression occurs in up to 10%–20% of mothers in North America. Some cases of postpartum depression are simply continuations of prepartum depression. As noted earlier, depression during pregnancy is common. Symptoms can begin any time from days to months

after birth but generally later than “baby blues” and ranging from 4 weeks to 12 months postpartum. The diagnostic process can be complicated by the similarity of symptoms of the aftermath of delivery and the stresses of caring for a newborn and the signs and symptoms of depression. New mothers are often tired, sleepless, distracted, and preoccupied with infant care rather than the enjoyment of previous pursuits. Their meal schedules and sleep are disrupted. It is useful to ask whether the mother can sleep when the baby sleeps.

Risk factors include previous depression, especially postpartum depression; complications of birth; and poor social supports. There appears to be some cross-cultural variation in the incidence of postpartum depression; this may be related to contrasting patterns of prepartum and postpartum care and social support. In many cultures, the newly delivered woman is traditionally provided with rest, warmth, and enriched nutrition (Kaewsarn et al. 2003). In North America, medical attention decreases drastically after an infant is delivered; few medical and social resources are available to the new family. Some evidence shows that postpartum calls and visits from health care professionals decrease the incidence of postpartum depression (Chabrol et al. 2002). Endocrine factors also play a major role; some women are particularly vulnerable to rapid changes in hormone levels. Estradiol and progesterone are strongly implicated (Bloch et al. 2003). Women with thyroid autoantibodies have an increased risk for postpartum depression, but thyroxine administration does not appear to reduce that risk (Harris et al. 2002; Oretti et al. 2003).

Anxiety accompanies pre- and postpartum depression in up to 50% of cases (Ross et al. 2003). In a recent Australian study of 408 primigravidas, the inclusion of panic disorder and acute adjustment disorder with anxiety doubled the cases of postpartum psychiatric illness identified. Antecedent anxiety disorders were a more important risk factor for postpartum depression than was antecedent depression (Matthey et al. 2003a).

The thought content of a woman with postpartum depression centers on mothering (e.g., ruminating that she is not a good mother and that her infant is suffering as a result). Sometimes the woman becomes obsessed with thoughts of harm coming to the infant and vividly imagines his or her injury or death. These thoughts are profoundly upsetting to the mother; they are thoughts, not intentions, and should be distinguished from the delusionally driven infanticidal impulses of postpartum psychosis.

Reassurance of eventual recovery is crucial to patient care. One of the fears of women with postpartum depression, and their families, is that the depression is the first

sign of a condition that will result in self-harm or infanticide. Relatives may be tempted to take over care of the infant of a depressed mother to allow her to rest and recuperate. This can be counterproductive, exacerbating her sense of failure and deprivation. It is preferable for them to help the mother with household tasks, allow her to care for the infant, and reinforce her sense of maternal adequacy.

Although obstetricians have become more aware of and responsive to postpartum depression as a result of the notorious cases in the media and educational initiatives by a variety of professional and advocacy organizations, they may not be in the optimal position to identify it. Women are discharged from the hospital within a day or two after delivery, with a rather cursory office follow-up visit 4–6 weeks later. Obstetric clinicians should be encouraged to increase their contacts with and availability to new mothers, both for screening and for prevention. Several validated scales are available for screening; the Edinburgh Postnatal Depression Scale (Matthey et al. 2003b) is the best known. However, a simple query about depressed mood is often successful in identifying cases (Wisner et al. 2002b). After the birth, the specialist women see most is the pediatrician. There have been attempts, with mixed success, to convince pediatricians to screen mothers for postpartum depression. Efforts are under way to develop screening instruments for use in non-Western populations (Mantle 2003). Researchers in Hong Kong determined that screening should be delayed for several days after delivery in order to be accurate (Lee et al. 2003), although earlier assessment has been found accurate in North America (Dennis 2003). Screening in an inner-city population in New York uncovered far more cases than were anticipated (Morris-Rush et al. 2003).

### *Postpartum Psychosis*

Many experts believe that most episodes of postpartum psychosis are bipolar (Attia et al. 1999; Chaudron and Pies 2003). The risk of postpartum relapse of bipolar disorder is 30%–50%; these relapses can be acute and severe. If pregnant women with bipolar disorder discontinue medication, there should be a plan for immediate medication resumption at delivery. Third trimester or immediate postpartum treatment significantly lowers the risk of recurrence (Cohen et al. 1995).

Postpartum psychosis is characterized by extreme agitation, delirium, confusion, sleeplessness, and hallucinations and/or delusions. Onset can be sudden and usually occurs between days 3 and 14 postpartum. The overall incidence of postpartum psychosis is estimated at 0.1%–0.2% and appears to have been stable for more than a century and among cultures. The risk of psychiatric hospitalization postpartum has been reported to be 18 times that

postpartum (Paffenbarger 1982), although these findings have been questioned more recently by a Danish study (Terp and Mortensen 1998). Only a fraction of these women will go on to attempt suicide or infanticide, but the risk and the stakes are high enough to warrant considering postpartum psychosis as a medical emergency and hospitalizing the patient, at least for a period of observation. Women who have schizophrenic episodes may have more difficulty parenting their children after recovery from the acute episode than do women with other kinds of postpartum psychosis (Riordan et al. 1999).

Trials and media coverage of cases of infanticide disclose major misunderstandings about the state and motivation of the perpetrators. Most often, the mother in these cases has command hallucinations or delusions and/or is suicidal and does not wish to leave the child behind, but wants to be reunited with him or her in Heaven. Gibson (1982) reported that 62% of the mothers in his series who committed infanticide committed suicide as well. Appleby et al. (1998) reported that the risk of suicide in the first postnatal year is “increased 70-fold.”

### *Custody*

Psychiatric illness in and of itself does not rule out the possibility of adequate mothering. For general evaluation, and the legal and medical records, when the question of custody arises, it is useful to perform a regular mental status examination. What are most important, however, are the parenting knowledge, attitudes, and behaviors of the newly delivered patient. Has she been able to arrange adequate accommodations for herself and the infant? How does she plan to feed the infant? Does she know approximately how often a newborn must be fed and changed? Does she have delusions about the infant?

Observation of mother–infant interaction is key. It is very difficult to predict how a person will behave with an infant in the absence of the infant. The postpartum staff should allow the mother as much observed time with the infant as possible and note how the mother responds to the infant’s cries and other needs, whether she can feed the infant and change his or her diapers, and how she relates to the infant overall. New mothers without psychiatric disorders can be tired and overwhelmed; expectations should be realistic.

Custody decisions can be life-or-death decisions. Removing a child from his or her mother, unless a well-disposed and capable relative can take over his or her care, exposes the child to the possibility of a lifetime in transient foster care situations. Allowing a severely ill mother to retain custody exposes the child to possible abuse and neglect. Interactions with child protective services can be problematic. Depending on current resources and recent

scandals, child protective services may take a child into custody without giving the mother a chance to show her ability to parent, or they may refuse to intervene with a dangerously psychotic mother because the infant has not yet been damaged. Often, the most appropriate approach, when available, is the provision of home help and/or visiting nurse services, which provide both support and further opportunities for observation of the parenting and the condition of the infant. Having a mental illness does not diminish, and may exacerbate, the grief and rage of a mother whose child is taken away.

Legal aspects of maternal competency are discussed in Chapter 3, “Legal Issues.”

## **Psychotropic Drugs, Psychotherapy, and Electroconvulsive Therapy in Pregnancy and Lactation**

---

No perfect solution exists for treating mental illness during pregnancy and lactation, and a risk–benefit decision must be made in the face of imprecise data. For example, untreated clinical depression can result in problems with maternal nutrition, sleeping, exercise, and adherence to prenatal care. Infants born to mothers with depression are more likely to have low birth weight for gestational age and be born prematurely (Stewart and Robinson 2001b). Although mental illness of mild to moderate severity may be treated with psychotherapy, support, or environmental changes, more severe illness usually requires psychotropic medications, which carry variable and sometimes unknown risks (Hendrick et al. 2003).

Three types of adverse fetal effects may occur when psychotropics are taken during pregnancy. *Teratogenic effects* may be incurred from first trimester exposure, *neonatal toxicity and withdrawal syndromes* are related to third trimester exposure, and *behavioral or developmental effects* may manifest later in childhood (Marcus et al. 2001; Wisner et al. 2002a). Note that changes in drug metabolism and extracellular fluid volume during pregnancy may require dose adjustment for several drugs. For example, approximately twice the usual dose of lithium carbonate is required in the second and third trimesters to achieve therapeutic serum levels (Stewart and Robinson 2001b). (See also Chapter 37, “Psychopharmacology,” for a discussion of pharmacotherapy during pregnancy.)

### Classification of Drugs

Current U.S. Food and Drug Administration (FDA) (2003) risk assignments of drugs in pregnancy range from A (no risk) through B, C, D, and X (contraindicated). This clas-

sification is primarily based on concerns about teratogenicity and neonatal toxicity, because few or no data exist for later child behavior or development. The FDA classification lags behind current data and experience. At present, bupropion, clozapine, and buspirone have a B designation (absence of human risk) with a caveat of limited data. Most SSRI antidepressants, some TCAs (including desipramine), newer antidepressants (such as mirtazapine, nefazodone, and venlafaxine), clonazepam, and most conventional and atypical antipsychotics have received a C designation (human risk should not be eliminated because of inadequate human clinical trials and no or some risk in animals). Lithium, carbamazepine, sodium valproate, most TCAs, and some benzodiazepines (other than clonazepam) have received a D designation, indicating evidence of fetal risk without an absolute contraindication during pregnancy. A long-standing debate has existed, with contradictory data from several studies, on whether diazepam in pregnancy is associated with cleft lip or cleft palate. Some benzodiazepines, such as triazolam, temazepam, and flurazepam, have received an X designation, indicating complete contraindication in pregnancy (Marcus et al. 2001). Although the strength of evidence for safety of all psychotropics in pregnancy is fair to poor, expert consensus guidelines have been developed on the basis of current information and recent use (Altshuler et al. 2001). Insufficient data are available to ensure safety for most novel antipsychotics; however, high-potency antipsychotics, such as haloperidol, appear to be relatively safer in pregnancy (Patton et al. 2002).

Early reports warned of congenital heart disease in infants exposed in utero to lithium carbonate, but subsequent analyses have shown these risks to be only slightly greater than those of the general population (Altshuler et al. 1996). Other mood stabilizers such as carbamazepine and valproic acid are associated with greater teratogenicity than lithium (Stewart and Robinson 2001b). For women with unstable bipolar disorder, it is reasonable to continue lithium throughout pregnancy, while carefully monitoring serum levels. Divided doses may be safer than once-daily dosing. An ultrasound during the first trimester may be used to identify possible congenital cardiac malformations. Dosage should be reduced after delivery to avoid lithium toxicity in the early postpartum period. Lithium is contraindicated while breast-feeding (Stewart and Robinson 2001b).

Because the FDA is currently revising its method of classifying drug risk in pregnancy, physicians should consult the most recent classification, as well as other new literature. As this chapter was going to press, new data were published showing that infants exposed in utero to SSRI antidepressants had a shorter mean gestational age, were

more active and tremulous, had more startles and sudden arousals, showed lower heart rate variability and lower peak behavioral status (Zeskind et al. 2004).

Disruptions in the wide range of neurobehavioral outcomes as well as seizures, respiratory and feeding problems prompted regulatory authorities in Canada to issue an advisory suggesting increased awareness of potential complications of all SSRIs in infants who were exposed during the third trimester of pregnancy. The FDA is currently considering a similar warning based on the advice of its Pediatric Advisory Committee.

## Adverse Effects

Only a few long-term studies of behavioral teratogenicity following exposure to psychotropic drugs have been done. More studies of fluoxetine have been published compared with other SSRIs following its use in pregnancy (Goldstein et al. 1997) and its effects on child development and behavior. Nulman et al. (2002) found no difference in social, cognitive, or motor development in children up to 86 months whose mothers had taken a variety of TCAs or fluoxetine in pregnancy. In several studies, sertraline, paroxetine, fluvoxamine, citalopram, and venlafaxine were shown as relatively safe in pregnancy when infants were assessed in the early postnatal period (Altshuler et al. 2001; Einarson et al. 2003; Heikkinen et al. 2002; Wisner et al. 2002a), but none of these studies provided longer-term follow-up. In one report, acute withdrawal effects occurred in infants whose mothers took paroxetine during the third trimester (Stiskal et al. 2001). Longer-term follow-up studies of infants exposed to antipsychotics in the uterus have relied on imprecise measures of intelligence compared with siblings or the general population (Kris 1965).

## Breast-Feeding and Psychotropic Drugs

The use of psychotropic drugs by breast-feeding women remains controversial. The amount of drug present in breast milk is small but extremely variable over time, even in the same woman. No controlled studies of the effects of psychotropic medication during breast-feeding exist, but several reviews provide further guidance (Altshuler et al. 1995, 2001; American Academy of Pediatrics Committee on Drugs 2001; Hendrick et al. 2001; Ilett et al. 2002; Stewart 2001; Wisner et al. 2001). In general, it appears relatively safe for depressed women to take antidepressants and typical antipsychotics while breast-feeding full-term and healthy babies. Fewer data are available for premature infants or newer antidepressants and atypical anti-

psychotics. Chaudron and Jefferson (2000) reviewed the literature on the use of mood stabilizers during lactation. They concluded that lithium is generally not recommended during lactation and that although carbamazepine and valproate may be considered acceptable, decisions about the care of women with a history of bipolar illness must be made on a case-by-case basis. The risk of recurrence is considerable, with significant implications for mother and child (Chaudron and Jefferson 2000).

Because new information on the use of drugs during pregnancy and lactation is frequently published, the reader is advised to consult the most recent reference in making risk–benefit decisions. The expert consensus guidelines (Altshuler et al. 2001) provide useful guidance on practice at that time. The clinician must be cognizant that untreated mental illness in pregnancy and postpartum also has risks to the woman and the developing fetus and newborn child. Decisions should be made in consultation with the woman (and partner, if appropriate) and other health care providers (such as obstetricians and pediatricians), and discussions should be carefully documented in the patient's chart.

## Psychotherapy in Pregnancy and Postpartum

Spinelli (1997) found interpersonal psychotherapy to be effective in the treatment of depressed pregnant women. Appleby et al. (1997) compared the effects of antidepressant treatment and six sessions of cognitive-behavioral counseling for postnatal depression and found both treatments to be effective. More recent work by P. Cooper and colleagues (2003) has shown that psychotherapy has only short-term benefits for maternal mood that are not superior to spontaneous remission in the long term. Murray and colleagues (2003) showed that early psychotherapy intervention was beneficial for short-term mother–infant relationships but had no effect on infant behavior problems, secure attachment, cognitive development, or any child outcome at 5 years. O'Hara and colleagues (2000) established the efficacy of interpersonal psychotherapy for postpartum depression. In general, interpersonal and cognitive-behavioral psychotherapy appear to be efficacious for mild to moderate depression. Because many women refuse to take medication while pregnant or breastfeeding, psychotherapy is often a viable alternative. However, its efficacy for severe depression is unproven.

## Electroconvulsive Therapy

ECT is generally regarded as a safe and effective treatment for severe depression, affective psychosis, and cata-

tonia in pregnancy and the puerperium. ECT is underused and should be considered in emergency situations in which the safety of the mother, fetus, or child is jeopardized; to avoid first-trimester exposure to teratogenic drugs; and in patients who are refractory to psychotropics or who have previously had successful treatment with ECT (Stewart and Robinson 2001b) (see also Chapter 39, "Electroconvulsive Therapy").

## Premenstrual Psychiatric Symptoms: Premenstrual Syndrome and Premenstrual Dysphoric Disorder

---

### Background

The study of premenstrual symptoms poses unique methodological challenges. Most women in North America, if asked, report premenstrual mood, behavior, and somatic changes. There is a strong cultural belief that the menstrual cycle is associated with such negative changes. This may be strong circumstantial evidence that such changes exist and are significant. However, it is also clear that both women and men attribute unpleasant or problematic feelings and behaviors to the menstrual cycle regardless of whether they are related. Many more than half of the women presenting for care of premenstrual symptoms, when assessed with prospective ratings and careful diagnostic interviews, have symptoms completely unrelated to their menstrual cycles. Investigators in this area tread between accusations that medical science has too long ignored women's cyclical suffering and allegations that reifying cultural beliefs about women's hormonal frailties does women a disservice. There has been virtually no investigation of the possibility that negative mood changes at one point in the cycle are counterbalanced by positive changes at another point. Strong feelings and methodological difficulties have made the diagnosis of premenstrual psychiatric syndromes controversial (Sveinsdottir et al. 2002).

### Etiology

Many attempts have been made, over decades, to identify circulating levels of reproductive hormones to account for mood symptoms occurring in concert with reproductive events and cycles and to treat those symptoms with hormones. By and large, these efforts have been unsuccessful. The reality is probably more complex than linear effects of hormone levels on mood. It would seem that some women are particularly sensitive, not to specific levels, but to changes in the levels of reproductive hormones.

Women who report premenstrual symptoms are more likely to experience postpartum depression and may be predisposed to mood symptoms around perimenopause as well (Stewart and Boydell 1993). Women report that their premenstrual symptoms first appeared, on average, when they were in their early 20s but that they did not seek medical care for as many as 10 years. Premenstrual symptoms persist into the perimenopause, when they become difficult to distinguish from symptoms of perimenopause (Grady-Weliky 2003).

## Diagnosis

Currently, premenstrual psychiatric symptoms are conceptualized and treated as part of the mood disorder spectrum. Experts, and the framers of DSM, have attempted to distinguish normative mood variations from symptoms worthy of medical attention by publishing research criteria for premenstrual dysphoric disorder (PMDD). For many years, the study of premenstrual psychiatric symptoms was complicated by the lack of a specific and uniform definition. More than 100 physical, emotional, and cognitive signs and symptoms have been attributed to premenstrual syndrome (PMS) (Janowsky et al. 2002). PMDD is listed in DSM-IV-TR as an example of a depressive disorder not otherwise specified (NOS) and is described as follows:

In most menstrual cycles during the past year, five (or more) of the following symptoms (e.g., markedly depressed mood, marked anxiety, marked affective lability, decreased interest in activities) were present for most of the time during the last week of the luteal phase, began to remit within a few days after the onset of the follicular phase, and were absent in the week postmenses....The disturbance markedly interferes with work or school or with usual social activities and relationships with others. (American Psychiatric Association 2000, p. 774)

PMDD, as distinguished from PMS, is said to affect up to 8% of cycling women. Given the tendency to retrospectively overattribute symptoms to the menstrual cycle, prospective daily ratings and careful evaluation for other psychiatric disorders are essential (Landen and Eriksson 2003; Lane and Francis 2003; M.N. Miller and Miller 2001).

## Psychosocial Effects

Another controversial aspect of PMDD is the severity or effect of the symptoms. The DSM definition specifies a significant negative effect on life function. It has been difficult to specify the distinction between PMS and PMDD in this regard (Smith et al. 2003). Preexisting beliefs about

work effect may color the findings in studies that use self-reports (Steiner et al. 2003). A large study of randomly selected members of a health maintenance organization found that women with PMDD reported decreased work productivity as compared with women with milder premenstrual symptoms, but the women with PMDD also reported lower productivity than the others in the follicular phase after the onset of menses, when their PMDD symptoms, according to the definition, should have been absent. This study did not produce significant evidence that premenstrual symptoms, regardless of their level of severity, caused women to stay in bed, reduce their hours at work, or decrease their activities at home or school (Chawla et al. 2002).

## Management

No specific, empirically supported treatments for PMS are available, but several approaches have proved helpful for both the symptoms and the patients' general health. These include taking vitamins (especially B vitamins), reducing or eliminating caffeine and nicotine, exercising, and using stress reduction techniques. As stated earlier, exogenous hormones are not effective treatments for PMS or PMDD. Many women with premenstrual symptoms attempt complementary or alternative approaches (Domoney et al. 2003). Recent publications claim effectiveness for fish oil and for acupuncture, among others (Habek et al. 2002; Sampalis et al. 2003). (See Girman et al. 2003 for a comprehensive review of this literature.) In one study, cognitive-behavioral therapy was found to be equally effective as fluoxetine; fluoxetine produced more rapid results, and cognitive-behavioral therapy produced more lasting results (Hunter et al. 2002). Calcium carbonate also has produced promising results (Thys-Jacobs et al. 1998).

Like other disorders in the mood spectrum, PMDD is best treated with SSRIs (Freeman 2002; Wyatt et al. 2002). As of this writing, fluoxetine, sertraline, and paroxetine have received FDA indications for PMDD. For reasons still poorly understood, although SSRIs generally require 2–4 weeks for therapeutic effectiveness in depression, they are apparently effective for PMDD when used only in the premenstrual phase (Halbreich et al. 2002). Evidence also indicates that symptoms recur rapidly when luteal-phase treatment is discontinued (Pearlstein et al. 2003).

The possibility of cyclical changes in symptoms and/or treatment response in all diagnostic categories should be considered in all menstruating women or at least in those whose diagnoses or treatment responses are puzzling or unsatisfactory (Landen and Karamchandani 2002).

## Perimenopause and Menopause

---

The average age at menopause in North American and European women is 51 years, although the entire period of transition may extend over several years. By definition, menopause is said to have occurred after 12 months of amenorrhea, and perimenopause is that period of time leading up to menopause but before 12 consecutive months of amenorrhea. During the perimenopause, the ovarian follicles gradually decline with age, estradiol and inhibin production by the ovary decreases, and follicle-stimulating hormone and luteinizing hormone levels rise (through loss of feedback inhibition). These changes are orchestrated through the hypothalamic-pituitary-ovarian axis, and cyclic variability often occurs throughout the transitional period (Baram 1997).

The perimenopause may be asymptomatic, but 70%–90% of women will experience some vasomotor symptoms consisting of hot flashes and night sweats. In addition, some women will experience palpitations, dizziness, fatigue, headaches, insomnia, joint pains, and paresthesias. Women also may complain of lack of concentration and loss of memory during the transitional period, but because men also complain of these symptoms, distinguishing them from normal aging is difficult (Baram 1997).

The association of psychiatric symptoms with the perimenopause is controversial. Large community surveys in the United States (Avis and McKinlay 1995), Europe, and Canada (Kaufert et al. 1992) show no increase in psychopathology with menopause; however, increases in depression and anxiety prevalence have been reported over the perimenopausal years (Avis and McKinlay 1995; Freeman et al. 2004). Whether these symptoms are caused by hormonal changes, sociocultural factors, or psychological factors remains uncertain (Avis 2003). Biological factors include the reduction of estradiol production by the ovaries, hypothalamic age-related changes, increase in the proportion of estrone compared with estradiol, and decrease in the production of ovarian androgens (Baram 1997). Sociocultural theories focus on the importance of role changes in parenting, marriage, sex, and work. In addition, attitudes toward aging and female roles vary by culture. A consistent finding is that women with lower socioeconomic class and education report more perimenopausal symptoms. Psychological theories focus on stress during the perimenopausal years as a result of diminished personal and family health, socioeconomic status, family and work changes, other losses, retirement, illness, and deaths (Avis 2003). In addition, recent work also has shown that a lifetime history of major depression may be associated with an early decline in ovarian function and earlier menopause (Harlow et al. 2003).

Although epidemiological surveys show no increase in rates of depression over the climacteric, women seeking treatment for physical symptoms in menopause clinics report a high prevalence of depression, irritability, mood lability, anxiety, lack of concentration, short-term memory loss, and decreased libido (Stewart and Boydell 1993). New-onset depressive symptoms have been found to be moderately associated with perimenopause and are related to the length and intensity of symptoms (Avis and McKinlay 1995). Investigators also have reported that subgroups of women appear to be more vulnerable to physiological hormonal changes associated with the premenstruum, postpartum, and perimenopause (Stewart and Boydell 1993). Other investigators have shown that prior depression is a risk factor for depression at perimenopause and that poor physical health, social circumstances, divorce, widowhood, and interpersonal stress are closely correlated with depression in menopausal women (Hunter 1990; Kaufert et al. 1992; Stewart and Boydell 1993).

The incidence of depression in women mirrors estrogen shifts across the life cycle, at puberty, premenopause, postpartum, and perimenopause (Stahl 2001). Estrogen receptors are present throughout the body and are particularly dense in the limbic system, which mediates emotion. Estrogen performs an organizational role during fetal life, resulting in trophic and permanent modifications in sex-specific brain differentiation. It increases again in adult life and contributes to sex-differentiated brain function. Estrogen is known to influence serotonin through inhibiting monoamine oxidase at high doses and displacing tryptophan from plasma albumin-binding sites, influencing serotonin receptor-binding downregulation and increasing endogenous catecholamine release. It is not surprising that the actions of estrogen in the central nervous system may affect mood and cognition (Stahl 2001).

The above biological findings have led to studies to determine whether estrogen therapy in perimenopause can alleviate symptoms of clinical depression. A study by Schmidt et al. (2000) randomized 34 women to estradiol-17-beta patches or placebo for 3 weeks, then crossed over the women in the placebo group to the estrogen condition. They found that the women with both major depression ( $n=8$ ) and minor depression ( $n=26$ ) taking estrogen reported significantly improved mood (as measured by the Center for Epidemiologic Studies Depression Scale), whereas those receiving placebo reported no improvement. Notably, 80% of the women receiving estradiol reported improved mood, despite no improvement in hot flashes or sleep function. In a more recent study, 50 perimenopausal women with major depression ( $n=26$ ), dysthymia ( $n=11$ ), and minor depression ( $n=13$ ) were treated

by randomizing them to transdermal patches of estradiol-17-beta 100 mg for 12 weeks. Of the women receiving estradiol, 68% showed improvement on the Montgomery-Åsberg Rating Scale for Depression and the Blatt-Kupperman Menopause Index, compared with 20% of those taking placebo ( $P=0.001$ ) (Soares et al. 2001). The improvement persisted after a 4-week washout, and the authors concluded that estradiol was a well-tolerated and effective treatment for perimenopausal depression.

Although estrogen appears to have a salutary effect on depression in some perimenopausal women, in contrast, progesterone and progestins are known to cause dizziness, drowsiness, and sedation in many women and may be associated with negative moods (Bjorn et al. 2000). Progestins are primarily used in women with an intact uterus to prevent an increase in endometrial cancer caused by unopposed estrogen therapy.

Studies also have been conducted on the role of estrogen as an augmentation agent with antidepressants. Women were given fluoxetine, with or without estrogen therapy. Women who were concurrently treated with estrogen had a threefold increased chance of responding to fluoxetine (Schneider et al. 1997). Further studies of estrogen and selective estrogen receptor modulators as psychotropic augmentation agents are needed.

Moreover, the role of estrogen in psychiatric disorders is not limited to depression. Work by Kulkarni et al. (2001), Seeman (2002), and others have shown a worsening in pre-existing schizophrenic illness and other psychoses associated with decreases in estradiol during perimenopause and beyond. Interestingly, some patients appear to respond to estrogen therapy combined with antipsychotic drugs.

Of concern, however, are results from the Women's Health Initiative (WHI), which have indicated that estrogen-progesterone therapy is associated with an increased risk of breast cancer, cardiovascular disease (Writing Group for the Women's Health Initiative Investigators 2002), cognitive dysfunction, and dementia (Rapp et al. 2003; Shumaker et al. 2003). The estrogen-only arm of the WHI was also prematurely terminated in 2004 when estrogen monotherapy was found to be associated with increased rates of stroke, dementia, and mild cognitive impairment (but not breast cancer) (Women's Health Initiative Steering Committee 2004).

Emerging evidence may affect current use, but at present, estrogen is useful to control severe vasomotor symptoms and vaginal dryness, with current FDA guidelines recommending the smallest dosage for the shortest time possible. Antidepressants such as fluoxetine, venlafaxine, and paroxetine are also known to decrease hot flashes (Loprinzi et al. 2000, 2002; Stearns et al. 2000). Phytoestrogens (soy) and black cohosh have been shown

to have contradictory results in diminishing hot flashes in perimenopausal women (Kronenberg and Fugh-Berman 2002). A study published in the *Journal of the American Medical Association* in 2003 compared placebo with two dietary phytoestrogen supplements and found no significant difference in the frequency of hot flashes at 12 weeks (Tice et al. 2003).

In conclusion, the many estrogen effects on brain function are complex. The role of estrogen in treating mood, cognition, and psychosis, and as a psychotropic augmentation agent, requires further adequately powered, randomized controlled trials. Personal, social, and physical factors always should be considered in assessing the individual woman, and psychotherapy may be helpful in navigating the many transitions at midlife.

## Urinary Incontinence

---

Urinary incontinence, the involuntary loss of urine, affects up to 23% of adults (Roe et al. 1999), with a prevalence in women that is twice that in men (Melville et al. 2002). Urinary incontinence affects the physical, psychological, social, and economic well-being of individuals and their families and imposes a considerable economic burden on health and social services. Many people are reluctant to seek help because they are embarrassed, are ashamed, or believe that the problem is a part of normal aging (Roe et al. 1999).

### Etiology and Classification

The etiology of urinary incontinence is multifactorial and may be caused by impairment of the lower urinary tract or the nervous system or by various external factors. There are several subtypes of incontinence, but the most common are 1) stress incontinence (the involuntary loss of urine due to an increase in intraabdominal pressure, such as coughing, laughing, or exercise); 2) urge incontinence (the involuntary loss of urine preceded by a strong urge to void whether or not the bladder is full); and 3) mixed incontinence (Melville et al. 2002).

### Psychosocial Effects

Urinary incontinence may affect quality of life, sexual function, and mood. Recent studies have found that incontinence has a major negative effect on quality of life (Melville et al. 2002). A recent population-based, cross-sectional study of nearly 6,000 American women between ages 50 and 69 found that 16% reported mild, moderate, or severe incontinence. After adjustment for medical mor-

bidity, functional status, and demographic variables, women with severe and mild-to-moderate incontinence were 80% and 40%, respectively, more likely to have depression than were continent women (Nygaard et al. 2003).

A study of more than 200 consecutive women with urinary incontinence found an overall prevalence of 16% for major depression and 7% for panic disorder. Patients with urge and mixed urinary incontinence were significantly more likely than those with stress incontinence to have a coexisting psychiatric illness. Comorbid major depression also has been found to have a significant effect on patients' urinary incontinence symptom reporting, incontinent-specific quality of life, and functional status (Melville et al. 2002).

A systematic review of the literature on sexual function in women with urinary incontinence (Shaw 2002) found that most studies were of poor quality. They concluded that further research in which standard definitions and measures of sexual impairment are used is needed to establish reliable information and prevalence estimates.

## Role of the Psychiatrist

Given the high prevalence of incontinence, particularly in middle-aged and older women, and their frequent reluctance to disclose their symptoms, psychiatrists may wish to tactfully ask about urinary problems, as well as comorbid psychiatric conditions and adjustment problems.

TCA's and duloxetine, the new dual serotonin-norepinephrine reuptake inhibitor, are useful treatments for stress urinary incontinence, particularly in women who have concurrent depression (Norton et al. 2002). Treatments that have been used for urinary incontinence include behavioral training with or without biofeedback, pelvic floor exercises, other drug therapies, and surgery (Hendrix 2002).

## Psychosomatic Obstetrics/Gynecology and Men

A woman's significant other may be female or male, but published studies of relationships' effects on obstetric and gynecological events have been performed on heterosexual couples. Virtually every study of the psychosocial aspects of an obstetric and gynecological event or treatment indicates that the attitude of the male partner is a (or the) major determinant of outcome. Women turn to their significant others for reaffirmation of their worthiness if infertile, for reaffirmation of their femininity after hysterectomy, and for help deciding whether to take psychotropic medications while pregnant and whether to breast-feed or bottle-feed. Failure to achieve consensus on such

decisions can cause serious long-term repercussions, as when a child is born with problems after (although not necessarily because of) the use of psychotropic medication during the mother's pregnancy, and the child's father blames the mother.

Fathers, brothers, sons, male partners, and husbands can be deeply affected by the obstetrical and gynecological experiences of the women they care about, but they often feel uncomfortable, ignored, and excluded when their female loved ones are receiving care (Abboud and Liamputtong 2003; Buist et al. 2003). As mentioned in the section on infertility, men and women may manifest their feelings differently. Women are more likely to show emotion and to want to talk to friends and relatives. Men are more likely to keep their emotions to themselves and to withdraw into work or other activities. Women can mistake this behavior for a failure to care. Men can feel that their presence only makes their loved ones cry. Sometimes, one of the most useful interventions a psychiatric consultant can perform is to facilitate communication within the family.

## Conclusion

---

Obstetricians and gynecologists are busy practitioners, challenged to deal with both specialized technological developments and primary care, and burdened by the likelihood of lawsuits. Despite the intense emotional aspects of much of their clinical work, obstetricians and gynecologists have relatively little training or time for psychiatric problems. The scope of psychosomatic medicine in the area of obstetrics and gynecology includes psychopathological aspects of normal reproductive events, psychiatric aspects of obstetrical and gynecological diseases and treatments, and psychiatric conditions specific to women's reproductive health. Gender-based medicine, which intersects psychosomatic obstetrics and gynecology at many points, is one of the most exciting and promising areas of research and clinical practice. Myriad opportunities exist for providing practical assistance to obstetricians and gynecologists and the women who are their patients, for educating fellow psychiatrists about developments in obstetrics and gynecology, and for basic and clinical research.

# 34 Pediatrics

---

Brenda Bursch, Ph.D.

Margaret Stuber, M.D.

**IN THIS CHAPTER**, we provide a brief overview of the major issues in psychiatric or psychological consultation to pediatrics. (For pediatric topics discussed elsewhere in this book, see Chapter 14, “Deception Syndromes: Factitious Disorders and Malingering”; Chapter 15, “Eating Disorders”; Chapter 29, “Dermatology”; and Chapter 30, “Surgery”). Many of the issues addressed in pediatrics are similar to those seen with adults. However, because the relative importance of development and of the family is sufficiently different in pediatrics as opposed to working with adults, these issues should be considered at the start of any evaluation, and they infuse every intervention and recommendation.

## General Principles in Evaluation and Management

---

### Children’s Developmental Understanding of Illness and Their Bodies

Children’s conceptions of their bodies vary widely and are obviously influenced by experiences with illness. However, in general, children appear to follow a developmental path of understanding their bodies that roughly corresponds to Piaget’s stages of cognitive development. *Sensorimotor children* (birth to approximately 2 years) are largely preverbal and do not have the capacity to create narratives to explain their experiences. Their perception of their bodies and of illness is therefore primarily built on sensory experiences and does not involve any formal reasoning. *Preoperational children* (approximately 2–7 years) also understand through perception, but they are able to use words and some very basic concepts of cause and effect. They tend to be most aware of parts of the body that they can directly sense, such as bones and heart (which

they can feel), and blood (which they have seen come out of their bodies). However, they do not have a clear sense of cause and effect and are therefore inclined to see events that are temporally related as causally related. They also have no real sense of organs, but conceptualize blood and food as going into or coming out of their bodies as though the body were itself the container. This leads to many humorous but confusing assumptions and misunderstandings. *Concrete operational children* (approximately 7–11 years) are able to apply logic to their perceptions in a more integrative manner. However, the logic is quite literal or concrete and allows for only one cause for an effect. They tend to be eager to learn factual information about the body and illness at this age, but will have difficulty with any concepts that require abstract reasoning. *Formal operational children* (11+ years) are able to use a level of abstract reasoning that allows discussion of systems rather than simple organs and can incorporate multiple causation of illness. It should not be assumed, however, that all adolescents approach the understanding of illness and their bodies at this level of cognition. In fact, most adults function at this level of thought only in areas of their own expertise, if at all.

As with all areas of cognition, education and experience make a difference. Children who have a medical problem (or who have a friend or family member with a medical history) may know more about the body and its function than other children. However, children will also often be able to repeat what has been said to them without any real understanding of what it means. It is always important to assess children’s level of understanding by asking them to explain in their own words or give their own version of why something is happening. This can alert you and the treating team to gross misunderstandings or fears that could influence adherence to the treatment plan.

## Family Systems

No pediatric patient can be considered in isolation from his or her family. Parents are the ones to whom children look to understand the world. It is from their reactions to the illness and the treatment that the child determines how dangerous this is and how to respond. Parents are also the legal decision makers for the child, and thus are involved in all aspects of his or her care. Parental helplessness, anger, or withdrawal is important to address. In the sections that follow, we review the role and impact of the parent as an integral aspect of care of the pediatric patient.

## Psychiatric Issues

---

### Psychological Responses to Illness

Psychological distress in response to serious pediatric illness has been a focus of many disease-specific and noncategorical studies over the years. Often symptoms of depression, anxiety, and behavioral problems are grouped together. For example, a recent review of empirical studies of pediatric heart transplant recipients found that 20%–24% of these children experienced significant problems of psychological distress (Todaro et al. 2000). A study of children with epilepsy, using the State Trait Anxiety Inventory and the Children's Depression Inventory (Oguz et al. 2002), found that the epileptic children reported significantly more depressed and anxious symptoms than a control group. Even in children undergoing a surgical procedure as minor as a tonsillectomy, 17% of 89 children followed prospectively had temporary symptoms consistent with a depressive episode (Papakostas et al. 2003). In some cases, the effects can be longer lasting, as was found in a study of 5,736 childhood cancer survivors, studied as young adults, who reported significantly more symptoms of depression than their sibling controls (Zebrack et al. 2002). The symptoms assessed in most of these cases would not necessarily meet criteria for a DSM diagnosis. However, these symptoms do appear to be associated with decrease in function. For example, the type of depression that is seen in association with chronic pain of various etiologies has been found to be strongly associated with functional disability (Kashikar-Zuck et al. 2001).

Social support appears to be a key element in psychological adjustment to illness. Social support was found to negatively correlate with problem behavior in adolescents with HIV over a period of 3 years (Battles and Wiener 2002). In a study of 160 pediatric rheumatology patients, children with higher classmate support had lower levels of

depression (von Weiss et al. 2002). Depressed parents of chronically ill children have been found to have depressed children (Williamson et al. 2002). Social support has medical implications as well. For example, families that are less caring or are in more conflict are associated with poorer metabolic control of children with juvenile-onset diabetes (Schiffrin 2001). Recent studies have shown that serious pediatric illness or treatment may also lead to chronic as well as acute symptoms of emotional distress in the parents, which may interfere with their ability to provide support for the children. This has been found with pediatric cancer patients (Kazak et al. 1997) and pediatric transplant recipients (Young et al. 2003).

In some cases, psychological distress and behavioral problems can be directly caused by physical manifestations of the illness or the treatment. For example, mood disorders and anxiety are relatively common manifestations of involvement of the central nervous system (CNS) in pediatric systemic lupus erythematosus (Sibbitt et al. 2002). Depression, anxiety, aggression, and school problems are observed as side effects of tacrolimus, given to prevent rejection of a transplanted kidney (Kemper et al. 2003). Use of steroids for inflammatory conditions, such as rheumatoid arthritis, can have significant impact on mood (Klein-Gitelman and Pachman 1998). Treatment of behavioral distress, depression, or anxiety in juvenile-onset diabetes mellitus must always consider the agitation that is symptomatic of hypoglycemia or the confusion associated with hyperglycemia (Goodnick et al. 1995).

Because psychological adjustment problems appear to be relatively common, it is recommended that children who are chronically ill, acutely ill, or injured be screened by pediatricians for depression, anxiety, and behavioral disturbance (Borowsky et al. 2003). Preventive programs are indicated for some pediatric inpatient services in which anxiety and depression are common. For example, in chronic, painful treatment situations, such as pediatric burns, where significant emotional distress is the norm, anxiety treatment programs are best built-in along with pain management programs (Sheridan et al. 1997; Stoddard and Saxe 2001). There is some evidence that this may help prevent development of posttraumatic stress disorder (PTSD) (see Saxe et al. 1998; Stoddard and Saxe 2001). In treatments with high mortality, such as bone marrow transplantation, in which different phases of treatment appear to have varying levels of depression or anxiety associated with them (Robb and Ebberts, 2003), consistent psychosocial support should be available from the start.

Effective treatment for anxiety that persists after normal adjustment and comfort issues are addressed is similar

to that provided in general psychiatric practice: cognitive-behavioral therapy (Kendall 1994; Ollendick and King 1998) and the use of selective serotonin reuptake inhibitors (SSRIs) (The Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001). Individual behavioral techniques, such as exposure and systematic desensitization, can be effective for patients with simple phobias such as needle phobia or food aversion. More extensive cognitive-behavioral treatment packages that address anxiety across many dimensions (including somatic, cognitive, and behavioral problems) are indicated for children with more complex anxiety disorders (Piacentini and Bergman 2001).

Pediatricians are familiar with the use of stimulants and some antidepressants in their practice (Efron et al. 2003), but there is yet a limited literature on the use of these medications in medically ill children. The strongest research effort in child psychiatry on effective medication treatments for depression and anxiety has been with SSRIs. In a five-center trial, fluvoxamine was superior to placebo in treating patients with separation anxiety disorder, social anxiety disorder, or generalized anxiety disorder (The Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001). Additionally, fluoxetine has been found to be effective for childhood obsessive-compulsive disorder (Liebowitz et al. 2002). Strong evidence does not exist to support the use of tricyclic antidepressants or benzodiazepines as a first-line treatment for child anxiety disorders (Riddle et al. 1999). Despite a lack of supporting data, low doses of benzodiazepines are frequently prescribed by pediatricians for acute anxiety or agitation in the hospital because they can have a more immediate effect than SSRIs. Therefore, it is important to note that some anxious children have agitated reactions to benzodiazepines. Psychiatric consultants can offer alternatives, including neuroleptics in cases where immediate response is necessary.

Because hospitalized and chronically ill children often experience many of the symptoms seen in depression, making a decision as to whether a pediatric patient should be treated for depression can be difficult. A depressed or irritable mood, diminished interest or pleasure in activities, significant weight loss or change in appetite, insomnia or hypersomnia, psychomotor agitation or retardation, and fatigue or loss of energy may be secondary to the medical condition or to prolonged separation from friends and family. Although medication may be indicated, often supportive and behavioral interventions can lead to significant improvements for such symptoms. Less common, and thus more concerning, are feelings of worthlessness or inappropriate guilt, diminished ability to think or concentrate, or thoughts of suicide (Goldston 1994). A care-

ful assessment is necessary, including suicidal fantasies or actions, concepts of what the child thinks would happen if suicide was attempted or achieved, previous experiences with suicidal behavior, circumstances at the time of the suicidal behavior, motivations for suicide, concepts and experiences of death, family situations, and environmental situations (Pfeffer 1986). Adolescents with suicidal intent and plan, family history of suicide, a comorbid psychiatric disorder, intractable pain, persistent insomnia, lack of social support, inadequate coping skills, a recent improvement in depressive symptoms, or impulsivity are at particular risk for suicide. Antidepressant medication should be started carefully in such cases. For some adolescents, the idea of suicide is an important source of control in the face of an unknown and uncontrollable illness course. Addressing a lack of perceived control, isolation, and distressing physical symptoms should be a high priority.

## Adherence

The term *adherence* is generally used to describe the extent to which a patient's health behavior is consistent with medical recommendations. Defined as such, adherence would include not only the taking of medications and attendance at clinical appointments but also diet, exercise, and other lifestyle issues such as smoking and use of sunscreen (Lemanek et al. 2001). Adherence is measured using blood levels, pill counts, and self-report, all of which are problematic (Du Pasquier-Fediaevsky and Tubiana-Rufi 1999; Shemesh et al. 2004). With such a wide definition, and different assessment strategies, the estimates vary as to the number of pediatric patients who adhere to medical regimens for chronic conditions (Rapoff 1999; Steele and Grauer 2003). Despite these problems, there is general agreement that nonadherence with medication regimens is a serious problem in pediatric patients with both acute and chronic conditions, resulting in significant clinical morbidity (Bauman et al. 2002; DiMatteo et al. 2002; Phipps and DeCuir-Whalley 1990; Serrano-Ikkos 1998).

Many variables have been cited as potential predictors of nonadherence. Increasing age of the child is correlated with increased nonadherence, as is longer time on treatment and lack of appropriate family support in most studies across a variety of illnesses (Griffin and Elkin 2001; Lurie et al. 2000; Rapoff et al. 2002; Strunk et al. 2002). The patient's health beliefs regarding barriers to care, severity of the illness, and susceptibility to problems have been found to be related to nonadherence in some studies (Soliday and Hoeksel 2000), whereas other studies have found that parental health beliefs did not predict adher-

ence (Steele et al. 2001). Some investigations have suggested that cultural beliefs may be equally or more important (Tucker et al. 2002; Snodgrass et al. 2001). Although lack of knowledge would seem to be an important predictor, this has proven more difficult to measure than might be expected (Ho et al. 2003; McQuaid 2003). Although one study actually found that mild anxiety was associated with better adherence (Strunk et al. 2002), others suggest that psychological distress is associated with nonadherence (Simoni et al. 1997).

Interventions to increase adherence have fallen under the general categories of educational (written and verbal instructions), organizational (simplification of regimens, improving access, increased supervision), and behavioral (reminders, incentives, and self-monitoring). A recent review of published studies of interventions to improve adherence found that different strategies appear to be more effective than others for specific illnesses. Although cognitive-behavioral approaches appear promising, no interventions have been found to meet criteria to be considered "well-established" for improving adherence in asthma, juvenile rheumatoid arthritis, or type 1 diabetes (Lemanek et al. 2001). A provocative pilot study found that treating liver transplant recipients for PTSD improved adherence to medication (Shemesh et al. 2000).

## Death, Dying, and Bereavement

One of the most difficult issues for anyone to cope with is the death of a child (Field et al. 2003). Because of the tremendous advances in medicine over the past 20 years and the seeming unfairness of death in childhood, pediatricians and families often resist making the transition from an emphasis on cure to a focus on comfort care. The psychiatric consultant is often called when there is disagreement within the team or between the team and the family about whether this point has been reached or about how this transition is to be approached. Sometimes these differences are the result of cultural or philosophical differences. Physicians who believe that life is to be pursued at all costs may have trouble understanding the feelings of nurses who feel that the child is being needlessly subjected to painful interventions. Families who are deeply religious and remain hopeful for a miracle may lead the medical team to request a psychiatric consult to address the family's "denial." Family members who wish to protect the child may feel that it is best to withhold information about disease prognosis or other potentially upsetting information. The psychiatric consultant can serve as the interpreter and facilitate these often highly emotionally charged discussions to allow the individuals to under-

stand one another well enough to plan together for the care of the child.

Although depression, withdrawal, and anxiety may be expected, a variety of emotional responses may be seen in terminally ill children and should be anticipated in conversations with parents. Children and adolescents may manifest their confusion and loss by negative, oppositional, aggressive, or emotional acting out, as well as with apathy and withdrawal from family and friends. They may frighten the medical staff or family as they talk about death or carry on conversations with someone who has died or with God. They may seem to know when they are going to die or "take a trip." What may initially appear to be confusion or delirium may actually be an attempt to communicate through a metaphor (Callanan and Kelley 1992). The approach of the consultant should be to allow such conversations to occur, and to support the staff and parents to tolerate these attempts of the child to cope with the process of dying. Play therapy or art therapy may be particularly helpful for younger children and for older children who prefer these modalities. In some cases, children will choose to specifically address unfinished business, such as saying good-bye, making amends, being absolved of perceived transgressions, planning their memorial service, or deciding who gets particular belongings (Gyulay 1989). Environmental interventions can relieve many physical discomforts. Interventions to improve communication and understanding can relieve many emotional discomforts and fears. If such interventions are not sufficient to resolve distressing symptoms, medications should be considered. It is important to recognize that children and parents vary in their preferences for sedation versus symptoms. It is important to understand these preferences when choosing medications. For a more thorough review of emotional and physical symptom management, see the article by Stuber and Bursch (2000) and the book by Behrman et al. (2004). For a more thorough review on the topic of talking to children about death, refer to the article by Stuber and Mesrkhani (2001).

Finally, consultants should be aware of community hospice services and be able to advocate for this approach to optimizing quality of life when indicated. Careful preparation and support are necessary if a family is to take a child home for the dying process. Parents typically need emotional and technical support as well as respite. Siblings will need age-appropriate information and emotional support. While it is often best for the child to be allowed to die at home, some families do not feel they can cope well with this plan. It is also important to consider that many palliative care treatment approaches can be used for symptom management well before a transition to hospice care is indicated or decided.

## Psychiatric Disorders

---

### Delirium

Although pediatric delirium (see Chapter 6, "Delirium") has received little research attention (Turkel et al. 2003) and appears to be less often diagnosed in pediatrics than on the adult units (Manos and Wu 1997), it is still a relatively common reason for psychiatric consultation. As in adults, it sometimes may present with what are interpreted to be psychotic symptoms (Webster and Holroyd 2000). The consultation request may also be put in terms of a request for an assessment of unexplained lethargy, depression, or confusion.

In adults, delirium has been found to be the strongest predictor of length of stay in the hospital, after controlling for severity of illness, age, gender, race, and medication (Ely et al. 2001). A recent evaluation of the widely used Delirium Rating Scale found that it does appear to be applicable to children, with scores comparable to those of adults. However, the scores or diagnosis of delirium in a child may not have the same implications that it has in adults. The scores for children, unlike those for adults, did not predict length of hospital stay or mortality (Turkel et al. 2003). Similarly, the Glasgow Coma Scale appears to be less effective in predicting prognosis for children than adults (Lieh-Lai et al. 1992).

Common causes of delirium include infections, metabolic disturbances, and toxicity of medications. These can often be determined with a careful chart review. Other potentially severe or life-threatening causes of confusion include stroke (Kothare et al. 1998), confusional migraine (Shaabat 1996), neuropsychiatric symptoms of systemic lupus erythematosus (Turkel et al. 2001), or inflammatory encephalopathy (Vasconcellos et al. 1999). Less common causes of acute confusional state in children would be multiple sclerosis (Gadoth 2003) or thiamine deficiency (Hahn et al. 1998). Conventional and quantitative electroencephalography (EEG) have been used to evaluate the etiology of delirium in adults, particularly elderly adults (S.A. Jacobson et al. 1993). In acute pediatric confusional states, EEG appears to be useful in differentiation of hepatic encephalopathy and convulsive pathology from other causes. Certain patterns had strong prognostic value (Navelet et al. 1998). Magnetic resonance imaging (MRI) and single photon emission computed tomography have been found to be useful in used in differentiation of inflammatory encephalopathy (Hahn et al. 1998) and systemic lupus erythematosus (Turkel et al. 2001), respectively.

Even after correction or treatment of the underlying etiology, the symptoms of delirium can last 1–2 weeks

(Manos and Wu 1997). Therefore, symptomatic treatment is essential. Support and orienting cues can be very helpful in reducing the fear and confusion. These include the presence of familiar objects, photographs, and people who can reassure and orient the child, as well as age-appropriate clocks, calendars, or signs. Education can help the parents understand what is happening, reduce their distress, and help them to provide support for the child rather than irritation or fear.

Pharmacological intervention is indicated only if the child is distressed by the delirium or is becoming dangerous because of his or her lack of cooperation with care. Because the research into pharmacological approaches to pediatric delirium is almost nonexistent, the general guidelines are pragmatic, based on the adult literature and the pediatric anesthesia literature. Intravenous haloperidol or droperidol are titrated with careful monitoring, avoiding or weaning off benzodiazepines, which appear to compound the confusion with sedation (Breitbart et al. 1996).

### Factitious Disorders and Malingering

#### *Illness Falsification*

The difference between factitious behavior and malingering is the primary motivation. *Factitious disorder* is defined as the intentional production or feigning (falsification) of physical or psychological signs or symptoms to assume the sick role. *Malingering* is the intentional falsification of physical or psychological signs or symptoms to achieve external gain or to avoid unwanted responsibilities or outcomes.

Little research has been conducted on the topic of illness falsification in children and adolescents. More is known about illness falsification in adults and in child victims of adults (see Chapter 14, "Deception Syndromes: Factitious Disorders and Malingering"). The literature suggests that adult factitious disorder may have origins in childhood for some individuals (Libow 2002), and that some children and adolescents falsifying illness in themselves may have had earlier experiences as a victim of illness falsification or as a recipient of caregiver reinforcement for illness falsification. The child victim experience, including feelings of powerlessness, chronic lack of control, and disappointment in the medical care system are possible dynamics in the future development of illness falsification.

Libow (2000) conducted the only literature review to date for cases of child and adolescent patients for illness falsification. She identified 42 published cases with a mean age of 13.9 (range 8–18 years). Most patients were female (71%), with the gender imbalance greater among older children. Patients engaged in false symptom reporting and

induction, including active injections, bruising, and ingestions. The most commonly falsified or induced conditions were fevers, ketoacidosis, purpura, and infections. The average duration of the falsifications before detection was about 16 months. Many admitted to their deceptions when confronted, and some had positive outcomes at follow-up. The children were described as bland, depressed, and fascinated with health care. See Chapter 14, “Deception Syndromes: Factitious Disorders and Malingering,” for assessment information.

### ***Child Victims of Illness Falsification***

Child victims of illness falsification (called *Munchausen syndrome by proxy* when the abuser's behavior is due to factitious disorder not otherwise specified [NOS]) experience significant psychological problems during childhood, including feelings of helplessness, self-doubt, and poor self-esteem; self-destructive ideation; eating disorders; behavioral growth problems; nightmares; and school concentration problems (Bools et al. 1993; Porter et al. 1994; Libow 1995). Adult survivors describe emotional difficulties, including suicidal feelings, anxiety, depression, low self-esteem, intense rage reactions, and PTSD symptoms (Libow 1995). Ayoub (2002) presented longitudinal data on a sample of 40 children found by courts to be victims of illness falsification. The findings revealed that child victims frequently develop serious psychiatric symptoms that vary depending on the child's developmental age, the length and intensity of his or her exposure, and the current degree of protection and support. PTSD and oppositional disorders are significant sequelae, as are patterns of reality distortion, poor self-esteem, and attachment difficulties.

Although these children can superficially appear socially skilled and well-adjusted, they often struggle with basic relationships. Lying is common, as is manipulative illness behavior and sadistic behavior toward other children. Many remain trauma-reactive and experience cyclical anger, depression, and oppositionality. Children who fared best were separated from their biological parents and remained in a single protected placement, or had an abuser who admitted to the abuse and worked over a period of years toward reunification.

## **Feeding Disorders**

### ***Food Refusal, Selectivity, and Phobias***

Feeding problems and eating disturbances in toddlers and young school-age children (see also Chapter 15, “Eating Disorders”) occur in 25%–40% of the population (Mayes et al. 1993). Most are transient and can be easily addressed

with parent training, education about nutrition or normal child development, child–caregiver interaction advice, and suggestions for food preparation and presentation. However, severe eating disturbances requiring more aggressive treatment occur in 3%–10% of young children and are most common in children with other physical or developmental problems (Ahearn et al. 2001; Kerwin 1999). These children are at risk for aspiration, malnutrition, invasive medical procedures, hospitalizations, limitations in normal functioning and development, liver failure, and death.

Some physical factors that can impair normal eating include anatomical abnormalities, sensory perceptual impairments, oral motor dysfunctions, and chronic medical problems (such as reflux, short-gut syndrome, inflammatory bowel disease, hepatic or pancreatic disease, or cancer). Other contributing factors can include the pairing of eating with an aversive experience, inadvertent caregiver reinforcement of progressively more selective food choices, or a lack of normal early feeding experiences.

Munk and Repp (1994) developed methods for assessing feeding problems in individuals with cognitive and physical disabilities that allow categorization of individual feeding patterns based on responses to repeated presentations of food. Complete food refusal or food selectivity can occur with or without an associated phobia and can be assessed by observing for fear and anxiety behaviors on food presentation (Kerwin 1999).

Food aversion and oral motor dysfunction is often treated by a speech pathologist and/or an occupational therapist. Effective behavioral interventions include contingency management with positive reinforcement for appropriate feeding and ignoring or guiding inappropriate responses. Desensitization techniques can be effectively used to address phobias or altered sensory processing. Although no research has directly examined the use of psychotropic medication in treating food refusal, selectivity, or phobias, it may be valuable to consider for use with children with associated anxiety disorders.

### ***Failure to Thrive***

It is helpful to think of failure to thrive (FTT) as a presenting symptom with varied and potentially multiple causes (Wren and Tarbell 1998). Parents might have a poor understanding of feeding techniques or might improperly prepare formula, or the mother may have an inadequate supply of breast milk. Biological contributors to failure to thrive include defects in food assimilation, excessive loss of ingested calories, increased energy requirements, and prenatal insults; environmental contributors include economic or emotional deprivation.

Research examining the role of the child–parent attachment reveals that feeding problems and growth deficiencies can occur within the context of organized and secure attachments; however, insecure attachment relationships may intensify feeding problems and lead to more severe malnutrition (Chatoor et al. 1998). In one study of FTT children (who had no identifiable biological contributors), 80% of the mothers reported they had a history of being victims of physical abuse (Weston et al. 1993).

Classic teaching has been that etiology can be determined by the child's ability to gain weight in the hospital, with a psychosocial etiology presumed if the child gains weight under these conditions. However, it is important to note that conclusions about likely FTT contributors cannot always be made on the basis of the child's ability to gain weight in the hospital. For example, some FTT children who have an inadequate caregiver will still lose weight in the hospital simply because they are separated from the caregiver. Former FTT children have been found to be smaller, less cognitively able, and more behaviorally disturbed than those children without a history of FTT, especially if their mothers are poorly educated (Drewett et al. 1999; Dykman et al. 2001).

The goal of treatment is to provide the medical, psychiatric, social, and environmental resources needed to promote satisfactory growth. Psychosocial treatment interventions need to be targeted at the likely contributors. Children with feeding skills deficits or maladaptive behavior related to food are likely to benefit from behavioral interventions. Primary caregivers with a history of abuse or with current psychopathology might require specific psychiatric assessment and treatment. Interventions targeting the child–parent relationship, sometimes including in-home intervention, might be effective for selected families (Black et al. 1995; Steward 2001). Interventions targeting the social–economic burdens of the family can be critical. In some cases of inadequate parenting, foster care is required while the parent receives needed parent training and psychiatric care. In such cases, the return to home should be closely monitored and based on the parents' demonstrated ability and resources to adequately care for their child.

### ***Psychosocial Short Stature***

Short stature can typically be attributed to defects in the growing tissues, abnormalities of the environment of the growing tissues (e.g., nutritional insufficiency or organ disease), or endocrine abnormalities. Psychosocial short stature is relatively rare, often confused with FTT, and not well studied (Wren and Tarbell 1998). It is distinguished from FTT in that it is considered a direct result

of adverse social–environmental factors on endocrine functioning (suppression of normal pulsatile growth hormone [GH] secretion) that results in a failure to make expected gains in *height* or *length*, as opposed to weight. Examples of adverse social–environmental factors include physical abuse, extreme deprivation, or a seriously disturbed child–parent relationship. Other behavioral and emotional disturbances, also induced by the adverse social–environmental issues, are common. One diagnostic feature is that it is reversible, with rapid acceleration in growth and development often observed, when the child is removed from the environment.

Consequently, the primary intervention is often placement in a safe, structured, stimulating environment with ample opportunity to develop new attachments (Green et al. 1984). Distress related to separation is less likely to temporarily hinder progress in psychosocial short stature (when compared with FTT), because of the severity of the adverse social–environmental factors endured before separation. Other treatments should be geared toward the specific symptoms and experiences of the child, but may include individual psychotherapy, family therapy, school assessment and intervention, and psychotropic medication. Case reports suggest that attempts at in-home intervention must be intensive and comprehensive to be effective. The involvement of child protective services is often essential.

### ***Pica***

*Pica* is defined as eating nonnutritious substances on a continued basis over a period of at least 1 month (Wren and Tarbell 1998). It is most frequently found in children with mental retardation or a pervasive developmental disorder. *Pica* also has a high prevalence in children with sickle cell disease, with preliminary studies suggesting that over 30% are affected (Bond et al. 1994; Ivascu et al. 2001). Mouthing and occasional eating of nonnutritious substances is considered normal in children under 3 years. Young children with *pica* are most likely to eat sand, bugs, paint, plaster, paper, or other items within reach. Adolescents are more likely to eat clay, soil, paper, or similar substances. *Pica* can be a conditioned behavior, an indication of distress or environmental neglect, or evidence of a vitamin or mineral deficiency. One study (Singhi et al. 1981) in children with iron deficiency anemia (50 with *pica* and 50 without *pica*, individually matched for age, sex, socioeconomic class, and degree of anemia) found that stress factors significantly associated with *pica* included maternal deprivation, caretaker other than the mother, parental separation, parental neglect, joint family, child beating, and too little parent–child interaction (mother or father). Medical assessment includes screening for ingestion of

toxic substances and evaluation for possible nutritional deficits. An evaluation and treatment plan to reduce psychosocial stress are also clearly important. Behavioral interventions have been shown to be effective in targeting the pica behavior, including food-versus-nonfood discrimination training, response interruption and positive practice over-correction, habit reversal, and brief-duration physical restraint (Fisher et al. 1994; Johnson et al. 1994; Paniagua et al. 1986; Woods et al. 1996; Winton and Singh 1983). Psychiatric medications are not generally used to treat pica unless it is comorbid with another psychiatric disorder.

### **Rumination**

Rumination syndrome is the effortless regurgitation into the mouth of recently ingested food followed by rechewing and reswallowing or expulsion (Clouse et al. 1999; Malcolm et al. 1997). Associated behavioral signs can include aversive posturing or gaze avoidance (Berkowitz 1999). Rumination can be conditioned after an illness, a sign of general distress, or a form of self-stimulation or self-soothing that appears to be associated with pleasure. It is most commonly seen in infants and the developmentally disabled, but also occurs in children and adolescents with normal intelligence (O'Brien et al. 1985; Soykan et al. 1997).

Patients with rumination syndrome can be misdiagnosed as having bulimia nervosa, gastroesophageal reflux disease, or upper gastrointestinal motility disorders (such as gastroparesis or chronic intestinal pseudo-obstruction). They might undergo extensive, costly, and invasive medical testing before diagnosis. Complications can include weight loss, fatal malnutrition, dental erosions, halitosis, dehydration, school absenteeism, hospitalizations, and iatrogenic problems from the extensive diagnostic testing (O'Brien et al. 1995).

Rumination syndrome is a clinical diagnosis based on symptoms and the absence of structural disease. However, the Rome II diagnostic groups include only "infant rumination syndrome," and criteria for older children have not been defined (Rasquin-Weber et al. 1999). Evaluation for gastroesophageal reflux disease is warranted if the rumination is accompanied by apnea, reactive airway disease, hematemesis, or food refusal.

In cases of rumination because of environmental neglect, the primary caretaker-child relationship and possible psychiatric disturbance in the primary caretaker should be evaluated and addressed. Operant behavioral methods can be used for conditioned rumination. Post-meal chewing gum has been used successfully to treat adolescents with rumination (Weakley et al. 1997). Habit reversal using diaphragmatic breathing as the competing re-

sponse can also be effective in older children and adolescents (Wagaman et al. 1998; Chial et al. 2003; Kerwin 1999). Rumination in the presence of other psychosocial problems or psychiatric disorders in the child or primary caretaker may require additional therapeutic interventions. Later experiences of stress, loss, or isolation can trigger a relapse, requiring the reinstatement of the previously effective intervention (Berkowitz 1999).

### **Chronic Somatic Symptoms**

Children and adolescents often report persistent physical concerns that are not clearly accounted for by identifiable medical illness (Campo and Fritsch 1994; Garber et al. 1991). In fact, the most common reason for a pediatric psychiatry consultation is for evaluation of unexplained physical symptoms (Simonds 1977; Tsai et al. 1995). Somatoform disorders can be considered the severe end of a continuum that includes functional somatic symptoms in the middle and minor transient symptoms at the other end (Fritz et al. 1997). Examples of disorders on this continuum include atypical migraines, cyclic vomiting, chronic nausea, dizziness, fibromyalgia, chronic fatigue, functional abdominal pain, irritable bowel syndrome, myofascial pain, palpitations, conversion paralysis, and pseudoseizures (Caplan 1998; Heruti et al. 2002; Krilov et al. 1998; Li and Balint 2000; Schanberg et al. 1998; Volkmar et al. 1984). Disabling somatic symptoms can occur in the presence or absence of an identifiable etiology and in the presence or absence of other medical or psychiatric disorders.

It is helpful to remember that experiences of somatic symptoms are the result of an integration of biological processes, psychological and developmental factors, and social context (Bennett 1999; Li and Balint 2000; Mailis-Gagnon et al. 2003; Peyron et al. 2000; Terre and Ghiselli 1997; Zeltzer et al. 1997). Traditionally, disability and symptoms in excess of what would be expected given the amount of tissue pathology has been considered psychogenic. Children and families are informed that the symptom has no physiological basis, with the intended or unintended suggestion that the child is fabricating the symptom. It is misleading and often confusing to families to dichotomize symptoms as organic versus nonorganic because all symptoms are associated with neurosensory changes and influenced by psychosocial factors. Maintaining the organic versus nonorganic dichotomy can lead to unnecessary tests and treatments, or to an unhelpful lack of empathy.

Psychiatric assessment is geared toward identifying psychiatric symptoms, behavioral reinforcements, and psychosocial stressors that could be exacerbating the symp-

toms. Common comorbid findings include anxiety disorders, alexithymia, depression, unsuspected learning disorders (in high-achieving children), developmental or communication disorders, social problems, physical or emotional trauma, family illness, and family distress (Bursch and Zeltzer 2002; Campo et al. 1999, 2002; Egger et al. 1998; Fritz et al. 1997; Garber et al. 1990; Hodges et al. 1985a; Hodges et al. 1985b; Hyman et al. 2002; Lester et al. 2003; Livingston 1993; Livingston et al. 1995; Schanberg et al. 1998; Stuart and Noyes 1999; Zuckerman et al. 1987).

The family and treatment team often worry about missing a life-threatening problem or a diagnosis that could be easily remedied. This fear is particularly strong when the patient exhibits significant distress about the symptoms. The treatment team must feel that a reasonable evaluation has been completed so that they can clearly communicate to the family that no further evaluation is indicated to understand and treat the problem. A rehabilitation approach can improve independent and normal functioning, enhance coping and self-efficacy, and serve to prevent secondary disabilities (Bursch et al. 1998; Campo and Fritz 2001; Heruti et al. 2002). Functioning, rather than symptoms, should be tracked to determine whether progress is being made. As functioning, coping skills, and self-efficacy improve, symptoms and the distress related to the symptoms often remit.

Specific treatment plans target the biological, psychological, and social factors that are exacerbating or maintaining the symptoms and disability. Treatment techniques designed to target underlying sensory signaling mechanisms and specific symptoms can include cognitive-behavioral strategies (e.g., psychotherapy, hypnosis, biofeedback, or meditation), behavioral techniques, family interventions, physical interventions (e.g., massage, yoga, acupuncture, transcutaneous electrical nerve stimulation (TENS), physical therapy, heat or cold therapies, occupational therapy), sleep hygiene, and pharmacological interventions (Fritz et al. 1997; Minuchin et al. 1978; Sanders et al. 1989, 1994; Zeltzer and Bursch 2002). In general, interventions that promote active coping are preferred over those that require passive dependency.

Most of the currently employed pharmacological strategies are extrapolated from adult trials without evidence of efficacy in children. Classes of medications to consider include tricyclic antidepressants or anticonvulsants for neuropathic pain or irritable bowel syndrome, SSRIs for symptoms of anxiety or depression, muscle relaxants for myofascial pain, and low-dose antipsychotics (especially those with low potency) for acute anxiety, multiple somatic symptoms with significant distress, and chronic nausea. Benzodiazepines sometimes elicit para-

doxical reactions in those children who are hypervigilant to their bodies and concerned about losing control. Blocks, trigger point injections, epidurals, and other invasive assessments and treatments that further stimulate the CNS can sometimes exacerbate the problem. Evidence-based treatments should be used whenever available. For example, in adolescent migraine headache, cognitive-behavioral interventions have better evidence for efficacy than triptans, and ibuprofen appears to be more effective than acetaminophen.

## Specific Medical Disorders

---

### Oncology

Pediatric cancer presents a number of challenges to patients and their families. Despite the numerous stressors, pediatric oncology patients report relatively few depressive symptoms during the time of active treatment. Children with cancer report fewer symptoms of depression than healthy school children or children with asthma, and self-esteem concerns and somatic symptoms do not differentiate between depressed and nondepressed children with cancer (Worchel et al. 1988; Gizynski and Shapiro 1990). In fact, pediatric cancer patients report so few symptoms that clinical researchers have hypothesized that these children use an avoidant coping style to deal with their emotional response to cancer (Phipps and Srivastava 1997, 1999) or that their emotional response is shaped by traumatic avoidance (Erickson and Steiner 2000). Interventions that address the contextual issues that are precipitating distress are generally sufficient for the depressive symptoms seen during active treatment (Kazak et al. 2002).

One area of intervention that has been extensively researched is preparation for the many invasive procedures children experience during cancer treatment. Cognitive-behavioral techniques, including imagery, relaxation, distraction, modeling, desensitization, and positive reinforcement, are well established as effective (Powers 1999). This is consistent with the literature that suggests depressive attributional style and avoidance coping are major predictors of anxiety and depression in pediatric oncology patients (Frank et al. 1997). Although all children have some distress with painful procedures, some appear to be more sensitive to pain and have differential responses to psychological interventions for procedural distress (Chen et al. 2000). In cases of children with severe distress, integration of pharmacological interventions has proven useful (Jay et al. 1991; Kazak et al. 1998). Topical anesthetic cream has been used with some success to alleviate the

pain of venipuncture or the topical pain of other invasive procedures with pediatric oncology patients (Robieux et al. 1990). In comparisons of conscious sedation and general anesthesia for lumbar punctures, the outcomes were similar, and the conscious sedation was generally preferred, as well as less expensive. However, for some children, the procedure could only be performed under general anesthesia because they were too distressed to cooperate (Ljungman et al. 2001). For conscious sedation, the amnestic effect of midazolam, as well as the ability to administer it nasally, rectally, or orally, has made it popular with anesthesiologists and intensivists. In a double-blind study, midazolam was shown to significantly reduce children's procedural anxiety, discomfort, and pain (Ljungman et al. 2000). For brief, general anesthesia, a combination of midazolam and ketamine has been found effective (Parker et al. 1997).

With increasing survival of childhood cancer patients, the long-term impact of cancer has become a major focus of psycho-oncology research over the past 20 years. Here again, depression does not seem to be a problem (Zebrack et al. 2002). However, a rapidly growing area is investigations of PTSD. A study of 309 childhood cancer survivors (ages 8–20), an average of almost 6 years after cancer treatment, found similar rates of PTSD symptoms in the cancer and comparison groups (219 healthy children) (Kazak et al. 1997). However, in a study of 78 young-adult (ages 18–37) survivors of childhood cancer, approximately 20% of the young adult survivors reported symptoms meeting diagnostic criteria for PTSD (Hobbie et al. 2000). Furthermore, PTSD in the young adults appeared predictive of adverse consequences. The young adult survivors who met criteria for PTSD were less likely to be married (none, compared with 23% of the non-PTSD group) and reported more psychological distress and poorer quality of life across all domains. The greatest differences reported were in social functioning, emotional well-being, and role limitations caused by emotional health and pain. Survivors without PTSD did not differ from population norms (Meeske et al. 2001). These findings indicate a need to prevent and intervene with children during the time of acute treatment, to prevent long-term consequences in much the same way that medical treatments are being adapted in light of the late effects of radiation and chemotherapy.

Parents report significant distress both during and after their children's cancer treatment (Best et al. 2002). Specific problem-solving therapy has been found to be effective in helping mothers deal with the stresses of treatment (Sahler et al. 2002), as have brief stress reduction techniques (Streisand et al. 2001). Rates of PTSD in parents of children off treatment appear comparable to those

of adult cancer survivors (Manne et al. 1998). In a large study of pediatric cancer survivors' parents, 3% of the survivors' mothers reported severe, and 18.2% reported moderate, symptoms of PTSD; whereas 7% of the survivors' fathers reported severe, and 28.3% reported moderate, PTSD symptoms (Kazak et al. 1997).

## Cystic Fibrosis

Cystic fibrosis (CF) affects approximately 30,000 children and adults in the United States and is the most common hereditary disease in white children. A defective gene causes the body to produce a thick, sticky mucus that clogs the lungs and leads to life-threatening lung infections. These secretions also obstruct the pancreas, preventing digestive enzymes from reaching the intestines. CF occurs in approximately one of every 3,200 live Caucasian births, with about 1,000 new cases diagnosed each year. More than 80% of patients are diagnosed by age 3; however, almost 10% are diagnosed at age 18 or older. The median age of survival is 33.4 years, and nearly 40% of those with CF are adults.

People with CF have a variety of symptoms that vary from person to person but include very salty-tasting skin; persistent coughing; wheezing or shortness of breath; an excessive appetite but poor weight gain; and greasy, bulky stools. Malnutrition can lead to poor growth, delayed puberty, impaired respiratory function, reduced exercise tolerance, and increased risk of infection. CF patients with end-stage pulmonary disease show marked nutritional failure. There is evidence that improving nutritional status may halt the decline in pulmonary function (Dalzell et al. 1992). Progressive respiratory failure is the most common cause of death.

The treatment of CF depends on the stage of the disease and the organs involved. Clearing mucus from the lungs is part of the daily CF treatment regimen; this entails vigorous clapping on the back and chest to dislodge the mucus from the lungs. Other types of treatments include antibiotics to treat lung infections and mucus-thinning drugs. A high-energy diet (a high-fat diet with significant amounts of carbohydrate and protein) aiming at 120% of the recommended daily intake for age has been linked to superior nutritional status. However, research has demonstrated that dietary adherence is poor, with up to 84% of CF children not reaching dietary goals. Both adherence and health status in children with CF are partially predicted by parental psychosocial variables, including knowledge specific to CF (Anthony et al. 1999; Patterson et al. 1993). More and more individuals with CF have received gene therapy or a lung, liver, and/or bowel transplant.

Many people with CF lead remarkably normal lives and maintain hope with the possibilities of gene therapy and organ transplantation in case of severe deterioration. Although early research suggested that eating disorders may be more prevalent in those with CF, recent work has suggested that this is not true. Similarly, rates of other psychiatric disorders among those with CF do not appear to be greater than the prevalence reported in the general population (Kashani et al. 1988a; Raymond et al. 2000). In one study of CF adolescents' health values, it was revealed that they are willing to trade very little of their life expectancy or take more than a small risk of death to obtain perfect health (Yi et al. 2003). Although there is little research on this topic, there are no apparent contraindications for standard assessment and treatments approaches for psychiatric disorders in those with CF. There is some data to suggest that family interventions can be successfully used to improve maternal mental health and treatment adherence among those at high risk (Goldbeck and Babka 2001; Ireys et al. 2001).

## Asthma

Asthma is the most common pediatric chronic illness, and both prevalence and morbidity are rising, despite better pharmacological treatments. Comorbid psychiatric problems and increased levels of stress are cited as possible factors for the increases (Wamboldt and Gavin 1998). Comorbid psychiatric disorders may reduce asthma treatment compliance, impair daily functioning, or have a direct effect on autonomic reactions and pulmonary function (Norrish et al. 1977). While the literature contains some contradictory findings about the prevalence and type of comorbid psychiatric problems, it appears that internalizing disorders are more common and that over one-third of asthmatic children have anxiety disorders. Additionally, those with moderate to severe asthma appear to be at a higher risk for anxiety disorders compared to those with mild disease. Although depression has been less consistently identified as a comorbid psychiatric disorder among pediatric asthma patients, the literature suggests that depression, along with other psychosocial problems, may be a risk factor for death in children with asthma. Consequently, the presence of depression in a child with uncontrolled or severe asthma requires serious attention (Bussing et al. 1996; Butz and Alexander 1993; Graham et al. 1967; Kashani et al. 1988b; MacLean et al. 1988; McNichol et al. 1973; Mrazek et al. 1985; Steinhilber et al. 1983; Strunk et al. 1985; Vila et al. 1999).

Twin studies suggest that there may be a genetic relationship between atopic disorders and internalizing disorders (Wamboldt et al. 1998). One possible explanation is

that panic anxiety acts as an asphyxia alarm system that is triggered by central chemoreceptors monitoring PaCO<sub>2</sub>. Children with a genetic vulnerability for panic disorder who also have periodic increased PaCO<sub>2</sub> from asthma exacerbations may thus have panic anxiety triggered by their asthma attacks. Left undiagnosed and untreated, this anxiety can develop into panic disorder. Indeed, recent prospective epidemiological studies indicate the primary risk factor for development of panic disorder in young adulthood is history of asthma as a child (Goodwin et al. 2003). Other reasons for increased comorbidity include the fact that most asthma medications (for example, steroids and beta-agonists) are known to cause symptoms that appear psychiatric in nature. An inflammatory allergic response may release cytokines and other mediators that cause fatigue, trouble concentrating, and irritability that could also be interpreted as depression. The physiological response accompanying strong emotions can trigger wheezing in some patients. Recent research indicates that not only can stress lead to increased asthma exacerbations, but those children with atopic illnesses have a reduced cortisol response to stress (Wamboldt et al. 2003). Stressors may thus have a direct effect on increased inflammation, leading to asthma symptoms or an increase in upper respiratory infections, which also exacerbate asthma. Depression and anxiety may indirectly influence asthma because distressed asthmatics tend to misperceive anxiety symptoms as asthma symptoms, often leading to unnecessary medication usage.

Vocal cord dysfunction (VCD) can mimic asthma and commonly occurs comorbidly with asthma. It is a condition of involuntary paradoxical adduction of the vocal cords during the inspiratory phase of the respiratory cycle (Wamboldt and Gavin 1998). It is often associated with anxiety or chronic stress; however, sexual abuse in this population is not as prevalent as previously believed (Brugman et al. 1994; Gavin et al. 1998). Patients with VCD frequently present with stridulous breathing, experience tightness in their throats, and feel short of breath. It can be quite anxiety provoking that their symptoms are unrelieved by asthma medications.

Clinicians should assess for 1) psychosocial disruption and psychiatric symptoms, especially symptoms of anxiety and depression (including medical trauma); 2) the likelihood of nonadherence; 3) ability to perceive symptoms; and 4) presence of VCD. Asthma can increase family burden, and having depressed primary caretakers increases the risk of poorer treatment adherence. New electronic monitoring of adherence with inhaled medications helps determine how much nonadherence is undermining outcome. Having patients guess their peak flow or rate their symptoms before spirometry or after a methacholine chal-

lenge is one way to assess if the patient is an accurate perceiver or not. Patients who have difficulty with symptom perception (either under- or overperceiving symptoms) can be trained to use objective assessment methods, such as peak flow meters. Clinicians can assess for VCD by asking patients where they feel short of breath and if there is throat tightness. A flow volume loop can be helpful in showing VCD, especially on the inspiratory part of the loop. Definitive diagnosis of VCD is made by visualization of adducted cords during an acute episode using laryngoscopy. Provocation of symptoms during laryngoscopy has been achieved using methacholine, histamine, or exercise challenges.

Pharmacological and psychological treatments with efficacy to treat anxiety and depression in children are largely applicable to those with asthma. Focused family therapy to improve asthma management skills has been shown to be effective and efficient (Godding et al. 1997; Gustafsson et al 1986; Lask and Matthew 1979; Panton and Barley 2004). The primary treatment for VCD is speech therapy or hypnotherapy geared toward increasing awareness and control of breathing and throat muscles (Wamboldt and Gavin 1998). Although some concern has been raised about the concurrent use of tricyclic antidepressants with medicines used in treating asthma, they appear to be safe, and the anticholinergic effects can sometimes be helpful (Wamboldt et al. 1997). Beta-receptor agonists are often used to treat asthma, which makes beta-blockers potentially dangerous. There is no contraindication for using neuroleptics, and they may be particularly indicated for steroid-induced psychosis. Lithium increases theophylline clearance, requiring that levels of both drugs be monitored (Wamboldt and Gavin 1998). Some children with asthma have difficulty tolerating stimulants. Bupropion has shown efficacy in the treatment of attention-deficit/hyperactivity disorder in young patients in controlled trials (Barrickman et al 1995; Conners et al 1996) and does not interact with asthma medications.

## Childhood Obesity

There has been a disturbing increase during the past 20 years in the prevalence of obesity in children and adolescents in the United States. Children and adolescents are considered obese if they have a body mass index (BMI) of greater than or equal to the 95th percentile for age and gender, and they are considered overweight if their BMI is between the 85th and the 95th percentiles (Dietz and Bellizzi 1999). Data from the third National Health and Nutrition Examination Survey, conducted from 1988 to 1994, indicated that approximately 11% of children were obese, and another 14% were overweight. These findings

can be compared with the 5% obesity reported in a similar study conducted between 1976 and 1980 (Troiano et al 1995). This dramatic increase in obesity has been attributed to the proliferation of inexpensive, calorie-rich foods that are quickly and readily available in this country and the increased number of hours children spend in sedentary activities, such as watching television and playing computer games (Ebbeling et al. 2002). Similar increases in childhood obesity have been documented in Europe and Asia (Chinn et al. 2001; Chunming 2000) and in developing societies (de Onis and Blossner 2000).

The impact of obesity is both immediate and long-lasting. Children and adolescents with a BMI at or above the 95th percentile for age and sex have been found to have significantly reduced health-related quality of life compared with healthy children and adolescents. In a study of 106 children, ages 5–18 years, the obese subjects were more than five times more likely to have significant impairment of physical functioning and almost six times as likely to have impaired psychosocial health. These findings are similar to those for children with cancer (Schwimmer et al. 2003). A survey of approximately 10,000 women, ages 16–24 years, found that obese adolescents were less likely to complete college than non-overweight adolescents with similar educational backgrounds. The obese young adults were much less likely to marry than nonobese young adults, after controlling for IQ and parents' education or income level. Those obese women who did marry were more often married to men in a lower socioeconomic class (Stunkard and Sabal 1995; Gortmaker 1993).

The immediate health consequences of childhood obesity are serious and include slipped capital femoral epiphysis, pseudotumor cerebri, asthma, sleep apnea, gallstones, insulin resistance, early puberty, dyslipidemia, and hypertension (see Morgan et al. 2002 for review). Although obese children are likely to become obese adults (Guo et al. 1994), the long-term health risks also include increased likelihood of atherosclerotic cardiovascular disease, gout, and colorectal cancer in men and arthritis and menstrual abnormalities in women, even after adult body mass is taken into account (Mossberg 1989; Must et al. 1999).

Genetic factors may account for as much as 70% of the variability in human body weight (Stunkard et al. 1990; Allison et al 1996). The recent discovery of leptin opens the door for future interventions through what appears to be the body's approach to energy balance (Segal and Sanchez 2001). However, the behavioral contribution is sufficient to make lifestyle interventions a priority for pediatricians and the psychologists and psychiatrists who work with pediatric patients. A review of 42 randomized

studies involving non-school-based programs found strong evidence for the efficacy of multicomponent behavioral treatments for children to decrease weight both short- and long-term when compared with placebo or education-only treatments. The smaller numbers of studies and shorter follow-up do not allow as much confidence about the effectiveness of such interventions with adolescents (Jelalian and Saelens 1999). Unfortunately, although the weight loss was significant, the majority of these children remained obese, and there is little evidence that behavioral interventions were effective with children who were morbidly obese. These results have led to recent investigations of the application of medication or surgery to treat serious obesity in adolescents.

There are currently no weight loss medications that have been approved for use in children and adolescents. Fenfluramine and phentermine, appetite suppressants that act by stimulating the release of serotonin and dopamine and selectively inhibiting their reuptake, were tested separately and jointly with children and adolescents but were not found to be consistently effective. Fenfluramine was later withdrawn from the market because of safety concerns (see Yanovski 2001 for review). However, sibutramine, an inhibitor of norepinephrine, serotonin, and dopamine reuptake, has proven useful and safe in adults and is now being tested with adolescents. Sibutramine appears to act by increasing satiety, rather than by decreasing appetite (Heal et al. 1998). A randomized, double-blind, placebo-controlled trial of 82 adolescents ages 13 to 17 years with a BMI of 32 to 44 studied the use of behavior therapy coupled with either sibutramine or placebo. Study participants were all given a 1200- to 1500-kilocalorie diet and followed for a year. The sibutramine group had significantly more weight loss than those who had placebo paired with the same diet and behavioral program, with a mean loss of 7 kg and reduction of 8.5% of BMI, compared with 3.2 kg and 4.0% for the control group. Hunger reported was also significantly reduced ( $P = .002$ ) in those receiving the sibutramine (Berkowitz et al. 2003). Although safety has not been fully studied, in this study there were clinically significant side effects of the medication. Doses of the medication were reduced in 23 subjects and discontinued in 10 to manage increases in blood pressure, pulse rate, or other symptoms. Such interventions are therefore still reserved for those who are dangerously obese, where the benefit may outweigh the cost.

There have been some initial studies of the feasibility of doing surgery to induce weight loss in adolescents with severe obesity, given the high levels of morbidity and mortality associated with this condition. However, bariatric surgery is viewed as "a last resort option for severely

obese adolescents" (Strauss et al. 2001, p. 503). Bariatric surgical interventions for adults are used only after behavioral approaches have failed and when medical complications of obesity outweigh the potential complications of the surgery (Fisher and Schauer 2002) (see also Chapter 30, "Surgery"). Restrictive approaches use gastric staples, bands, or bypasses to reduce the capacity of the stomach, decreasing the volume of food which can be consumed at one sitting, and increasing a sense of satiety. Mean loss of excess weight with the most popular method, the Roux-en-Y, ranges from 65% to 75% in adults. Morbidity is reported at 10% and includes deep venous thrombosis or pulmonary embolism, anastomotic leaks, and wound infection. Iron and vitamin B<sub>12</sub> deficiency occur in more than 30% of patients. Mortality rates are less than 1%. Malabsorptive operations bypass parts or all of the duodenum or jejunum, reducing intestinal absorption of nutrients. Mean loss of excess weight is 75%–80% with excellent weight maintenance, and immediate mortality and morbidity is similar to that after restrictive procedures. However, 30% of the patients develop anemia, 30%–50% develop fat-soluble vitamin deficiencies, and diarrhea and foul-smelling stools are common (see Brodin 2002 for review). Given the likelihood of adolescents to be non-adherent with diet and other instructions, the potential interference with growth, and the lack of information on long-term consequences, surgical interventions should be reserved for those who have not responded to more conventional intervention and have significant complications of their obesity (Yanovski 2001).

## Sickle Cell Anemia

The sickle cell gene for hemoglobin S is the most common inherited blood condition in the United States, with an estimated 72,000 people affected. Symptoms do not usually appear until late in the first year of life and may include fever; swelling of the hands and feet; pain in the chest, abdomen, limbs, and joints; nosebleeds; and frequent upper respiratory infections. Pain is the most common complaint after infancy, as are the added problems of anemia, fatigue, irritability, and jaundice. Children and adolescents may experience delayed puberty, severe joint pain, progressive anemia, leg sores, gum disease, long-term damage to major organs, stroke, and acute chest syndrome. A compromised spleen can cause increased susceptibility to infections. Current treatments for sickle cell disease are prolonging and improving quality of life. Although most people with sickle cell anemia were not previously expected to survive childhood, the majority now live into adulthood with about half living beyond 50 years (Platt et al. 1994).

Sickle cell crises are acute pain episodes that are usually followed by periods of remission and a relatively normal life. Some patients have few crises, others need to be frequently hospitalized, and some have clusters of severe attacks with long intermittent remissions. Crises become less frequent with age for some. The risk for a crisis is increased by anything that boosts the body's oxygen requirement (including illness, physical stress, or being at high altitudes). The first day of the crisis is usually the worst, with sharp, intense, and throbbing pain in the arms, legs, and back. Shortness of breath, bone pain, and abdominal pain are also common. The liver can become enlarged, causing pain, nausea, low-grade fever, and jaundice. Males may experience priapism. Acute chest syndrome can be life threatening.

Stroke is a common cause of death for sickle cell patients over 3 years (Kinney et al. 1999; Ohene-Frempong 1991; Ohene-Frempong et al. 1998;). Although transfusions may be preventive, 8%–11% of those affected suffer strokes. One study comparing sickle cell children with and without a history of stroke revealed relative deficits on measures of attention and executive functioning. Rodgers et al. (1984) provided positron emission tomography evidence of altered frontal lobe metabolism. Another study examined social information processing, social skills, and adjustment difficulties in children with sickle cell disease and learning and behavior problems, with or without CNS pathology on MRI. Children with CNS pathology displayed more errors on tasks of facial and vocal emotional decoding than did the control children (Boni et al. 2001).

Although children and adolescents with sickle cell disease do not appear to have a greater risk for psychiatric disorders than those in the same-race outpatient clinic control group, children attending outpatient medical clinics are at a higher risk for mental disorders than nonmedical populations (Cepeda 1997; Yang et al. 1994). Most well-designed studies report a prevalence rate of 25%–30% for psychiatric disorders among pediatric sickle cell patients, with internalizing disorders being most prevalent (Cepeda et al. 1997), similar to other pediatric outpatients (Costello and Shugart 1992; Costello et al. 1988). Psychosocial factors have accounted for more variability than biomedical ones in both depressive symptoms and anxiety, with social assertion, self-esteem, use of social support, and family factors accounting for a significant amount of the variability in adaptation (Burlew et al. 2000; Telfair 1994). Two studies suggest that pica (not often assessed) has a relatively high prevalence (up to 30%) in children with sickle cell disease (Bond et al. 1994; Ivascu et al. 2001).

Psychiatric assessment should look for 1) psychosocial disruption or psychiatric symptoms, especially related to

pica, anxiety and depression; 2) school or social problems that could reflect subtle neurocognitive problems; and 3) chronic pain problems. Pharmacological and psychological treatments with efficacy to treat psychiatric disorders in children are applicable to those with sickle cell anemia. Problems with academic or social functioning might be assessed via neurocognitive testing and addressed within the school system with an Individualized Educational Program (IEP). Pain in sickle cell patients is most commonly medically managed pharmacologically with nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, and adjuvant medications (American Pain Society 1999). Chronic as well as acute pediatric pain can also be reduced with behavioral, psychological, or physical interventions (American Pain Society 1999). Behavioral interventions might include relaxation, deep breathing, biofeedback, behavioral modification, or exercise. Psychological intervention might include cognitive therapies, hypnotherapy, imagery, distraction, or social support. Physical interventions might include hydration, heat, massage, hydrotherapy, ultrasound, acupuncture, TENS, or physical therapy. Successful treatment of anxiety symptoms can reduce pain and pain-related distress. Although there are no contraindications for the use of psychotropic medications with this population, it is important to remember that phenothiazines may antagonize the analgesic effects of opiate agonists; and tricyclic antidepressants, MAOIs, and other CNS depressants may potentiate adverse effects of opioids. It is important to note, however, that these agents may also serve to successfully augment pain control efforts and should be considered if needed.

## Renal Disease

Each year 20,000 children are born with kidney abnormalities, and 4,500 children require dialysis for renal failure. Hemodialysis (at a center or at home) and peritoneal dialysis are used in children. The basic principles of treatment of end-stage renal disease (ESRD) are similar in adults and children (see Chapter 22, "Renal Disease"). However, attention to dialysis adequacy, control of osteodystrophy, nutrition, and correction of anemia are crucial because these factors can influence growth, cognitive development, and school performance (Warady et al. 1999).

Pediatric patients with chronic renal failure exhibit more problems in psychiatric adjustment than do healthy children, with a trend toward more psychological difficulties in those with higher illness severity (Garralda et al. 1988). However, even less severely physically ill children appear to have increased difficulties in school adjustment and feelings of loneliness (Garralda et al. 1988). Separation

tion anxiety disorder in particular may be a relatively common disorder (up to 65.4%) among children on continuous ambulatory peritoneal dialysis (Fukunishi and Kudo 1995). This may be due to the forced dependence on parents for daily renal care. The burden for families caring for children with ESRD can be significant, especially when it involves dialysis. Disruption of family life, marital strain, and a tendency for more mental health problems in the parents also appear to be related to the severity of the child's renal illness and its associated care burdens (Reynolds et al. 1988). Children with ESRD (with or without transplant) have been shown to have lower-than-expected IQs and achievement scores. Lower achievement test scores were predicted by younger age at the time of renal disease diagnosis, increased time on dialysis, and caregiver's lower achievement (Brouhard et al. 2000; Fennell et al. 1984; Qvist et al. 2002). Overall, former pediatric ESRD adults appear to have a long-term favorable adjustment, with lower self-esteem related to early onset of the disease and to educational and social dysfunction (Morton et al. 1994).

According to the latest statistics (May 30, 2003) from The United Network for Organ Sharing (UNOS), 749 children were waiting for a kidney transplant in the United States, including 3 under 1 year, 79 in the 1- to 5-years age group, 121 in the 6- to 10-years age group, and 546 in the 11- to 17-years age group. The majority of transplanted kidneys come from cadavers. However, family members or unrelated individuals who are a good match may be able to donate one of their kidneys and live healthy lives with the kidney that remains. Pediatric kidney transplantation is associated with improved physical health, emotional health, and family functioning; however, poor peer relationships, school maladjustment, and other adjustment problems (as well as adherence problems) can remain after transplant (Fukunishi and Kudo 1995; Reynolds et al. 1991). Living with a transplant is a lifelong process requiring daily medications and monitoring for rejection. Medication nonadherence rates for pediatric renal transplant patients can be as high as 64% (Ettenger et al. 1991). Adverse consequences of nonadherence include medical complications and hospitalizations, higher health care costs and family stress, and increased risks for loss of the organ (Arbus et al. 1993; Bittar et al. 1992; Fukunishi and Honda 1995; Salvatierra et al. 1997; Swanson et al. 1992).

Those conducting mental health evaluations of children with renal disease should consider the impact of possible cognitive deficits, adaptation difficulties, and family strain on social and academic functioning, as well as adherence. The level of family stress and distress, as with all pediatric patients, is essential to evaluate and address as

part of a larger treatment approach. Recommendations related to the use of psychotropic medication must be extrapolated from adult studies (see Chapter 22, "Renal Disease") because these data are not available for children.

## Diabetes

Juvenile-onset diabetes mellitus affects 1.9 of every 1,000 school-age children in the United States (Sperling 2000). Type 1 diabetes mellitus is caused by autoimmune destruction of insulin-producing pancreatic beta cells and must be treated with exogenous insulin. Type 2 diabetes mellitus is the result of resistance to insulin rather than deficiency, can often be treated with diet or hypoglycemic agents, and is generally later in onset than type 1. There are genetic predispositions to both type 1 and type 2 diabetes mellitus (Drash 1993). Obesity and atypical antipsychotic medications appear to contribute to the development of type 2. Both can contribute to mortality and may cause significant morbidity, including retinopathy, nephropathy, peripheral neuropathy, and cardiovascular disease. Injected insulin may also precipitate potentially life-threatening episodes of hypoglycemia (DCCT Research Group 1993, 1994).

The complexity of the management of type 1 diabetes mellitus leads to frequent problems with adherence to medical instructions. Patients on Humalog (or regular) and NPH (neutral protamine Hagedorn) regimens must inject themselves with insulin and test their blood glucose at least three times a day to maintain "tight" control, decreasing the incidence or delaying the onset of complications. Patients on Lantus must take a shot every day and another every time they eat more than 15 grams of carbohydrates (e.g., an apple). Even on an insulin pump, blood glucose must be tested at least four times a day. Diet and exercise must be regulated, as both have significant impact on the need for exogenous insulin.

The physiological changes of puberty can lead to increased insulin resistance. In addition, the importance of peer acceptance and the withdrawal of parental supervision with the normal developmental focus on identity and autonomy lead to significant adherence problems during adolescence (Hauser et al. 1990). Poor control of diabetes has been repeatedly demonstrated using HbA1c (glycosylated hemoglobin), which allows one to get an estimate of glycemic control over past 3 months. The medical consequences of such poor control were demonstrated in a study of 78 adolescents with type 1 diabetes, ages 11–18 years, followed for 8 years. Their mean HbA1c peaked in late adolescence. Serious diabetic complications were seen in 38% of the females and 25% of the males (Bryden et al. 2001).

Studies of the utility of intervention with pediatric diabetic patients have found that interventions to enhance adherence must be intense and early to make a significant difference in long-term outcome. A study of 1,441 patients, ages 13–39 years, followed for a mean of 6.5 years demonstrated a decrease in long-term complications with intensive treatment. Retinopathy developed in 47% of the intensive intervention group, versus 76% in the comparison group, and neuropathy in 57% versus 69%. The price, however, was a two- to threefold increase in severe hypoglycemic events. A study of primary versus secondary intervention followed 195 patients, ages 13–17 years, for a mean of 7.4 years and found that the HbA1c values separated significantly by 6–12 months and were maintained throughout the study. Retinopathy and nephropathy were significantly reduced, although there was no statistical difference in neuropathy between the groups. Again, there was a two- to fourfold increase in severe hypoglycemia, as well as a twofold increase in becoming overweight in the intensive treatment group (DCCT Research Group 1993, 1994).

Psychiatric comorbidity in diabetic individuals is also a major issue for psychiatric consultants to pediatrics. Some moodiness and feelings of isolation and of loss or grief, as well as mild anxiety about the future, are to be expected as normal responses to diabetes. However, assessment for possible intervention is indicated if patients demonstrate aggression, school absences, hopelessness, or nonadherence to the insulin regimen (A.M. Jacobson 1996). In a study of 92 pediatric patients, ages 8–13 years, followed over 9 years, 42% developed at least one psychiatric disorder, and 26% developed two or more disorders. Of these, the most common were depression in 26% and anxiety in 20%, with various behavioral disorders in 16%. Children who were at higher risk of developing psychiatric comorbidity were those in the first year after diagnosis and those who had preexisting anxiety or mothers with psychopathology (Kovacs et al. 1997). Eating disorders are also relatively common. A study of 91 adolescent girls, ages 12–18 years, followed for 5 years found highly or moderately disordered eating in 29% at baseline and in 33% at follow-up (Rydall et al. 1997).

Treatment of comorbid psychiatric disorders with medications requires careful monitoring because most antidepressant, mood stabilizer, and atypical antipsychotic medications may stimulate appetite or affect glucose tolerance, inducing hypoglycemia or hyperglycemia. Beta-blockers should be avoided, as they mask the early warning signs of hypoglycemia, eliminating the window of opportunity for patients to address the problem themselves before requiring the assistance of others (Goodnick et al. 1995).

Effective behavioral interventions for children with diabetes and their parents include identifying readiness for change and improving self-efficacy, the belief that one can maintain behavior change despite regular challenges (Anderson et al. 1996, 1999). In 110 young adults (ages 18–35) with insulin-dependent diabetes mellitus, self-efficacy was more predictive than self-esteem of self-care and metabolic control. Factoring in previous adherence, self-efficacy continues to be predictive of self-care and HbA1c (Johnston-Brooks et al. 2002). A growing area of research is the application of motivational interviewing to work with adolescents with diabetes mellitus (Berg-Smith et al. 1999; Dunn et al. 2001; Williams et al. 1998).

## Cardiac Disease

### *Congenital Heart Defects and Disease*

Congenital heart defects and disease include patent ductus arteriosus, atrial septal defects, and ventricular septal defects. About 40,000 children are born with a heart defect each year, and most can benefit from surgery. It appears that heart defects are multidetermined by factors that include genetics as well as exposure during pregnancy by the mother to certain viruses (such as rubella, or German measles) or drugs (such as alcohol, anticonvulsants, or lithium). Acquired heart diseases that develop during childhood include Kawasaki disease, rheumatic fever, and infective endocarditis. Van Horn et al. (2001) studied concerns expressed by mothers of children with congenital heart disease during hospitalization and again 2–4 weeks after discharge. During hospitalization, mothers were most concerned about medical prognosis. Mothers' concerns, anxiety, and depressed mood decreased after discharge. At follow-up, mothers' perceptions of medical severity were related to distress about psychosocial issues. Overall, it appears that children with heart disease psychiatrically resemble a normal population without elevations in anxiety, depression, or behavioral problems (Connolly et al. 2002; DeMaso et al. 2000; Visconti et al. 2002). However, similar to the case in healthy or other chronically ill children, socioeconomic factors, medical severity, and family distress appear to be related to symptoms of depression, anxiety, or behavioral problems (Alden et al. 1998; Visconti et al. 2002; Yildiz et al. 2001). DeMaso et al. (2000) studied pediatric patients with recurrent cardiac arrhythmias who underwent radiofrequency catheter ablation of ectopic myocardial foci. Although these patients psychiatrically resembled a normal population before the procedure, they demonstrated reductions in their "fear of their heart problem" and increases in "the things that they enjoy" after the ablation (DeMaso et al. 2000, p. 134). Those who experienced a curative ablation

had better functioning than those who did not experience improvement.

### *Heart Transplant Recipients*

Serrano-Ikkos et al. (1999) compared the psychosocial outcome of pediatric heart and heart-lung transplant recipients with children and adolescents who underwent conventional cardiac surgery. Preoperatively, rates of psychiatric disorders (including anxiety and phobic states, depression and adjustment reaction) were relatively the same in all groups (26%–28.5%). The prevalence of psychiatric disorder was unchanged after transplant in the transplant groups but decreased in the conventional cardiac surgery group. DeMaso et al. (1995) similarly found that the majority of pediatric heart transplant patients studied (78.3%) had good psychological functioning after their heart transplantation. It was further noted that patients with psychological difficulties before and after transplantation had more hospitalizations after transplantation. Finally, Uzark et al. (1992) found that pediatric heart transplant recipients did not differ from peers on measures of self-concept and anxiety but demonstrated less social competence and more behavior problems than a normative population. Behavior problems were frequently suggestive of depression and related to greater family stress and diminished family resources for managing stress. Relaxation and imagery techniques have been successfully used for routine endomyocardial biopsies after heart transplantation (Bullock and Shaddy 1993). A review of the literature related to cognition revealed that children and adolescents generally function normally on measures of cognitive functioning posttransplant, but a complicated transplant course (caused by infections or rejections) may increase risk for cognitive difficulties (Todaro et al. 2000). Serrano-Ikkos et al. (1998) found medication adherence to be relatively high, with 91% adherence confirmed by cyclosporine levels; however, adherence to medical diary keeping was lower, at about 70%. Variables associated with poor adherence to medication were heart-lung as opposed to heart transplantation, one-parent or blended families, and family adjustment.

### *Chest Pain*

Chest pain as a presenting symptom in a previously healthy child is not as ominous a symptom as in an adult because it is rarely a sign of underlying cardiac disease (Driscoll et al. 1976; Tunaoglu et al. 1995). Idiopathic chest pain is the most common diagnosis made, followed by functional pain associated with anxiety, and musculoskeletal pain (Selbst 1985). Laboratory tests are not typically helpful in establishing the etiology of chest pain. This topic is

more fully discussed in the section on “Chronic Somatic Symptoms.”

### Psychotropic Medication

The American Heart Association (Gutgesell et al. 1999) has published recommendations for the use of psychotropic medications in children. Briefly, stimulants cause clinically insignificant increases in heart rate and blood pressure. Tricyclic antidepressant (TCA) treatment of pediatric patients is associated with cardiovascular changes that are likely of minor clinical significance (Wilens et al. 1996). The electrocardiographic effects of TCA administration include an increase in heart rate (by 20%–25%), PR interval (by 5%–10%), QRS duration (by 7%–25%), and QT interval (by 3%–10%). Malignant arrhythmias have not been documented except for the ventricular fibrillation observed in one pediatric patient with a family history of sudden death. To date, deaths in children on TCAs have not been conclusively linked to the medication and have not been demonstrated to be more frequent than expected in the population base. SSRIs have minimal cardiovascular effects. Clonidine has been associated with two deaths (in patients who also received methylphenidate), but the mechanism for these deaths is unknown and may have been sudden cessation of treatment. Adverse effects have occurred when the P450 system was inhibited, leading to elevated levels of medications that prolong the QT interval and produce ventricular tachycardia. Most notable have been deaths related to nonsedating histamine-blocking agents, now off the market. Other medications that inhibit or are metabolized by the P450 cytochrome system include antidepressants, calcium channel blockers, histamine blockers, gastrointestinal motility agents, and steroids. Antiarrhythmic drugs of class IA and class III prolong the QT interval, and therefore use of psychotropic medications with these drugs is not recommended.

Recommendations include taking a careful history, obtaining an electrocardiogram (ECG) at baseline before TCA or phenothiazine therapy is begun (primarily to detect unsuspected instances of long-QT syndrome) and another when steady state is achieved, careful monitoring of all prescribed medications along with heart rate and blood pressure, and avoiding use of psychotropic medications with medications that are metabolized by or inhibit the P450 enzyme system (Gutgesell et al. 1999). History that should be obtained includes past history of syncope, near syncope, or palpitations; family history of deafness, sudden unexpected cardiac death, syncope, or tachyarrhythmias; and a medication history to document all medications that may have direct or indirect effects on the

cytochrome P450 system or ECG intervals. Some cardiologists argue that ECG screening in children with no symptoms of cardiovascular disease is less efficient and helpful than simply asking about patient and family history of syncope or sudden death. However, there are no data to clearly settle this question. The American Academy of Child and Adolescent Psychiatry does not specifically address this issue in its policy statement related to prescribing. Nevertheless, the recommendation to conduct ECG screens was recently reiterated (Francis 2002; Labellarte et al. 2003).

## Fetal Alcohol Syndrome and Alcohol-Related Neurological Disorder

Prenatal alcohol exposure represents one of the leading preventable causes of congenital neurological impairment, affecting as many as 1 in 100 children born in the United States yearly (May and Gossage 2001), with severe, life-long consequences for affected individuals. Fetal alcohol syndrome (FAS) is defined by a characteristic pattern of facial anomalies, growth retardation, and CNS dysfunction in one or more of the following areas: decreased cranial size at birth, structural brain abnormalities, and neurological hard or soft signs (Stratton et al. 1996). However, alcohol exposure to the fetus can result in neurocognitive changes even when none of the characteristic facial anomalies are present (Streissguth and O'Malley 2000).

The facial characteristics most frequently described in individuals with FAS include short palpebral fissures and abnormalities in the premaxillary zone, including a thin upper lip and flattened philtrum (Astley and Clarren 2001; Stratton et al. 1996). Neurocognitive changes include structural changes in the brain (Roebuck et al. 1998); verbal learning and memory problems; attention deficits; problems in executive functioning characterized by difficulties in planning, organizing, and sequencing behavior; and problems in abstract and practical reasoning (Adnams et al. 2001), complex nonverbal problem solving (Goodman et al. 1999), flexible thinking (Schonfeld et al. 2001), and behavioral inhibition (Mattson et al. 1999). These changes appear to last into adulthood (Streissguth and O'Malley 2000). Secondary disabilities include high levels of psychiatric illness, school failure, social problems, delinquency, and trouble with the law. No safe level of prenatal alcohol consumption has been established, making abstinence the best policy for those who are hoping to conceive. Because many women are often not aware of when they conceived and may continue to drink alcohol at least until pregnancy recognition, preconception counseling is suggested for all women of child-bearing age who consume alcohol.

# 35 Physical Medicine and Rehabilitation

---

Jesse R. Fann, M.D., M.P.H.

Richard Kennedy, M.D.

Charles H. Bombardier, Ph.D.

**PHYSICAL MEDICINE AND** rehabilitation, or *rehabilitation medicine*, is concerned with helping people reach the fullest physical, psychological, social, vocational, and educational potential consistent with their physiological or anatomic impairment, environmental limitations, and desires and life plans (DeLisa et al. 1998). The patients encountered in the rehabilitation setting are highly diverse, and their problems include those listed in Table 35–1. As can be seen, the medical and surgical issues range from acute to chronic and can involve nearly any organ system. Rehabilitation can take place in outpatient, inpatient, and extended-care programs and includes both prevention and treatment of disorders. Striving for maximum independence is central to the goal of maximizing quality of life.

Rehabilitation is generally a multi- or interdisciplinary effort. Rehabilitation medicine physicians (physiatrists) usually lead the team of other specialized professionals, including physical therapists, occupational therapists, speech pathologists, clinical and neuropsychologists, vocational rehabilitation counselors, recreation therapists, social workers, and nurses. Rehabilitation programs often have a dedicated psychologist on staff whose job is to conduct psychological and neuropsychological assessments; provide counseling to patients and families; oversee behavioral programs; and generally assist staff in the management of cognitive, behavioral, affective, and social aspects of rehabilitation.

Psychiatrists have an increasing role in the care of patients in the rehabilitation setting. As advances in medical care have increased survival in many medical and trau-

matic conditions that previously were fatal—the so-called epidemic of survival—opportunities and challenges have emerged that did not previously exist in the rehabilitation of thousands of individuals each year. Data from the 2000 National Health Interview Survey suggest that 12% of the United States population has a physical limitation in one or more activities (Schoenborn et al. 2003). For the first time, *Healthy People 2010: Understanding and Improving Health* (U.S. Department of Health and Human Services 2001), the national agenda for improving the health of Americans, includes a chapter on “Disability and Secondary Conditions,” acknowledging that disability is a critical risk factor for many other health-related conditions.

The World Health Organization has shifted its framework for classifying functioning, health, and health-related states from an emphasis on “consequences of disease” found in the previous *International Classification of Impairments, Disabilities and Handicaps* (ICIDH) (World Health Organization 1980) to an emphasis on “components of health” in the current *International Classification of Functioning, Disability and Health* (ICF) (World Health Organization 2001). The ICF conceptually differentiates health and health-related components of the disabling process at the levels of 1) *body structures* (anatomic parts of the body, such as organs, limbs, and their components) and *functions* (physiological functions of body systems, including psychological functions), and 2) *activities* (execution of a task or an action by an individual) and *participation* (involvement in a life situation). The ICF defines *impairments* as problems in body function or structure,

such as a significant deviation or loss, and focuses on *activity limitations* rather than disabilities and *participation limitations* rather than handicaps. A further change has been the inclusion of a section on *environmental factors* as part of the classification, with the recognition of the important role of environment in either facilitating functioning or creating barriers for people with disabilities. Environmental factors interact with a health condition to restore functioning or create a disability, depending on whether the environmental factor is a facilitator or barrier. Figure 35–1 illustrates the interactive and dynamic dimensions of this model. The ICF puts the burden of all diseases and health conditions, including mental illness, on an equal footing. Psychosocial factors can cause impairment and limit activities and participation in many ways, thus affording opportunities for multifaceted psychosocial interventions in the rehabilitation setting.

In this chapter, we focus on the psychiatric issues encountered in the treatment of traumatic brain injury (TBI) and spinal cord injury (SCI), two common and highly complex rehabilitation problems with aspects that may require psychiatric intervention. Although many of

the other disorders encountered in the rehabilitation setting are covered in other chapters of this text, many of the principles discussed in this chapter also apply to them.

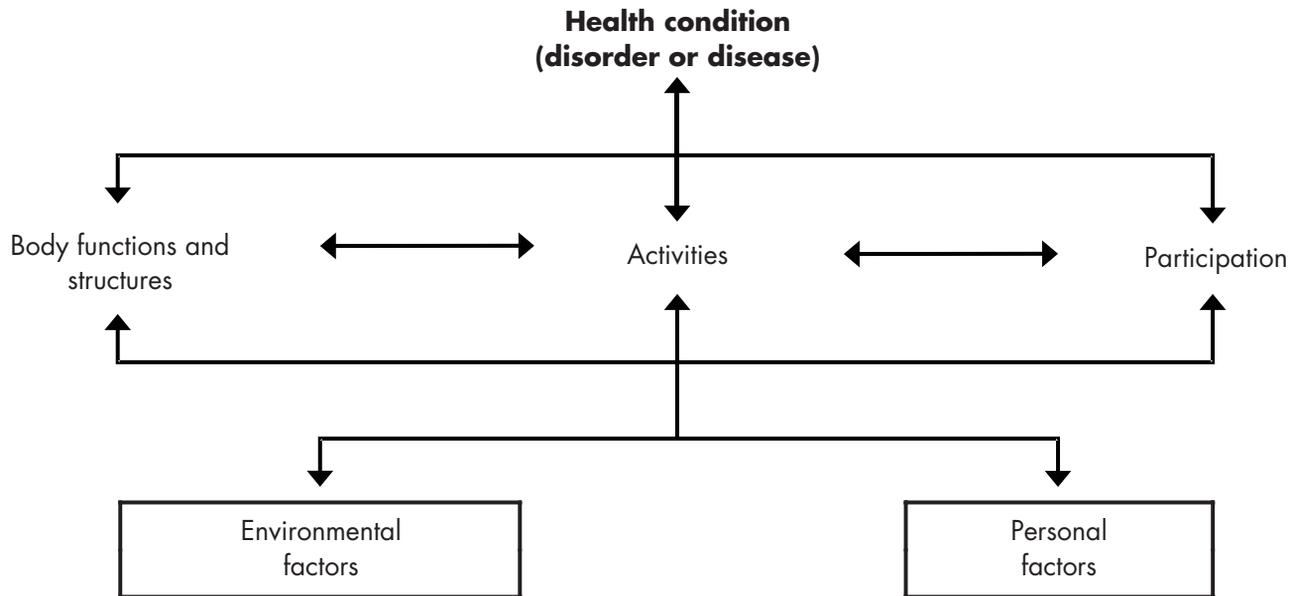

## Traumatic Brain Injury

---

### Epidemiology

TBI is a significant problem from both an individual and a public health perspective. An estimated 1.5 million Americans sustain TBI each year; of these, approximately 230,000 are hospitalized and survive, 50,000 die, and 80,000–90,000 experience the onset of long-term disability (Centers for Disease Control and Prevention 1999). According to data from hospitalized individuals, at least 5.3 million persons in the United States, or about 2% of the population, live with disabilities resulting from TBI (Thurman et al. 1999). Although about 80% of TBIs are mild in severity, many of these individuals experience long-term somatic and psychiatric problems that may lead to disability (Brown et al. 1994; Guerrero et al. 2000). TBI is often referred to as the *invisible epidemic* because TBI-related disabilities are not readily visible to the general public.

With improved medical care, TBI mortality and hospitalizations have declined 20% and 50%, respectively, since 1980 (Thurman et al. 1999), leading to more long-term morbidity and disability. The peak incidence of TBI is in 15- to 24-year-olds (mostly from motor vehicle accidents), with a secondary peak among those 60 years and older (mostly from falls) (J.F. Kraus and McArthur 1999). Because TBI affects a predominantly younger population, the effects of disability are much greater than for illnesses occurring later in life. Approximately one in four adults with TBI is unable to return to work 1 year after injury (Centers for Disease Control and Prevention 1999). In the United States in 1995, direct and indirect costs of TBI totaled an estimated \$56.3 billion (Thurman 2001). Recent figures show that the total acute care and rehabilitation costs of TBI are \$9–\$10 billion per year (National Institutes of Health Consensus Development Panel on Rehabilitation of Persons With Traumatic Brain Injury 1999), and about \$13.5 billion is necessary for continuing care of those who experienced TBI in previous years (J.F. Kraus and McArthur 1999). About 65% of TBI-related costs are accrued among survivors. Statistics from 1985 estimate that TBI-related work loss and disability cost approximately \$20.6 billion (Max et al. 1991); this figure would be much higher today because of the rapid increase in the number of individuals with TBI surviving their injury but requiring supportive care (J.F. Kraus and McArthur

**FIGURE 35-1.** Interactions between components of health as defined in the *International Classification of Functioning, Disability and Health*.

Source. Reprinted from World Health Organization: *International Classification of Functioning, Disability and Health: ICF*. Geneva, Switzerland, World Health Organization, 2001. Used with permission.

1999). Long-term disability has primarily been attributed to neurobehavioral factors (Sander et al. 1997; Witol et al. 1996). Thus, many psychiatrists will be involved a some level in the care of individuals with TBI.

## Severity and Classification

Original severity classifications for TBI focused on the Glasgow Coma Scale (GCS) (Jennett and Bond 1975) because of its widespread use. A TBI with a lowest postresuscitation GCS score of 3–8 is considered severe, 9–12 is moderate, and 13–15 is mild. However, although the GCS is useful for predicting mortality after TBI, it has less utility in predicting level of disability and neurobehavioral outcome, particularly at the upper end of the scale. It is recognized that the group of individuals with GCS scores of 13–15 are quite heterogeneous in levels of impairment and outcome (Dikmen et al. 2001; Williams et al. 1990). Durations of coma and of posttraumatic amnesia are also used to describe TBI severity.

The American Congress of Rehabilitation Medicine has put forth a definition of mild TBI that is widely used, requiring loss of consciousness (LOC) of 30 minutes or less, posttraumatic amnesia of 24 hours or less, and any alteration of mental state at the time of the injury (including feeling dazed, disoriented, or confused) or a focal neurological deficit, in addition to a GCS score of 13–15 (Kay et al. 1993). Patients with a GCS score of 13–15 who have

imaging evidence of intracranial pathology have outcomes more similar to those of moderate TBI and are often classified as “complicated mild” injuries (see Williams et al. 1990).

## Functional Pathophysiology

There has been considerable progress in understanding the pathophysiological mechanisms of TBI in recent years. The physical forces in TBI initiate mechanical and chemical changes that lead to neurological dysfunction. These are divided into *primary damage*, which occurs at the moment of injury, and *secondary damage*, which is initiated at injury but evolves over time. The latter is subdivided into direct injury, occurring within the neuron itself, and indirect injury, occurring outside the neuron but affecting its function.

Primary damage consists of injuries such as skull fractures, brain contusions and lacerations, and intracranial hemorrhage (McIntosh et al. 1996). Because these occur at the time of injury, the key treatment is prevention. Diffuse axonal injury is the predominant mechanism of injury in most cases of TBI (Meythaler et al. 2001), with shearing forces resulting in temporary or permanent disruption of axonal function. Diffuse axonal injury can evolve over a period of 24–72 hours after injury (Povlishock et al. 1983), making it potentially amenable to pharmacological intervention; however, no current ther-

apeutic modality is known to influence its progression (Doppenberg and Bullock 1997).

Direct secondary injury occurs via neurochemical changes evolving over time after the mechanical disruption of neuronal pathways (McIntosh et al. 1996). The acute phase of this process has been well described, with a global increase in cerebral metabolism after injury (Bergsneider et al. 2001; Yoshino et al. 1991). This is accompanied by a period of excessive activity of neurotransmitters, including acetylcholine, glutamate, dopamine, norepinephrine, and various growth factors (Hayes et al. 1992; McIntosh et al. 1996). This may lead to abnormal activation of receptors, causing changes in intracellular signaling that lead to long-lasting modifications of cell function (Hamm et al. 2000). In addition, excessive transmitter activity may have direct neurotoxic effects, leading to apoptosis and permanent dysfunction. A key event in the early phase of injury is excessive influx of calcium (Genarelli and Graham 1998), which may lead to gene activation, triggering preprogrammed cell death and enzyme activation, leading to damage to the cellular cytoskeleton and free radical generation.

The neurochemical changes in the subacute phase of TBI have been less intensively investigated, but current evidence indicates that this phase is associated with a dramatic reversal of acute processes. Cerebral metabolism and function of many neurotransmitters, including glutamate, acetylcholine, dopamine, and norepinephrine, become depressed (Hamm et al. 2000; Hayes and Dixon 1994); given the prominence of these neurotransmitters in psychiatric disorders, these alterations would potentially account for cognitive and neurobehavioral deficits in TBI. Research in animal models of TBI has successfully identified pharmacotherapies to reduce behavioral and histological complications (McIntosh et al. 1998). However, clinical investigations of such agents have been disappointing (Povlishock 2000). Interventions explored include anticholinergics, cholinomimetics, anti-inflammatory agents, calcium channel blockers, free radical scavengers, glutamate antagonists, and hypothermia (Bullock et al. 1999; McIntosh et al. 1998).

## Psychiatric Disorders in Traumatic Brain Injury

Although useful data have been collected in recent years regarding the epidemiology of psychiatric disorders after TBI, the numbers of studies and subjects for each disorder remain small. Other limitations of many studies include selection bias (examining only hospitalized subjects or those referred for psychiatric evaluation), varying assessment periods, use of unstructured psychiatric inter-

views, and limited assessment of premorbid psychiatric history (Van Reekum et al. 2000). Such factors lead to wide variation in the estimates of incidence and prevalence of psychiatric disorders after TBI. Other complex disturbances seen after TBI are not adequately captured by current diagnostic systems such as DSM-IV-TR (American Psychiatric Association 2000). Some symptoms, such as fatigue or impulsivity, may cause significant impairment but may not fit into a specific diagnosis. Also, individuals with TBI may lack insight into, and not report, their deficits. Psychiatrists may give greater weight to the reports of family and treating clinicians for this reason. However, family ratings may be influenced by other factors, including caregiver personality characteristics (McKinlay and Brooks 1984). Similarly, the clinician's emotional response to the patient may interfere with accurate assessment of deficits (Heilbronner et al. 1989). In addition to these general concerns, there may be differences in the presentation and phenomenology of specific disorders in the context of TBI.

The development of psychiatric disorders involves a complex interplay between premorbid biological and psychological factors, postinjury biological changes, and psychosocial and environmental factors. The role of many risk factors has yet to be well elucidated, and many are specific to a given disorder. A recent review (Rao and Lyketsos 2002) compiled risk factors for the development of psychiatric sequelae in general (shown in Table 35-2). These are divided into highly significant risk factors (sufficient evidence exists for their role in psychiatric disorders) and less significant risk factors (evidence is still controversial). In a large unselected primary care population, Fann et al. (2004) found psychiatric history to be a highly significant risk factor for psychiatric illness in the 3 years following TBI. Their data suggested that moderate to severe TBI may be associated with higher initial risk for psychiatric problems, whereas mild TBI and prior psychiatric illness may increase the risk for more persistent psychiatric problems. The authors hypothesized that psychiatric symptoms that arise immediately after TBI may be etiologically related to the neurophysiological effects of the injury, consistent with the early relation between TBI severity and psychiatric risk, whereas other factors, such as psychological vulnerability, self-awareness of deficits, social influences, and secondary gain, may play roles over time, particularly in individuals with prior psychiatric illness and prior injury.

The role of TBI in the etiology of psychiatric disorders after TBI may have significant implications for prognosis and treatment, as well as medicolegal ramifications (Van Reekum et al. 2001). Although several psychiatric disorders are common after TBI, establishing a causal link between these remains difficult. Van Reekum and

**TABLE 35-2. Risk factors for psychiatric illness after traumatic brain injury****Highly significant risk factors**

- Preinjury psychiatric history
- Preinjury social impairments
- Increased age
- Alcohol abuse
- Arteriosclerosis

**Less significant risk factors**

- More severe injury
- Poor neuropsychological functioning
- Marital discord
- Financial instability
- Poor interpersonal relationships
- Low preinjury level of education
- Compensation claims
- Female gender
- Short time since injury
- Lesion location (especially left prefrontal)

colleagues (2000, 2001) noted that there is some evidence for causality, in that studies (particularly in experimental animals) have shown that TBI disrupts neuronal systems involved in mood and behavior. However, other lines of evidence are inconclusive. The following suggestive findings point to other possible associations: 1) the psychiatric disorder increases the risk for TBI (Fann et al. 2002); 2) the risk for both TBI and the psychiatric disorder is due to a common third factor, such as substance abuse; and 3) a postinjury condition, such as pain or change in family status, contributes to the psychiatric disorder. Evidence for a biological gradient, in which more severe injuries are associated with higher risk for psychiatric disorders, is mixed. There is also a lack of specificity: TBI has been postulated to cause a variety of psychiatric disorders and conditions rather than a single specific syndrome. Assigning TBI as the definitive cause of psychiatric disturbances in most instances is not possible under current evidence.

### **Depression**

Varney (1987) noted that 77% of 120 outpatients with TBI who were referred for evaluation were depressed according to DSM-III (American Psychiatric Association 1980) criteria. Studies that used structured interviews noted lower rates. Fann and colleagues (1995) used the National Institute of Mental Health Diagnostic Interview Schedule (DIS) to assess 50 consecutive outpatients presenting to a rehabilitation clinic for evaluation of TBI. Of these, 26% were given the diagnosis of major depression, and another 28% had had major depression with onset af-

ter injury that had since resolved. Hibbard and colleagues (1998) administered the Structured Clinical Interview for DSM-IV (SCID) to 100 patients with TBI who were randomly selected from a larger quality-of-life study. Depression was found in 61%, with the onset of depression after injury in 48%. Deb and colleagues (1999) examined 164 outpatients previously admitted to the emergency department with a diagnosis of TBI. Assessment based on the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) indicated that the rate of depression was 18%. Ashman et al. (2004) administered the SCID to 188 outpatients 3 months to 4 years after injury as part of a longitudinal follow-up of TBI. Major depression was present in 20% of patients before injury and in 24%–35% of patients during the first year of follow-up.

In a systematic examination of depression after TBI, Federoff and colleagues (1992) examined 66 consecutive trauma center admissions with the Present State Examination (PSE), a forerunner of the SCAN. Approximately 1 month after injury, 26% had symptoms that met criteria for major depression. Jorge and colleagues (1993a, 1993b) carried out follow-up examinations on this cohort. At 3 months after injury, 12 of 54 patients (22%) had major depression; at 6 months, 10 of 43 (23%) had major depression; and at 12 months, 8 of 43 (19%) had major depression. Although the prevalence of depression remained fairly stable, some individuals had resolution of depression during the course of the year, whereas others had onset of depression. Of the 41 patients without depression seen for follow-up, 11 (27%) developed depression during the study: 4 (10%) at 3 months, 4 (10%) at 6 months, and 3 (7%) at 12 months. Jorge et al. (2004) subsequently replicated these results in another cohort of 91 consecutive hospital admissions for TBI, showing 33% of the patients developing major depression during the first year after injury: 17% at initial evaluation, 10% at 3 months, and 6% at 6 months.

Kreutzer and colleagues (2001) examined the scores of 722 outpatient referrals for neuropsychological evaluation with the Neurobehavioral Functioning Inventory (NFI), which assesses a wide range of functions after TBI. By mapping 37 of the NFI items to DSM-IV diagnostic criteria, the authors reported that the prevalence of depression was 42%. A subsequent study (Seel et al. 2003) that used the same methodology in 666 patients at 17 TBI Model Systems centers found a rate of 27%. These studies had large sample sizes, but it remains unclear how the authors' mapping of NFI items corresponds with the diagnosis of depression on the basis of DSM-IV criteria in a clinical interview.

In their cohort, Jorge and colleagues (1993b) noted no difference between depressed and nondepressed patients with respect to demographic variables, type or severity of

TBI, family history of psychiatric disorder, or degree of physical or cognitive impairment. Those with depression were significantly more likely to have a premorbid history of psychiatric disorders, including substance abuse. Subjects with depression had significantly poorer social functioning prior to injury, and poor social functioning was the strongest and most consistent correlate of depression on follow-up. Findings from their later cohort were generally consistent with these observations, except that individuals with depression were not more likely than individuals without depression to have a history of substance abuse (Jorge et al. 2004). In their original study (Federoff et al. 1992), depression at 1 month was strongly associated with lesions in the left dorsolateral frontal and/or left basal ganglia regions on computed tomography scanning. Right parieto-occipital lesions were associated with depression to a lesser extent. Pure cortical lesions were associated with a decreased probability of depression. However, no relation was found between lesion location and depression in subsequent follow-ups (Jorge et al. 1993a). In their later study (Jorge et al. 2004), major depression was associated with reduced volume in the left prefrontal cortex at 3-month follow-up. Replication is needed to confirm these correlations.

Fann et al. (2004) found that patients with mild TBI had a higher risk for affective disorders (including depressive and anxiety disorders) than did patients with moderate to severe TBI (e.g., relative risk 2.7 vs. 1.0 in the first 6 months following TBI) among 939 health maintenance organization enrollees with TBI. This finding is consistent with other reports that more severe TBI is not necessarily associated with a higher risk of depression (Fann et al. 1995; Hibbard et al. 1998).

Early studies of major depression showed high rates of vegetative symptoms among individuals with TBI that exceeded the reported rate of depression in these patients. These symptoms include psychomotor slowing, reported at 67%–74% (Cavallo et al. 1992; McKinlay et al. 1981); difficulty concentrating, 38%–88% (Cavallo et al. 1992; Oddy et al. 1978b); fatigue, 33%–71% (Cavallo et al. 1992; Oddy et al. 1978b); insomnia, 27%–56% (Fictenberg et al. 2001); and decreased interest, 21%–55% (Oddy et al. 1978b; Thomsen 1984). Although these investigations did not include a structured psychiatric assessment, the findings raised concern about the validity of using physical symptoms in the diagnosis of depression after TBI. The “inclusive,” “etiological,” “substitutive,” and “exclusive” approaches used in the medically ill have similar advantages and disadvantages in the TBI population. Although no studies have compared these approaches per se in TBI, Jorge et al. (1993a) did use a similar methodology to explore this issue. They found that TBI patients who reported

depressed mood had higher rates of both physical and psychological symptoms of depression (as assessed with the PSE) than did those without depressed mood. The group with depressed mood also endorsed more DSM-III-R (American Psychiatric Association 1987) symptoms of major depression than did those without depressed mood. The symptoms of suicidal ideation, inappropriate guilt, anergia, psychomotor agitation, and weight loss or poor appetite occurred with significantly greater frequency in the depressed group. Studies from patients with other forms of brain injury are similarly encouraging for the use of DSM diagnostic criteria. Paradiso et al. (1997) examined patients with acute stroke; the frequency of major depression was 18% by the inclusive strategy and 22% by the substitutive strategy. Thus, it appears that the diagnosis of major depression can be accurately made with DSM criteria in brain-injured patients.

The course of major depression is the best described of disorders that develop after TBI. Jorge and colleagues found that the mean duration of depression was 4.7 months. Subjects with anxious depression had a significantly longer duration of symptoms than did those with depression and no anxiety (7.5 months vs. 1.5 months). In their follow-up study, 33% of the patients met criteria for major depression during the year after injury. In half of these patients, the depression developed acutely; in the other half, the depression was of delayed onset. The mean duration of depression was 4.7 months for those who received antidepressants and 5.8 months for those who did not. Collectively, these data show that the onset of depression is not immediately linked to the occurrence of TBI in a significant number of individuals.

### *Mania*

The prevalence of bipolar disorder after TBI is difficult to determine because most reports have been single cases or small case series. Varney et al. (1987) noted that 5% of their sample met the criteria for manic episodes, although it is unclear how many of these cases of mania predated the injury. A prevalence of 2% was reported by Hibbard et al. (1998), with all occurring after TBI; and Jorge et al. (1993c) reported that 9% of their subjects met the criteria for mania at some point during the year after injury. In contrast, none of the subjects developed bipolar disorder in the study by Fann et al. (1995). Thus, although TBI may increase the risk for developing bipolar disorder, it still appears to be a relatively rare consequence of injury.

Phenomenologically, all forms of bipolar disorder, including bipolar I, bipolar II, and rapid-cycling variants, have been reported (McAllister 1992). The largest study addressing this topic suggested that patients are more likely to present with irritable than with euphoric mood

(Shukla et al. 1987). Shukla and colleagues (1987) observed that mania after TBI was associated with posttraumatic seizures but not with family history of bipolar disorder. Jorge and colleagues (1993c) noted that mania after TBI was significantly related to basopolar temporal lesions but was not associated with type or severity of TBI, degree of physical or intellectual impairment, family or personal history of psychiatric illness, or posttraumatic epilepsy. They also reported on the course of mania occurring in their subjects. Of the six cases of subjects developing mania after TBI, five occurred within 3 months after injury and one within 6 months after injury. The duration of the manic episode was only 2 months, but elevated or expansive mood persisted for a mean of 5.7 months. These limited data suggest that episodes of bipolar disorder may occur soon after TBI. Its duration is relatively brief, although patients may have subsyndromal disturbances present after mania resolves.

### *Anxiety*

A recent area of interest and controversy has been the development of acute stress disorder and posttraumatic stress disorder (PTSD) after TBI. Early opinion was that PTSD could not develop after TBI; investigators argued that LOC or posttraumatic amnesia would prevent patients from having reexperiencing and avoidance because memories were not encoded (Harvey et al. 2003). This was supported by the studies of Mayou et al. (1993), Sbordone and Llitera (1995), and Warden et al. (1997), each noting that none of their sample that had LOC during injury went on to develop PTSD. However, the first two studies relied on clinical interviews to determine PTSD; and the last used a modified version of the PSE, which assessed only two of the five criterion B (reexperiencing) symptoms. Thus, some experts have raised legitimate concerns that these studies did not adequately assess for PTSD.

Studies with more detailed, structured assessments of PTSD have yielded different results. Hibbard et al. (1998) noted that 19% of their subjects had symptoms that met criteria for PTSD. Mayou and colleagues (2000) examined consecutive admissions to an emergency department with the PTSD Symptom Scale, another structured interview providing DSM-IV diagnosis. Ten of the 21 subjects (48%) with definite LOC met the criteria for PTSD at 3 months, compared with 9 of 39 (23%) with probable LOC, and 179 of 796 (22%) without LOC. At 1-year follow-up, the rates of PTSD were 33%, 14%, and 17%, respectively. Levin and colleagues (2001) interviewed a sample of 69 patients with mild to moderate TBI drawn from admissions to a major trauma center. Twelve percent of the patients received diagnoses of PTSD at 3 months according to the SCID, which was identical to the rate in general

trauma control subjects. Ashman et al. (2004) found that 10% of their subjects met criteria for PTSD prior to injury, with 18%–30% meeting criteria during the first year of follow-up.

A series of studies by Bryant and Harvey represents the most extensive exploration of the topic. Bryant and Harvey (1995) examined 38 hospital admissions with mild TBI with the PTSD Interview, a structured interview for DSM-III-R symptoms of PTSD. Approximately 27% of the subjects met the criteria for diagnosis, although these were not consecutive admissions. In another study, Harvey and Bryant (1998) reported on 79 consecutive hospital admissions with mild TBI. According to the Acute Stress Disorder Interview, a structured clinical interview based on DSM-IV symptoms of acute stress disorder, 14% fulfilled diagnostic criteria. Seventy-one of these subjects participated in follow-up at 6 months (Bryant and Harvey 1998), undergoing assessment with the PTSD module of the Composite International Diagnostic Interview, with 50 following up at 2 years (Harvey and Bryant 2000). Rates of PTSD were 25% at 6 months and 22% at 2 years. Bryant and colleagues (2000) also examined 96 subjects drawn from admissions to a brain injury rehabilitation unit with severe TBI. Approximately 27% of the subjects met the criteria for PTSD on the basis of the PTSD Interview; however, again, subjects were not consecutive admissions, and these data cannot be used to estimate overall prevalence of PTSD after TBI.

Several of these studies also examined risk factors for, and the phenomenology of, PTSD. Bryant and Harvey (1998) noted that 82% of the mild TBI patients who met criteria for acute stress disorder went on to develop PTSD, whereas only 11% of those without acute stress disorder eventually developed PTSD. It is not entirely clear whether memory of the traumatic event is necessary for the development of PTSD. In some cases, those who are “amnesic” for the event will actually have “islands” of traumatic memories that are involved in PTSD. In other cases, patients who do not recall their injury may develop PTSD around traumatic experiences involved in hospitalization, which they do recall. However, patients with mild TBI initially may have low rates of posttraumatic symptoms such as intrusive memories, but these may increase over time to meet criteria for PTSD (Bryant and Harvey 1999). Among those with severe TBI, Bryant and colleagues (2000) noted that the overwhelming majority of patients with PTSD did not have nightmares or intrusive memories but met reexperiencing criteria on the basis of marked psychological distress in response to reminders of the trauma. This area clearly warrants further investigation to determine the appropriateness of a PTSD diagnosis for such individuals.

It seems rather certain that those who do have memories of traumatic events are at increased risk for developing PTSD and should be monitored accordingly (Hiott and Labbate 2002). This is particularly important in light of research suggesting that PTSD occurring after TBI may be less likely to spontaneously remit, with more than 80% of the patients meeting criteria for acute stress disorder having PTSD on reassessment 2 years later (Harvey and Bryant 2000).

Other anxiety disorders also may be fairly common, although the number of investigations into this topic remains quite small. Fann et al. (1995) found that 24% of subjects met the criteria for generalized anxiety disorder (GAD) and 4% had panic disorder after TBI. In the study by Jorge et al. (1993b), 7 subjects (11%) met the criteria for GAD, with all 7 also having major depression. In the follow-up study (Jorge et al. (1993b), 23 (76.7%) of the patients with major depression also met criteria for comorbid anxiety disorder, compared with 9 (20.4%) of the patients without major depression. Hibbard et al. (1998) reported rates of 14% for obsessive-compulsive disorder (OCD), 11% for panic disorder, 7% for phobias, and 8% for GAD after injury. Deb et al. (1999) noted that 9% of their subjects had panic disorder, 3% had GAD, 2% had OCD, and 1% had phobias. Finally, Ashman et al. (2004) found that 16% of their subjects met criteria for other anxiety disorders besides PTSD prior to injury, with 19%–27% having other anxiety disorders during the first year of follow-up. The paucity of studies precludes any firm statements about risk factors for development of anxiety disorders other than PTSD.

### **Psychosis**

Relatively few studies have examined psychosis after TBI. Davison and Bagley (1969) reviewed eight studies before 1960, showing between 0.7% and 9.8% of the patients with TBI having a schizophrenia-like psychosis (but diagnosis was not based on structured criteria). In a different approach, Wilcox and Nasrallah (1987) performed a retrospective review of 659 hospital admissions, finding a significantly higher rate of prior head trauma in patients with schizophrenia compared with control subjects admitted for depression, mania, or general surgery. However, this study would not allow causal inferences to be made. Malaspina and colleagues (2001) examined 1,830 individuals who were first-degree relatives of patients with schizophrenia or bipolar disorder. Compared with other first-degree relatives, those individuals with a history of TBI were significantly more likely to develop schizophrenia. This suggested a synergistic relation between schizophrenia and TBI, in which familial factors among schizophrenic

patients and their relatives increased the risk of TBI, and TBI further increased the risk of schizophrenia in those with genetic vulnerability.

Only a few studies have examined other forms of psychosis. Violon and DeMol (1987) performed a retrospective review of 530 patients with TBI admitted to a neurosurgical unit, noting that 3% had delusions during follow-up. Koponen and colleagues (2002) noted that 3 patients (5%) in their sample met criteria for delusional disorder, and 1 (2%) met criteria for psychotic disorder not otherwise specified. Fann et al. (2004) also found a higher rate of psychotic disorders among persons with TBI, compared with matched non-TBI control subjects, especially in those with moderate to severe TBI and with prior psychiatric illness.

Risk factors and phenomenology are similarly understudied. Sachdev and colleagues (2001) compared symptoms of 45 patients with TBI and psychosis with symptoms of 45 patients with TBI but no psychosis. They noted that auditory hallucinations and paranoid delusions were more common than negative symptoms. Fujii and Ahmed (2002) reviewed descriptions of psychosis after TBI in 69 patients from 39 publications, with particular emphasis on studies that used neuroimaging or neurophysiological measures. Delusions, most commonly persecutory, were much more common than hallucinations, and hallucinations were more likely to be observed in delayed-onset psychosis. Negative symptoms seen in schizophrenia were relatively uncommon.

In their review, Davison and Bagley (1969) identified several risk factors for psychosis, including left hemisphere and temporal lobe lesions, closed head injury, and increasing severity of TBI. Others have noted that more extensive brain injury, greater cognitive impairment, male gender, and having TBI in childhood are associated with psychosis (Fujii and Ahmed 2002; Sachdev et al. 2001).

Electroencephalogram abnormalities (especially in the temporal lobe) were common, and the rates for seizure disorder among individuals with psychosis after TBI were much higher than estimates for the rate of seizures after TBI in general (Fujii and Ahmed 2002). Neuroimaging lesions (predominantly in the frontal and temporal lobes) were also frequent. Finally, the severity and duration of psychosis occurring after TBI may be less than that of idiopathic psychotic disorders, with only about one-third having a chronic course similar to schizophrenia in the studies examining this issue (Hillbom 1960; Violon and DeMol 1987). The onset of psychotic symptoms is typically gradual and delayed, often occurring more than a year after injury (Fann et al. 2004; Fujii and Ahmed 2002; Sachdev et al. 2001).

### *Anger, Aggression, and Agitation*

Many patients with TBI have difficulty modulating emotional reactions and controlling impulses (Rao and Lyketos 2002), often described in the TBI literature as *post-traumatic agitation* (Sandel and Mysiw 1996). However, as noted by Yudofsky et al. (1997), *agitation* is a poorly defined term encompassing behaviors ranging from “constant unwarranted requests” to assaultiveness. Although measures such as the Agitated Behavior Scale (ABS) (Corrigan 1989) have been well validated for TBI, they are rarely used in clinical practice (Fugate et al. 1997). Brooke and colleagues (1992b) used the Overt Aggression Scale (Yudofsky et al. 1986) to measure agitation in 100 patients with severe TBI. Only 11% of the patients had agitation; an additional 35% were classified as “restless” but not severely enough to be labeled “agitated.” Bogner and Corrigan (1995) examined 100 consecutive patients admitted to an inpatient TBI unit. Of these, 42% had agitation (as measured by the Agitated Behavior Scale) during at least one shift. Episodes of anger or aggression are also common (Auerbach 1989).

Although aggression may be a symptom of many disorders, several features are characteristic of aggression after TBI (Yudofsky et al. 1990). Such behavior is typically *nonreflective*, occurring without any premeditation or planning, and *nonpurposeful*, achieving no particular goals for the individual. It is also *reactive*, triggered by a stimulus, but often a stimulus that would not normally provoke a strong reaction. Aggression after TBI is *periodic*, occurring at intervals with relatively calm behavior in between, and *explosive*, occurring without a prodromal buildup. Finally, it is *ego-dystonic*, creating a great deal of distress for the patient.

The lack of precise definitions of agitation and aggression in the literature makes identification of risk factors difficult, although some have been reported. Agitation is more likely to occur with frontotemporal injuries (Van der Naalt et al. 1999). Disorientation, comorbid medical illness, and use of anticonvulsant medications are also associated with agitation (Galski et al. 1994). Risk of aggression is increased with a premorbid history of impulsive aggression (Greve et al. 2001), arrest (Kreutzer et al. 1995), or substance abuse (Dunlop et al. 1991). For these risk factors, it is often difficult to ascertain whether the aggression is a direct result of TBI, premorbid character pathology, or both (Kim 2002). Little is known about the course of agitation or aggression after TBI. However, in their review of the literature, Silver and Yudofsky (1994a) noted that 31%–71% of the individuals had these behaviors in long-term follow-up ranging from 1 to 15 years. Thus, it appears that agitation and aggression may

be chronic problems not confined to the early stage of recovery. This would be expected for such behaviors that predate the injury; it is currently unclear whether agitation and aggression directly resulting from TBI follow this chronic course.

### *Substance Use Disorders*

Substance abuse and dependence are of great concern in the TBI population, at the time of injury and afterward. Substance use disorders not only are highly prevalent and often the underlying cause of injury but also adversely affect outcomes, including agitation, length of coma, post-acute neuropsychological functioning, risk of reinjury, and the ability to reintegrate into the community (Bombardier 2000). Literature reviews have shown that in higher-quality studies, 44%–66% of the patients with TBI have a history of significant alcohol-related problems before injury and that 36%–51% are intoxicated at the time of injury (Bombardier 2000; Corrigan 1995). Those with a history of significant alcohol-related problems before injury are 11 times more likely to have alcohol problems after injury compared with those without alcohol problems before injury (Bombardier et al. 2003). Studies that used informal interviews and screening measures found that 21%–37% report a history of illicit drug use (Bombardier et al. 2002; Kolakowsky-Hayner et al. 1999; Kreutzer et al. 1991, 1996; Ruff et al. 1990). In one study, 37.7% had a positive toxicology screen at the time of injury for one or more illicit drugs (marijuana 23.7%, cocaine 13.2%, amphetamine 8.8%; Bombardier et al. 2002).

Substance abuse declines after TBI but remains significant. Longitudinal data indicate that, depending on the criteria used, rates of remission from alcohol problems range from 31% to 56% during the first year after injury (Bombardier et al. 2003). Data on post-acute heavy drinking and alcohol problems are relatively consistent in that 22%–29% of patients were moderate to heavy drinkers (Bombardier et al. 2002; Kreutzer et al. 1996) or met the criteria for substance abuse or dependence (Hibbard et al. 1998). However, some studies report much lower rates of substance abuse or dependence—8% by Fann and colleagues (1995), 4% by Deb and colleagues (1999), and 10%–14% by Ashman and colleagues (2004). Research in which less formal measures were used has shown that 14%–43% of individuals report significant alcohol or drug use after their injury (Kolakowsky-Hayner et al. 2002; Kreutzer et al. 1990, 1991). Timing of assessment, sensitivity of screening measures, and whether patients were unselected or from referral populations may play critical roles in explaining some of these variations. Risk

factors for postinjury substance abuse include history of legal problems related to substance abuse, substance abuse problems among family and/or friends, age younger than 25 years, and less severe injuries (Taylor et al. 2003).

Brain injury rehabilitation may represent a window of opportunity for intervening in substance abuse disorders (Bombardier et al. 1997). More than 75% of TBI patients considered to be “at-risk” drinkers indicated that they were intending to reduce or were contemplating reductions in their alcohol use during inpatient rehabilitation (Bombardier et al. 2002). Of these patients, 17%–20% reported wanting to enter treatment or try Alcoholics Anonymous, and about 70% wanted to try changing on their own. Several potentially effective interventions, including TBI-specific education, physician advice to cut down or abstain, and brief motivational interventions, should be considered within rehabilitation (Bombardier 2000). Referral to outside substance abuse treatment programs also may be considered, especially when staff at available programs are comfortable with the cognitive and physical disabilities associated with TBI. If such specialized programs are not available, professionals with expertise in TBI should consider educating the program staff about the consequences of injury and assisting with treatment planning (Taylor et al. 2003).

### **Cognitive Impairment**

Much effort has been devoted to characterizing the cognitive deficits that occur after TBI. Some have suggested that deficits can be divided into four time periods (Rao and Lyketsos 2000). The first is the period of LOC that results from the injury. After emerging from unconsciousness, many individuals enter a phase consisting of multiple cognitive and behavioral deficits, which some have described as posttraumatic delirium (Kwentus et al. 1985; Trzepacz 1994). The third period is a rapid recovery of cognitive function, which plateaus over time. This leads to the fourth period of permanent cognitive deficits. TBI is associated with deficits in multiple domains, including impaired memory, language deficits, reduced attention and concentration, slowed information processing, and executive dysfunction (Capruso and Levin 1996).

Although TBI is associated with an acute decrement in cognitive function that typically improves over time, recovery is very individualized, and there is no universally applicable description of the recovery process. Rao and Lyketsos (2000) offer the following general timeline: the first two periods of recovery will last from a few days to a month, the third period will last 6–12 months, and the fourth period will last 12–24 months. Such guidelines are more characteristic of moderate to severe injuries. By definition, individuals with mild TBI will have LOC of less

than 30 minutes, with many having none at all (Kay et al. 1993). It is also estimated that about 95% of patients with mild TBI will recover to baseline status within 3–6 months and not enter the fourth phase of permanent deficits (Binder et al. 1997). Even among individuals with moderate to severe TBI, some recovery of cognitive function may occur 2 years or more after injury, although the gains are typically small (Millis et al. 2001). A few patients may experience decline late in the course of recovery, perhaps caused by depression (Millis et al. 2001). Thus, these time frames must be considered general approximations only.

Descriptions of the period of recovery from TBI vary in the rehabilitation literature. One classical term is *posttraumatic amnesia*, which occurs “from injury until recovery of full consciousness and the return of ongoing memory” (Grant and Alves 1987). This would include the first two periods described above and potentially extend into the third. However, characterization of the deficits after TBI as purely amnesic is an oversimplification because multiple cognitive deficits occur (D.I. Katz 1992). Stuss and colleagues (1999) advocated discarding *posttraumatic amnesia* for the concept of *posttraumatic confusion*, although this has not gained widespread use in the TBI literature. Another common term for the period of recovery after TBI is *posttraumatic agitation*, characterized by “excesses of behavior that include some combination of aggression, akathisia, disinhibition, and/or emotional lability” (Sandel and Mysiw 1996, p. 619). This would correspond closely to the second period described earlier.

Unfortunately, the terminology used in the rehabilitation literature does not correspond exactly to DSM-IV psychiatric diagnoses. Most definitions of posttraumatic amnesia would be consistent with a period of delirium followed by an amnesic phase (Trzepacz and Kennedy 2005). The term *posttraumatic confusion* more closely resembles the diagnosis of delirium yet still omits features such as mood and perceptual disturbances. Posttraumatic agitation is defined by some experts as a subtype of delirium (Sandel and Mysiw 1996), yet others have noted that agitation may resolve while the confusional state persists (Van der Naalt et al. 1999). A recent study (Thompson et al. 2001) examined this issue in detail by concurrently rating inpatients with TBI on the Delirium Rating Scale (DRS) (Trzepacz et al. 1988), a standardized measure for delirium; the Galveston Orientation and Amnesia Test (GOAT) (Levin et al. 1979), a measure of posttraumatic amnesia; and the Agitated Behavior Scale (ABS) (Corrigan 1989), a measure of posttraumatic agitation. Of those with a diagnosis of delirium, 22.5% had normal scores on the ABS, and 7.5% had normal scores on the GOAT. Among those without delirium, 7.5% had abnormal scores

on the ABS, and 27.5% had abnormal scores on the GOAT. A combination of GOAT and ABS scores classified the delirium diagnosis with 77.5% accuracy. Thus, although the terms *delirium*, *posttraumatic amnesia*, and *posttraumatic agitation* describe conditions that share many common features, they are not synonymous.

The long-term, diffuse cognitive deficits seen after TBI would be categorized as dementia due to head trauma or cognitive disorder not otherwise specified under DSM-IV-TR. This would include the fourth period described earlier and potentially the third period when the recovery process is slow. Rehabilitation experts have expressed concern with use of the term *dementia* in the TBI population (Leon-Carrion 2002). The impairments seen after TBI, unlike those seen in most dementias, tend to be either static or improving over time. Experts also have expressed concern that application of DSM criteria would lead to diagnoses of dementia in the vast majority of individuals with moderate and severe TBI, with potential legal and social ramifications. Clearly, these implications should be further studied and addressed, but the DSM framework provides a useful, standardized approach to diagnosis in this population that might otherwise be lacking.

Preliminary studies suggest that delirium after TBI shows phenomenological similarities to other types of delirium (Sherer et al. 2003b), with both hypo- and hyperactive subtypes noted in other patient populations. The hyperactive subtype appears more common and is associated with agitation and high frequency of hallucinations or delusions. Several risk factors for delirium in the medical-surgical population would likely apply to individuals with TBI (Trzepacz and Kennedy 2005), who are at increased risk for several medical illnesses (Kalisky et al. 1985; Shavelle et al. 2001). Risk factors for prolonged posttraumatic amnesia include older age, low initial GCS score, non-reactive pupils, coma duration, higher number of lesions detected by neuroimaging, and use of phenytoin (Ellenberg et al. 1996; Wilson et al. 1994). These would likely be risk factors for delirium as well. Unfortunately, patients who are traditionally considered to have a higher risk for delirium—especially alcoholic patients, elderly patients, those with psychiatric and neurological histories, and those with prior brain injury—are nearly always excluded from posttraumatic amnesia studies (Trzepacz and Kennedy 2005).

For dementia, severity of injury is consistently associated with the degree and duration of cognitive impairments. The extent of impairment is also influenced by premorbid intellectual abilities and the time after injury at which the patient is assessed (Dikmen et al. 1995). As with other dementias, the cognitive domains affected will vary from patient to patient (Kreutzer et al. 1993). Pa-

tients with TBI also may be at increased risk for developing dementia from other causes, such as Alzheimer's disease (Amaducci et al. 1986; Graves et al. 1990).

### *Postconcussive Syndrome*

The diagnosis of postconcussive syndrome has been a source of wide controversy. It is important to differentiate postconcussive *symptoms* from postconcussive *syndrome*. The *symptoms* of postconcussive syndrome are very non-specific and include disturbances such as headache, dizziness, irritability, fatigue, and insomnia. Indeed, several studies have documented high base rates of postconcussive *symptoms* among subjects without TBI, often at rates similar to those in individuals with mild TBI (Caveness 1966; Gouvier et al. 1988; McLean et al. 1983; Tuohimaa 1978). There is disagreement as to the number and types of symptoms required for postconcussive *syndrome*. Most experts concur that the diagnosis of postconcussive syndrome requires the presence of multiple concurrent symptoms (Brown et al. 1994; Mittenberg and Strauman 2000), although disagreement may remain over which specific symptoms are required. More recently, standardized diagnostic criteria for postconcussive syndrome have been developed. DSM-IV-TR lists provisional criteria for postconcussional disorder (Table 35–3), indicating that the diagnosis may still undergo refinement.

The most widely published criteria are those in ICD-10 (World Health Organization 1992), listed in Table 35–4. Unfortunately, few studies have used either of these criteria sets (Mittenberg and Strauman 2000). The adoption of such standard definitions will be a necessary step in advancing the study and treatment of postconcussive syndrome.

Because postconcussive symptoms are not specific to TBI, it is important to consider their differential diagnosis. Alexander (1995) and Mittenberg and Strauman (2000) noted that postconcussive syndrome has significant overlap with psychiatric disorders. Both major depression and postconcussive syndrome have symptoms of depressed mood, irritability, sleep disturbance, fatigue, and difficulty with concentration. However, unlike major depression, postconcussive syndrome does not include symptoms of changes in appetite, psychomotor changes, or suicidal ideation. PTSD and postconcussive syndrome have common symptoms of anxious mood, difficulty sleeping, irritability, poor concentration, and difficulty recalling the injury. Postconcussive syndrome is not associated with persistent reexperiencing of the event or with numbing of responsiveness, and PTSD is not associated with the headaches, dizziness, or general memory disturbance that characterize postconcussive syndrome. Symptoms such as headache, fatigue, dizziness, blurred vision,

**TABLE 35-3. DSM-IV-TR research criteria for postconcussional disorder**

- A. A history of head trauma that has caused significant cerebral concussion.  
 Note: The manifestations of concussion include loss of consciousness, posttraumatic amnesia, and, less commonly, posttraumatic onset of seizures. The specific method of defining this criterion needs to be established by further research.
- B. Evidence from neuropsychological testing or quantified cognitive assessment of difficulty in attention (concentrating, shifting focus of attention, performing simultaneous cognitive tasks) or memory (learning or recalling information).
- C. Three (or more) of the following occur shortly after the trauma and last at least 3 months:
- (1) becoming fatigued easily
  - (2) disordered sleep
  - (3) headache
  - (4) vertigo or dizziness
  - (5) irritability or aggression on little or no provocation
  - (6) anxiety, depression, or affective lability
  - (7) changes in personality (e.g., social or sexual inappropriateness)
  - (8) apathy or lack of spontaneity
- D. The symptoms in criteria B and C have their onset following head trauma or else represent a substantial worsening of preexisting symptoms.
- E. The disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning. In school-age children, the impairment may be manifested by a significant worsening in school or academic performance dating from the trauma.
- F. The symptoms do not meet criteria for dementia due to head trauma and are not better accounted for by another mental disorder (e.g., amnesic disorder due to head trauma, personality change due to head trauma).

memory disturbance, and hypochondriacal preoccupation with health may be part of postconcussive syndrome or of a somatoform disorder. Postconcussive syndrome is not associated with the gastrointestinal symptoms often seen in somatization disorder, and it is also not associated with marked motor or sensory deficits or nonepileptic seizures often seen in conversion disorder. Patients with chronic pain also may have symptoms of headaches, fatigue, poor sleep, poor concentration, depressed mood, and dizziness that overlap with postconcussive syndrome.

**TABLE 35-4. ICD-10 criteria for postconcussive syndrome**

- A. History of head trauma with loss of consciousness precedes symptom onset by maximum of 4 weeks.
- B. Three or more symptom categories
1. Headache, dizziness, malaise, fatigue, noise intolerance
  2. Irritability, depression, anxiety, emotional lability
  3. Subjective concentration, memory, or intellectual difficulties without neuropsychological evidence of marked impairment
  4. Insomnia
  5. Reduced alcohol tolerance
  6. Preoccupation with above symptoms and fear of brain damage with hypochondriacal concern and adoption of sick role

Thus, the presence of psychiatric disorders may lead to high rates of reporting of postconcussive symptoms, regardless of TBI history (Fox et al. 1995; Suhr and Gunstad 2002; Trahan et al. 2001). Careful history taking and diagnosis are needed to avoid mislabeling these patients as having postconcussive syndrome. The clinician also must keep in mind that individuals may have both postconcussive syndrome and a psychiatric disorder, which may blur the boundaries between the two.

Studies have examined risk factors and time course for the development of postconcussive syndrome. However, failure to use standardized diagnostic criteria for postconcussive syndrome in most studies makes generalization difficult. Most studies of postconcussive syndrome have focused on individuals with mild TBI, although postconcussive syndrome can occur with more severe injuries as well. The symptoms of postconcussive syndrome are extremely common after mild TBI, with 80%–100% of patients experiencing one or more symptoms in the immediate postinjury period (Levin et al. 1987a). Several studies have shown that such symptoms resolve completely within 3 months in most patients (Alves et al. 1986; R.W. Evans 1996; Leininger et al. 1990). However, other prospective studies have shown that 20%–66% of patients have persistent symptoms at 3 months (Alves et al. 1986; Englander et al. 1992) and that 1%–50% have persistent symptoms at 1 year (Middleboe et al. 1992; Rutherford et al. 1979). Alves and colleagues (1993) followed up the resolution of these symptoms in 587 consecutive adult hospital admissions with mild TBI, with assess-

ments at baseline and at 3, 6, and 12 months. Approximately two-thirds of the patients had symptoms of postconcussive syndrome at discharge, with progressive decline in prevalence during recovery. At 3 months, 40%–60% experienced such symptoms; at 6 months, 25%–45%; and at 12 months, 10%–40%. Most of these subjects reported only one or two postconcussive symptoms and would not qualify for a diagnosis of postconcussive syndrome under DSM or ICD. Subjects with multiple symptoms consistent with a diagnosis of postconcussive syndrome were rare—between 1.9% and 5.8% of those studied. For this and many other studies, the lack of an appropriate control group makes it difficult to determine how many of these symptoms could be attributed to the TBI itself.

Because the symptoms of postconcussive syndrome are nonspecific, some have questioned whether it constitutes a true disorder or syndrome (King 1997, 2003). There also is a long-standing debate as to whether postconcussive syndrome constitutes a neurological or a psychiatric syndrome (King 2003; Mittenberg et al. 1996). Currently, the acute syndrome is thought to be related to neurological factors, whereas chronic symptoms are more likely to persist because of psychological factors (Larrabee 1997; Mittenberg and Strauman 2000). Complaints of poor sleep, difficulty concentrating, and memory disturbances that arise shortly after TBI may be caused by direct neuronal injury (Alexander 1997). Dizziness may be due to central or peripheral vestibular injury, and pain complaints may be due to musculoskeletal or scalp injury (Alexander 1997). It is not known how these putative neurological injuries, which should resolve quickly, transition into chronic postconcussive syndrome. Symptom expectations, in which patients fear that their symptoms will not resolve, may play a role (King 2003; Mittenberg and Strauman 2000; Mittenberg et al. 1996). However, the precise role of psychological factors in persistent postconcussive syndrome is far from clear (Dikmen et al. 1989). Thus, the risk factors for postconcussive syndrome are a mixture of biological and psychological.

The more commonly reported risk factors are female gender (Bazarian et al. 1999; Fenton et al. 1993; McCauley et al. 2001; McClelland et al. 1994), older age (Alexander 1997; McCauley et al. 2001), history of previous TBI (Alexander 1997; McCauley et al. 2001), psychosocial stress (Fenton et al. 1993; Moss et al. 1994; Radanov et al. 1991), and poor social support (Fenton et al. 1993; McCauley et al. 2001). Low socioeconomic status and ongoing litigation also increase risk (Alexander 1997; Binder and Rohling 1996; McCauley et al. 2001). However, for the latter, it should be noted that few individuals involved in litigation have improvement in postconcussive syn-

drome after settlement (King 2003). Finally, in examining postconcussive symptoms among individuals without TBI, Gouvier and colleagues noted that females had higher rates of symptom reporting, and rates of reporting increased with levels of psychosocial stress (Gouvier et al. 1992; Santa Maria et al. 2001).

A significant association is seen between depression and postconcussive symptoms, including those postconcussive symptoms that do not overlap with depression (Fann et al. 1995; King 2003), and severity of depressive symptoms predicts risk for postconcussive syndrome (McCauley et al. 2001). McCauley and colleagues (2001) used portions of the SCID to identify major depression and PTSD as significant moderators of postconcussive syndrome. It appears that psychiatric disorders, particularly depression, may significantly amplify the presentation of postconcussive symptoms.

Although the vast majority of the persons with mild TBI experience good recovery (Binder et al. 1997), Ruff (1999) identified a “miserable minority” of 10%–20% of mild TBI patients with poor outcome, and Malec (1999) noted that 20%–40% of mild TBI patients have residual long-term symptoms or disability. In many cases, such individuals complain of symptoms of postconcussive syndrome, indicating that ongoing postconcussive syndrome may be an important source of disability. Studies of such patients also have found significant deficits on a variety of neuropsychological tests (Bohnen et al. 1992; Guilmette and Rasile 1995; Leininger et al. 1990), although it remains unclear how these difficulties develop during the course of postconcussive syndrome. The severity of postconcussive symptoms is consistently correlated with severity of impairment in information-processing speed, but correlations with other cognitive domains (such as verbal and visuospatial abilities) are equivocal (King 2003). In particular, Larrabee (1999) commented on two of these studies, which consisted of patients experiencing postconcussive symptoms after TBI with LOC of less than 30 minutes. The effects on neuropsychological testing seen in these patients were equivalent to the effects observed in patients with 1–4 weeks of coma in other studies (Dikmen et al. 1995). These data suggest that individuals with persistent postconcussive syndrome differ in significant respects from most individuals with TBI, although the reasons for these differences remain unexplained. Investigators also have found that high rates of postconcussive symptoms were better predictors of neuropsychological test performance than was actual history of mild TBI (Hanna-Pladdy et al. 1997; Pinkston et al. 2000). These results cast further doubt on the contention that the cognitive impairment in persistent postconcussive syndrome is due to TBI.

## Psychological Aspects

In addition to the defined DSM-IV-TR psychiatric disorders, TBI is associated with psychological challenges that may not fit into specific diagnostic categories. Four areas of importance are the neurological disorder and resultant cognitive deficits, the psychological meaning of deficits and effect on the patient, psychological factors that exist independently of TBI, and the broader social context (Lewis 1991).

Deficits due to neurological impairment may have a direct effect on psychological functioning. Impaired self-awareness is common after TBI, with 76%–97% of TBI patients showing some degree of impairment (Sherer et al. 1998c, 2003a). Many individuals with TBI also have deficits in awareness of their behavioral limitations (Prigatano and Altman 1990), which may be one of their most troubling problems (Ben-Yishay et al. 1985; Prigatano and Fordyce 1986). Awareness of cognitive and emotional changes tends to be worse than awareness of physical dysfunction (Sherer et al. 1998c). There is little agreement on the most appropriate way to measure lack of awareness (Sherer et al. 1998b, 2003a). Comparisons of patient reports with those of family members (D.J. Fordyce and Roueche 1986; Hendryx 1989; McKinlay and Brooks 1984; Prigatano 1996; Prigatano and Altman 1990; Prigatano et al. 1990; Walker et al. 1987) or rehabilitation providers (D.J. Fordyce and Roueche 1986; Gasquione 1992; Gasquione and Gibbons 1994; Heilbronner et al. 1989; Ranseen et al. 1990) may be biased by respondent characteristics. Comparing patient reports with neuropsychological test results can eliminate much of this subjectivity but may not allow the consultant to gauge the accuracy of patient self-reports of real-world functioning (Allen and Ruff 1990; Anderson and Tranel 1989; Heaton and Pendleton 1981). The method of questioning is also important, because studies have shown that patients are much less likely to report deficits when asked general questions rather than specific ones (Gasquione 1992; Sherer et al. 1998b).

Impaired awareness has both neurological and psychological dimensions. At one extreme is anosognosia, wherein the person has no awareness of neurological impairments (Prigatano 1999). At the other extreme is “defensive denial,” which represents the person’s attempt to cope with overwhelming anxiety associated with neurological impairment by minimizing the implications. Apparent impaired awareness also can be the result of moderate to severe memory impairment that prevents the person from consolidating and acting on new information about his or her condition. The neuroanatomic underpinnings of impaired self-awareness are not well documented,

but hypoarousal associated with subcortical damage and various types of cortical damage are thought to contribute (Prigatano 1999). Few studies have attempted to separate neurological from psychological causes of decreased awareness (Boake et al. 1995; McGlynn and Schacter 1989). Phenomenologically, decreased awareness might appear the same regardless of cause but has significant treatment implications. Interventions designed to address denial and other forms of decreased awareness resulting from psychological causes may be ineffective when the decreased awareness is due to neurological dysfunction that cannot be reversed.

Finally, most studies of awareness have focused on individuals who overestimate their abilities compared with the reports of others. However, some patients underestimate their abilities; the deficits that these individuals have in awareness have not been well studied (Prigatano and Altman 1990). Although more than a half-dozen instruments have been developed for measurement of awareness in the TBI population, there has been little work on the psychometric properties or factor structures of these instruments (Seel et al. 1997; Sherer et al. 1998b). Currently, the most systematically studied are the Patient Competency Rating Scale (PCRS; Prigatano and Fordyce 1986) and the Awareness Questionnaire (Sherer et al. 1998a). The available literature suggests that such deficits are common immediately after TBI, with gradual improvement over time (C. Evans et al. 2003).

The patient’s psychological state and the perceived meaning of physical and cognitive deficits may be strongly linked. Patients with depression or anxiety appear to perceive their injury and associated cognitive problems as more severe (Fann et al. 1995, 2000). Many patients with TBI experience grief in reaction to their disability and loss of their “former self.” For many years, rehabilitation researchers have relied on bereavement concepts to explain the adjustment-to-disability process (Stewart and Shields 1985; Vargo 1978). However, long-held assumptions about the symptoms and process of normal bereavement have not withstood empirical testing (Marwit 1996; Stroebe et al. 2001; Wortman and Silver 1989). For example, the 2-month time limit placed on a “normal” grieving process in DSM-IV has been called into question (Parkes and Weiss 1983; Wortman and Silver 1989). Also, contrary to the belief that a person must make a “show” of grief, some support exists for the benefits of focusing on positive emotions (Bonanno and Kaltman 1999). Finally, advances in the understanding of grief following loss of a loved one, with few exceptions (Niemeier and Burnett 2001), have not yet been applied to the emotional experience of individuals with functional and cognitive losses due to illness or injury.

Psychological defenses and adaptations used by the patient prior to TBI are also important. In many cases, patients will continue to use previously learned defenses. However, in some instances, coping mechanisms used before the injury may no longer be available because of the degree of neurocognitive impairment; this can cause considerable distress for the patient. Evidence indicates that many behavioral traits are exacerbated by TBI rather than developing *de novo* after injury (Prigatano 1991). Such alterations would be diagnosed as personality change due to TBI in DSM-IV-TR.

Finally, as with many other chronic illnesses, TBI has a significant effect on family and social functioning. Patients with TBI may be unable to return to their former roles as breadwinner, parent, or spouse, placing significant demands on other members of the family system (Kay and Cavallo 1994). In general, neurobehavioral disturbances are the most important source of stress for the family, but this effect can be mediated by good social support (Ergh et al. 2002; Groom et al. 1998). Family members are at significantly increased risk for psychiatric disorders, particularly anxiety and depression, and for increased substance use (Hall et al. 1994; Kreutzer et al. 1994; Livingston et al. 1985). Caregivers may experience problems such as unemployment or financial loss, placing additional stresses on the patient and family (Hall et al. 1994). Sexual dysfunction after TBI stresses intimate relationships (Hibbard et al. 2000a), and partners may be uncomfortable with the dual role of caregiver (parentlike) and sexual partner (spouse) (Gosling and Oddy 1999). Rates of separation and divorce are also elevated for individuals with TBI (Webster et al. 1999).

## Spinal Cord Injury

---

### Epidemiology

SCI results from trauma to the spinal cord and may cause changes in motor, sensory, or autonomic functioning. SCI is an uncommon but often catastrophic injury with an annual incidence of 30–40 per million and a point prevalence of 183,000–230,000 in the United States (Go et al. 1995). Those that sustain spinal cord injuries are predominantly males (80%), young (half are aged 16–30), and Caucasian (89%). At the time that they are injured, those sustaining SCI are less likely to be married, twice as likely to be divorced, and slightly less educated than the general population. The most common causes of SCI are motor vehicle crashes (44.5%), falls (18.1%), sports activities (12.7%), and violence (16.6%).

Early survival and overall life expectancy rates for persons with SCI have improved dramatically over the

last 30 years. However, life expectancy with SCI remains below that of the general population, especially among those that are ventilator-dependent (DeVivo et al. 1999). Leading causes of death are heart disease (19%); external causes such as accidents, suicide, and violence (18%); respiratory illness, especially pneumonia (18%); and septicemia (10%) (DeVivo et al. 1999). Death from suicide is approximately five times more common in people with SCI than in the general population (59.2 per 100,000) and represents about 9% of deaths. Most suicides occur within 5 years of injury (Charlifue and Gerhart 1991).

### Severity and Classification

*Tetraplegia* (or quadriplegia) denotes SCI that affects all four limbs, whereas *paraplegia* denotes injuries affecting only the lower extremities. SCI usually is described in terms of the level and the completeness of injury. The level of injury refers to the most caudal segment with normal motor or sensory function. Neurological level of injury may vary on the right and the left side, and segments also may be partially innervated. More than half of all injuries (54%) result in tetraplegia, whereas 46% are classified as resulting in paraplegia. The midcervical region is the most common site of injury. Injury severity is most commonly described according to the American Spinal Injury Association (ASIA) Impairment Scale (Table 35–5). Approximately half of all injuries are considered ASIA-A or “complete.” Of those admitted with an ASIA-A SCI, only about 2% are expected to improve to the point of having functional motor recovery below the level of their injury. In contrast, those admitted with an ASIA-B injury have about a 35% chance of regaining functional motor abilities below the level of their lesion. Those admitted with an ASIA-C injury have a 71% chance of regaining functional motor ability below the level of their injury (Marino et al. 1999).

### Acute Management and Management of Secondary Complications

Emergency management of SCI involves immobilization of the spine as well as ensuring an open airway, breathing, and circulation. In many settings, standard practice is to administer a large intravenous bolus of methylprednisolone within 8 hours of injury to minimize secondary injury due to swelling within the spinal canal. Unstable spine fractures may require surgical decompression and stabilization. Various orthoses are used to maintain external spinal stabilization after surgery, typically for 3 months.

**TABLE 35-5. American Spinal Injury Association (ASIA) Impairment Scale**

- A Complete**—No sensory or motor function is preserved in the sacral segments S4/5.
- B Sensory Incomplete**—Sensory but no motor function is preserved below the neurological level and includes the sacral segments S4/5.
- C Motor Incomplete**—Motor function is preserved below the neurological level, and more than half of the key muscles below the neurological level have muscle grade less than 3 (active movement against gravity). There must be some sparing of sensory and/or motor function in the sacral segments S4/5.
- D Motor Incomplete**—Motor function is preserved below the neurological level, and at least half of the key muscles below the neurological level have a muscle grade greater than or equal to 3. There must be some sparing of sensory and/or motor function in the sacral segments S4/5.
- E Normal**—Sensory and motor functions are normal. Patient may have abnormalities of reflex examination.

Key aspects of postsurgical care include respiratory management and prevention of pneumonia, management of orthostatic hypotension associated with blood pooling in the lower extremities, and prevention of deep venous thrombosis and pulmonary embolus from venous stasis and hypercoagulability. Neurogenic bladder and bowel management begins with indwelling or intermittent catheterization and establishment of a regular bowel regimen. After injury, heterotopic ossification, the deposition of new bone in and around joints, may cause loss of range of motion. Spinal reflexes are initially depressed during the period of “spinal shock” but then become hyperactive during the first 6 months after injury. Daily range of motion and static muscle stretch are used to reduce spasticity and prevent contractures, along with medication such as baclofen, diazepam, and clonidine. Pain is a common problem; 25% complain of severe pain, and 44% report that pain interferes with daily activities (Staas et al. 1998). Several different types of pain are noted, including radicular pain, central or diffuse pain, visceral pain, musculoskeletal pain, and “psychogenic” pain (Staas et al. 1998). Of the patients with recent SCI, 10%–60% may have cognitive impairment (Davidoff et al. 1992). Cognitive deficits may be attributable to a variety of factors, including pre-injury learning disabilities and substance abuse as well as traumatic or hypoxic brain injury sustained at the time of SCI. Behavior problems such as noncompliance, anger,

and agitation may be attributable to premorbid traits or undetected brain injury. A severe complication for people with midthoracic or higher spinal cord injuries is autonomic dysreflexia. Autonomic dysreflexia is often triggered by a noxious stimulus below the level of lesion that leads to sympathetic discharge uninhibited by descending neural control. Immediate steps must be taken to control hypertension and to identify and reverse the triggering stimulus. The most common secondary medical complication during the first year postinjury is pressure ulcers (McKinley et al. 1999).

## Acute Rehabilitation

Patients are usually transferred to specialized rehabilitation programs once they are medically stable and can participate in therapies for at least 3 hours per day. Inpatient rehabilitation typically focuses on education, physical training, strengthening, and basic skills building needed to return to maximal functional independence for living in the community. People with paraplegia are usually expected to be able to function and live independently once their rehabilitation is complete. Those with low cervical lesions (C7–8) should be independent in most functional tasks. Depending on their neurological level, people with higher cervical lesions require different degrees of assistance for activities of daily living, such as managing bowel and bladder, bathing, dressing, eating, and transferring to and from a wheelchair. Whatever his or her level of injury, the person with SCI is expected to be independent in guiding others to care for him or her in areas the person cannot perform on his or her own.

## Adjustment to Spinal Cord Injury

Following discharge from acute rehabilitation, 91% of the people with SCI are discharged to a home environment (Eastwood et al. 1999). Estimates of employment rates after SCI have varied from 13% to 69%. Recent data show that, overall, 27% were employed, with 14% employed within 1 year and 35% employed within 10 years postinjury (Krause et al. 1999). Subjective well-being and quality of life are somewhat controversial, especially with regard to patients with high tetraplegia. The controversy relates to the tendency of health care workers to overestimate depressed mood and underestimate potential quality of life in survivors of SCI (Caplan 1983; Gerhart et al. 1994; Trieschmann 1988). In sharp contrast with what health care workers predict, more than 90% of the people living in the community with high tetraplegia, including those with ventilator dependence, report that they are “glad to be alive” (Gerhart et al. 1994). Nevertheless, people

with SCI tend to report lower subjective quality of life compared with nondisabled persons (Gerhart et al. 1994). It is somewhat surprising that quality of life is generally unrelated to level of injury or injury severity, weakly related to physical impairment, and more strongly related to one's ability to carry out day-to-day tasks and participate in school, work, or other community activities (Dijkers 1997). Therefore, factors such as environmental and psychosocial variables may play major roles in quality of life after SCI. Quality of life is higher among those with a longer time since injury, those who are working, and those with few or no medical problems, especially pain (Westgren and Levi 1998).

Common biased expectations among rehabilitation staff and their misapplication of stage models have interfered with appropriate understanding and intervention to promote psychological adjustment to SCI (Elliott and Frank 1996; Trieschmann 1988). In numerous studies, rehabilitation staff, primarily nurses and therapists, have been found to regularly overestimate depressed mood in SCI patients (Trieschmann 1988). Rehabilitation staff also tend to view signs of depression as a normal, even necessary, stage of grief. An SCI patient wrote that the most depressing part of his rehabilitation program was that staff expected him to be depressed, an expectation dubbed "the requirement of mourning" (Trieschmann 1988). Empirical data contradict popular conceptualizations of grief. Most people who sustain significant losses (including SCI) do not become depressed and do not go through traditional "stages of grief" (Bonanno et al. 2002; Wortman and Silver 1989). In a study that used the Beck Depression Inventory to measure depressive symptoms weekly during inpatient rehabilitation, about 60% of the SCI patients never scored in the depressed range, 20% endorsed significant depressive symptoms only once, and 20% reported significant depressive symptoms at multiple time points requiring treatment with antidepressants (Judd et al. 1989). Viewing persisting depression as a normal or even healing part of the grief process may interfere with appropriate recognition and treatment of major depression. Conversely, staff may judge the absence of depression to be pathological, a sign of denial or poor adjustment and an indication that the staff should confront the patient more forcefully with the implications of his or her impairments.

In the absence of empirically supported approaches to manage grief and poor adjustment, the consultant is advised to "do no harm" by eschewing confrontational approaches that may only damage relatively healthy defenses or increase patient resistance. We recommend tolerance of adjustment patterns that are not interfering with rehabilitation. We also attempt to educate staff and

family members about countertherapeutic myths of coping with loss, such as the belief that it is necessary to "work through" the loss, that patients should reach a state of "acceptance," and that the absence of grief is pathological (Wortman and Silver 1989).

## Psychiatric Disorders in Spinal Cord Injury

### *Depression*

Major depressive disorder is probably the most common psychiatric disorder after SCI (Fullerton et al. 1981). The prevalence of major depression after SCI ranges from 23% to more than 30% in 12 separate studies (see Elliott and Frank 1996 for review). There is reasonable consistency across studies on rates of major depression based on diagnostic interviews and self-report measures. Some studies suggest that depression may be more common soon after injury but may remit after several months (Kishi et al. 1994, 1995). In unselected cases, mood tends to improve over the first year after injury (Richards et al. 1986). However, other studies suggest that a subgroup of about 30% of patients develop significant depressive and anxiety symptoms soon after injury and remain highly depressed and anxious through at least 2 years after injury (Craig et al. 1994).

Depression is a significant and disabling problem for persons with SCI. Depression is associated with longer lengths of hospital stay and fewer functional improvements (Malec and Neimeyer 1983) as well as less functional independence and mobility at discharge (Umlauf and Frank 1983). Depression is associated with the occurrence of pressure sores and urinary tract infections (Herrick et al. 1994), poorer self-appraised health (Schulz and Decker 1985), less leisure activity (Elliott and Shewchuck 1995), poorer community mobility and social integration, and fewer meaningful social pursuits (Furher et al. 1993; MacDonald et al. 1987). Persons with SCI and significant depression spend more days in bed and fewer days outside the home, require greater use of paid personal care, and incur greater medical expenses (Tate et al. 1994). Moreover, symptoms consistent with depression, such as documented expressions of despondency, hopelessness, shame, and apathy, are the variables most predictive of suicide 1–9 years after SCI (Charlifue and Gerhart 1991).

### *Anxiety*

Relatively few studies have examined PTSD or other anxiety disorders in this population. Rates of current PTSD have been found in 14%–22% of the patients with SCI (Kennedy and Evans 2001; Radnitz et al. 1998). Rates of PTSD appear to vary as a function of level of injury, with lower rates found among those with tetraplegia (2%)

compared with those with paraplegia (22%; Radnitz et al. 1998). This variability has been attributed to diminished experience of psychophysiological arousal, which may occur in higher-level injuries (Kennedy and Duff 2001). Current PTSD appears to be no more prevalent in persons with SCI than in other trauma survivors. People with SCI who are war theater veterans, have prior exposure to violence, or have limited social support may be at higher risk for PTSD (Kennedy and Duff 2001). Elevated levels of general anxiety also have been found in people with SCI (Craig et al. 1994; Kennedy and Rogers 2000), particularly in a subgroup of patients with chronic comorbid depression.

PTSD symptoms are also common in families of persons with SCI. Boyer and colleagues (1998) found that 25% of pediatric SCI survivors reported significant current PTSD symptoms, but 41% of mothers and 36% of fathers also endorsed significant PTSD symptoms on self-report measures.

### Substance Use Disorders

High rates of alcohol and drug abuse problems are found among trauma patients generally and SCI patients specifically (Bombardier 2000). Preinjury alcohol problems are common (35%–49%) (Bombardier and Rimmele 1998; Heinemann et al. 1988). Rates of alcohol intoxication at the time of injury range from 36% to 40% (Heinemann et al. 1988; Kiwerski and Krauski 1992). After SCI, substance abuse appears to decline but remains somewhat higher than in the general population and, importantly, may be more harmful because of its association with poorer health maintenance behaviors (Krause 1992). Acute SCI rehabilitation is a potential “teachable moment” for patients with a history of alcohol abuse or dependence to initiate changes in their drinking behavior (Bombardier and Rimmele 1998). Most do not have severe dependence and, depending on the person’s history, may benefit from advice, brief motivational interventions, relapse prevention skills, or referral to specialist treatment (Turner et al. 2003).

### Sexual Dysfunction

SCI affects erectile functioning, ejaculation, and emission in males and lubrication in females as a function of level (upper motor neuron vs. lower motor neuron) and completeness of injury (Table 35–6). Clinicians must test the integrity of the sacral reflex arc to determine whether injury at the level of sacral roots is upper motor neuron or lower motor neuron. This examination involves testing of the bulbocavernosus or “anal wink” reflex. Reflex erection ability is dependent on sacral stimulation and the parasympathetic nervous system, whereas psychogenic erection is dependent on the integrity of the hypogastric plexus, which includes both the T11–L2 segments and the sacral plexus (Sipski and Alexander 1997).

Recent laboratory research confirms that women with complete upper motor lesions affecting the sacral segments are likely to have vaginal lubrication from reflexive but not psychogenic mechanisms. Incomplete upper motor lesions affecting the sacral segments retain the capacity for reflex lubrication but will have psychogenic lubrication only if they have intact pinprick sensation in the T11–L2 dermatomes. Women with incomplete lower motor lesions affecting the sacral segments are expected to achieve psychogenic lubrication in 25% of cases and no reflex lubrication.

By contrast, achieving orgasm is less well studied but appears to be relatively independent of level and completeness of injury. Among males with SCI, 38%–47% report achieving orgasm, which may be experienced as similar to or different from preinjury experiences. In a laboratory study, about 50% of the women with SCI reported experiencing orgasm, with longer stimulation, greater sexual knowledge, and higher sexual drive associated with higher rates of orgasm (Sipski et al. 1995). Sexual desire, activity, and pleasure tend to decrease after SCI for both women and men, but most remain interested in sexual activity. Erogenous zones and preferences for type of sexual activity may change.

Numerous treatments are available for sexual dysfunction related to SCI (see also Chapter 17, “Sexual Disorder”).

**TABLE 35–6. Male sexual functioning by level and type of lesion**

Male sexual functioning	Psychogenic erection (%)	Reflex erection (%)	Anterograde ejaculation (%)
Upper motor neuron—complete	0	70–93	4
Upper motor neuron—incomplete	19	80	32
Lower motor neuron—complete	26–50	0	18
Lower motor neuron—incomplete		67–95	70

Source. Adapted from Sipski and Alexander 1997.

Erectile dysfunction can be managed with sildenafil and other selective phosphodiesterase inhibitors, vacuum erection devices, pharmacological penile injections, and penile implants. Ejaculatory dysfunction and related infertility are treated with vibratory or electroejaculation procedures in conjunction with intrauterine insemination, in vitro fertilization, or intracytoplasmic sperm injection, depending on sperm quality and motility. A free on-line manual of resources for male infertility related to SCI is available at [www.scifertility.com](http://www.scifertility.com) (Amador et al. 2000). Decreased lubrication in females can be managed by water-based lubricants. Regarding sexual enjoyment, patients can benefit from many standard counseling strategies adapted for people with SCI, such as communication skills, sensate focus exercises, addressing performance anxiety, and generally dispelling common counterproductive beliefs about sexual relationships (Zilbergeld 1978). It is important to broach the subjects of sexuality and fertility while the person is undergoing acute rehabilitation, but studies indicate that during this time many patients rate other rehabilitation concerns as more important and may prefer to discuss sexual concerns in more detail after the acute rehabilitation phase (Hanson and Franklin 1976).

The PLISSIT sexual counseling model is a useful framework when offering sexually related counseling to patients in a rehabilitation setting (Anon and Robinson 1980). First, one asks for **P**ermission to discuss sexuality during acute rehabilitation with all patients. If permitted, the clinician should provide **L**imited **I**nformation, generally educational in nature, about sexual functioning. The clinician should give **S**pecific **S**uggestions about how to manage sexuality or fertility problems and refer the patient to a sexual counseling specialist for **I**ntensive **T**herapy when indicated.

## Personality and Psychological Testing

Personality assessment among persons with SCI has received justifiable criticism. Critics allege that clinicians are guilty of a negative bias, of overreliance on measures designed only to detect pathology, and of attributing behavior patterns only to intrapsychic and not to situational or environmental factors (Elliott and Umlauf 1995). Measures such as the Minnesota Multiphasic Personality Inventory (MMPI) and the Hopkins Symptom Checklist-90 (SCL-90) should be interpreted cautiously and with the aid of norms correcting for disability-related factors (Barncord and Wanlass 2000). Nonpathological measures such as the NEO Personality Inventory (NEO-PI), the 16 Personality Factor Questionnaire (16PFQ), and the Meyers-Briggs Type Indicator may be more appropriate

tests of personality functioning in this population (Elliott and Shewchuck 1995). Yet, evidence indicates that certain premorbid personality characteristics are more prominent among individuals with SCI than in the uninjured population. Nearly two-thirds of the patients with SCI have personality characteristics suggesting a strong physical orientation, difficulty expressing emotion, a preference for working with things rather than people, and a dislike of intellectual or academic interests (Rohe and Krause 1998). Neuropsychological evaluation that documents areas of cognitive impairment and strength can be critical in guiding treatment and vocational rehabilitation, especially when comorbid TBI is suspected (see Chapter 2, "Neuropsychological and Psychological Evaluation").

## Treatment of Psychiatric Disorders in Traumatic Brain Injury and Spinal Cord Injury

---

### General Principles

A patient's specific physical (e.g., spasticity) and cognitive impairments (e.g., defects in executive functions) must be considered in designing a treatment plan for psychiatric disorders in the rehabilitation setting. A detailed understanding of the patient's physical and psychological stage in rehabilitation and functional goals will help in choosing the most appropriate psychopharmacological or psychotherapeutic treatment modality. Consulting with other members of the multidisciplinary rehabilitation team will provide clues as to the patient's motivation and treatment limitations. Knowledge of the patient's current functional, social, and vocational status is required to tailor the psychiatric treatment to specific practical needs and limitations. For example, initial treatment with an activating antidepressant in a fatigued, cognitively impaired, depressed TBI patient who is not participating optimally in physical therapy may be more appropriate than attempting to engage the patient in cognitive-behavioral therapy (CBT).

Once rapport has been established, it is helpful to discuss the events that led up to the patient's impairment (e.g., the circumstances of the car accident that led to the TBI, the stroke that led to the left-sided hemiparesis) in order to explore the psychodynamic significance of these events. For example, patients will often blame themselves for their predicament, with such self-attribution leading to guilt and depression. In contrast, the patient may not associate his or her psychiatric symptoms with his or her physical impairment, which may affect readiness for psychotherapy.

Interviewing the patient's family, friends, and caregivers can provide critical information about the patient's past and present mental state. How patients handled prior losses and health problems can provide clues as to how resilient they will be during rehabilitation. Moreover, patients may report different symptoms from those observed by those close to them. For example, a patient often focuses on physical and cognitive deficits, whereas family members may consider the patient's emotional changes as more disabling (Hendryx 1989; Oddy et al. 1978a; Sherer et al. 1998b). Patients often report significantly less frequent symptoms of depression, aggression, and memory and attention problems on self-rating compared with ratings by their significant others (Hart et al. 2003). Close communication with family and other caregivers and acquaintances can provide critical longitudinal information about the progress of psychiatric treatment.

Because SCI may result in marked weight loss, alterations in appetite and sleep, and reduced energy and activity, diagnosing depression can be complicated. However, vegetative symptoms should not be dismissed because altered psychomotor activity, appetite change, and sleep disturbance are predictive of major depression (Clay et al. 1995). Core symptoms of depression in people with physical disabilities such as arthritis and SCI are worthlessness or self-blame, depressed mood, and suicidal ideation (Frank et al. 1992). The patient's own experience and interpretation of the vegetative symptoms can aid the diagnostic process (Elliott and Frank 1996).

As discussed earlier with TBI and SCI, the phenomenological presentation of psychiatric symptoms in rehabilitation patients may differ from symptoms that arise *de novo* or in other medical settings. Although psychopathology based on DSM-IV-TR criteria should be thoroughly explored, psychiatric symptoms that do not meet DSM diagnostic criteria but that still lead to significant functional impairment are common in the rehabilitation setting (e.g., the depressed TBI patient who has four depressive symptoms but shows apathy that affects his or her level of functioning, or the severely anxious SCI patient with few autonomic symptoms). These syndromes, or symptom clusters, still may warrant close monitoring and treatment to maximize functioning. Therefore, in addition to monitoring and documenting psychiatric signs and symptoms, functional status (e.g., activities of daily living, progress in physical and occupational therapy, role functioning) should be monitored closely as an indicator of overall progress. Consistent with the rehabilitation process's basic tenet of working toward realistic and measurable goals, psychiatric intervention should begin with defining treatment end points according to measurable outcomes. Examples of useful measures include the Patient

Health Questionnaire (PHQ) (Spitzer et al. 1999) for depression and anxiety, the Neurobehavioral Rating Scale (NBRS) (Levin et al. 1987b) for behavior and cognition, and the Rivermead Postconcussion Questionnaire (King et al. 1995) or the Overt Aggression Scale (OAS) (Yudofsky et al. 1986) for severe agitation.

Realistic expectations, including the possibility of incomplete remission of symptoms, must be conveyed at the outset so that the patient, who is already frustrated with the often slow and arduous rehabilitation process, does not become even more hopeless or overwhelmed if some symptoms persist (Roy-Byrne and Fann 1997). A recent survey of 16,403 community-dwelling elderly and disabled Medicare beneficiaries found that persons with disabilities reported poor communication and lack of thorough care as negative aspects of their care (Iezzoni et al. 2003). Collaboration with rehabilitation psychologists and counselors can provide significant depth of assessment and breadth of intervention. Attending rehabilitation team meetings is often a valuable and efficient way of communicating and coordinating needs and treatment. Because the patient is likely already feeling overwhelmed about his or her situation, framing the psychiatric consultation and intervention as another modality, similar to, for example, occupational or speech therapy, that can help him or her achieve the rehabilitation goals during a period of intense stress and adaptation can quickly put the patient at ease. Often, appropriately applied treatments may not have been given ample time to work. This problem may be exacerbated by recently imposed pressures on rehabilitation centers to work within predetermined payment structures and lengths of stay on the basis of medical diagnoses (Carter et al. 2000).

Treatment of psychiatric problems in the rehabilitation setting typically warrants a combination of pharmacological and psychosocial interventions. Because treatments for most chronic diseases are covered in other chapters, the following treatment recommendations focus on TBI and SCI.

## Psychopharmacology

Several common physiological changes in SCI (Table 35–7), often more pronounced in tetraplegia than in paraplegia, can have an effect on the pharmacokinetics and tolerability of many psychotropic medications. The goals and potential side effects of pharmacotherapy should be explained thoroughly to the patient and caregivers because unanticipated symptoms caused by medications may be viewed as a sign that the underlying condition is worsening. For example, urinary retention from an anticholinergic psychotropic drug may signal to the patient with SCI

**TABLE 35-7. Common physiological changes associated with spinal cord injury**

Increased body fat and glucose intolerance
Decreased gastrointestinal motility
Reduced cardiac output
Anemia
Orthostatic hypotension
Bradyarrhythmia
Decreased blood flow to skeletal muscle
Venous thrombosis
Osteoporosis

---

that the spinal lesion is progressing. Medications that can cause weight gain, constipation, dry mouth, orthostatic hypotension, or sexual dysfunction also may exacerbate already present pathophysiology. Medications that are sedating are of particular concern in TBI and SCI because they may impair mobility and cognition, increase risk for pressure sores, and interfere with rehabilitation. Sedation is a frequent problem because many patients with TBI and SCI are taking multiple central nervous system (CNS) depressants, such as anticonvulsants, muscle relaxants, and opioid analgesics (for discussion of interactions between neurological and psychiatric drugs, see Chapter 32, “Neurology and Neurosurgery,” and Chapter 37, “Psychopharmacology”).

Because patients with TBI or SCI are often more susceptible to sedative, extrapyramidal, anticholinergic, epileptogenic, and spasticity effects (Fann 2002), psychotropic dosages should be started at lower-than-standard levels and be titrated slowly. Despite this need for caution, some patients still may ultimately need full standard doses (Silver and Yudofsky 1994b).

Neuropsychiatric polypharmacy is common in TBI patients and should be critically examined. When multiple psychotropics are needed, they should be initiated one at a time, when possible, to accurately determine the therapeutic and adverse effects of each medication. This practice may become difficult to follow if patients' behavior endangers them or staff or significantly impairs rehabilitation, but it usually will prove beneficial in the long term.

Because few randomized, placebo-controlled studies exist that tested pharmacotherapy for psychiatric conditions in TBI and SCI populations, many of the following recommendations are based on case series or are extrapolated from other neurological populations. Heterogeneous study populations, including those varying in time elapsed since injury, confound the interpretation of study results. When TBI or SCI occurs in the context of a pre-existing psychiatric illness, it is logical to continue a previously effective medication regimen, but previously ab-

sent side effects may emerge that require changes in dosages and/or drugs. Electroconvulsive therapy for refractory depression (Crow et al. 1996), mania (Clark and Davison 1987), and prolonged posttraumatic delirium and agitation (Kant et al. 1995) may be considered. However, efforts should be made to lessen cognitive dysfunction in TBI patients (e.g., by using high-dose unilateral electrode placement or twice-weekly treatment frequency), and caution should be exercised in treating patients with SCI who may have unstable spinal columns (see also Chapter 39, “Electroconvulsive Therapy”).

### *Depression, Apathy, and Fatigue*

The existing literature on the efficacy of pharmacological treatment of depression after TBI is limited to small studies varying widely in design, diagnostic and outcome assessment, severity of brain injury, and time after injury.

Because of a favorable side-effect profile, a selective serotonin reuptake inhibitor (SSRI) usually is the first-line antidepressant for patients with TBI. A single-blind, placebo run-in study of 15 patients (Fann et al. 2000) and a case series of 9 patients (Cassidy 1989) suggested that SSRIs are efficacious and well tolerated in TBI populations. The study by Fann et al. found that 67% had remission of their major depression after 8 weeks of sertraline and that treatment also was associated with improvements in postconcussive symptoms, neuropsychological functioning, functional status, and self-ratings of injury severity and distress. The areas of cognitive functioning that improved included short-term memory, mental flexibility, cognitive efficiency, and psychomotor speed. Perino et al. (2001) assessed 20 depressed post-TBI patients before and after administration of citalopram and carbamazepine and found that depression, anxiety, inappropriate and labile affect, and somatic overconcern improved significantly. SSRIs should be started at about half of their usual starting dose and titrated slowly. SSRI-induced akathisia sometimes can be mistaken for TBI-related agitation (Hensley and Reeve 2001). Escitalopram, citalopram, and sertraline all have low potential for significant drug-drug interactions. For patients at high risk for noncompliance (e.g., because of cognitive impairment), fluoxetine should be considered because of its lower risk for withdrawal symptoms.

No clinical trials of antidepressants in persons with SCI are available to help guide pharmacotherapy. The Paralyzed Veterans of America and their partners in the Consortium for Spinal Cord Medicine (1998) have published a clinical practice guideline for depression for primary care physicians, extrapolated from research conducted in the general population or among other disability groups. Although SSRIs are likely efficacious in patients with SCI,

the risk for spasticity is increased (Stolp-Smith and Wainberg 1999).

The data on the efficacy and tolerability of tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) after TBI are more inconsistent (Dinan and Mobayed 1992; Saran 1985; Wroblewski et al. 1996). Because of the potentially problematic adverse effects of TCAs and MAOIs (e.g., sedation, hypotension, and anticholinergic effects) in patients with CNS impairment and their narrow therapeutic index (which can lead to inadvertent overdose in patients with cognitive impairment), these medications should be used with extreme caution in TBI patients. Autonomic dysfunction in patients with SCI makes them more vulnerable to TCA-related anticholinergic and orthostatic side effects. If a TCA is chosen, nortriptyline or desipramine may cause the fewest side effects.

Although not yet systematically studied, venlafaxine is likely safe and effective in patients with TBI. Mirtazapine, nefazodone, and trazodone may prove to be too sedating for some patients, particularly if they have cognitive impairment or gait instability, but if insomnia is a major problem, these drugs may be helpful. Venlafaxine and mirtazapine have low drug–drug interaction potential. Moclobemide, a reversible inhibitor of monoamine oxidase A, showed efficacy in an open subgroup analysis of 26 depressed patients with TBI (Newburn et al. 1999).

Some data suggest that antidepressants, especially TCAs and bupropion, are associated with an increased risk of seizures (Davidson 1989), a particular concern following severe TBI (Wroblewski et al. 1990); however, if the drugs are titrated cautiously, most patients will not experience increased seizures, particularly if they are taking an anticonvulsant (Ojemann et al. 1987).

The symptoms of apathy and fatigue, often associated with CNS impairment, can occur concomitantly with or independently of depression and are often mistaken for primary depression (Marin 1991). For apathy and fatigue, medications that augment dopaminergic activity appear to be the most useful (Marin et al. 1995). Methylphenidate and dextroamphetamine are generally safe at standard dosages (e.g., methylphenidate 10–30 mg/day in divided doses) and have been used successfully to enhance participation in rehabilitation (Gualtieri and Evans 1988). Methylphenidate and dextroamphetamine also have been shown in case series and double-blind studies to be effective in improving some aspects of mood, mental speed, attention, and behavior, although improvement was not always sustained long term (Bleiberg et al. 1993; R. W. Evans et al. 1987; Gualtieri and Evans 1988; Kaelin et al. 1996; Mooney and Haas 1993; Plenger et al. 1996; Speech et al. 1993; Whyte et al. 1997). Dextroamphetamine may exacerbate dystonia and dyskinesia in some cases.

Therapeutic use of these oral psychostimulants in the medically ill rarely leads to abuse in patients without a personal or family history of substance abuse (Masand and Tesar 1996), but substance abuse is overrepresented in the TBI and SCI populations.

Modafinil has been efficacious in treating fatigue in patients with multiple sclerosis (Rammahan et al. 2000; Terzoudi et al. 2000; Zifko et al. 2002) and excessive daytime sleepiness in patients with TBI (Teitelman 2001). Bupropion (Marin et al. 1995) and dopamine agonists, such as amantadine (Cowell and Cohen 1995; Gualtieri et al. 1989; M. F. Kraus and Maki 1997; Nickels et al. 1994), bromocriptine (Catsman-Berrevoets and Harskamp 1988; Eames 1989; Gupta and Mlcoch 1992), and levodopa/carbidopa (Lal et al. 1988), have been used for apathy states, fatigue, and cognitive impairment. Bupropion's stimulating properties may be of particular benefit in the fatigued or apathetic depressed patient. Stimulants and dopamine agonists can increase the risk for delirium and psychosis and thus should be used with caution in more vulnerable patients. Amantadine has been associated with an increased risk of seizures (Gualtieri et al. 1989), but methylphenidate, dextroamphetamine, and bromocriptine do not appear to lower seizure threshold at typical doses. The TCA protriptyline also has been used to improve arousal and behavior (Wroblewski et al. 1993).

There is great interest in pharmacological agents that could improve not only arousal and attention following TBI but also memory; however, data are lacking. Preliminary evidence indicates that the acetylcholinesterase inhibitor donepezil may improve memory and global functioning (Taverni et al. 1998; Whelan et al. 2000; Whitlock 1999).

Another secondary benefit of some antidepressants in TBI and SCI patients is their analgesic properties (Onghena and Van Houdenhove 1992) (see also Chapter 36, "Pain"). TCAs have been shown to be effective for the treatment of chronic nonmalignant pain, including neuropathic pain (McQuay et al. 1996). SSRIs have not been shown to be effective in neuropathic pain (Jung et al. 1997). Venlafaxine and duloxetine may be effective in treating a variety of pain syndromes, including neuropathic pain (Diamond 1995; Lang et al. 1996; Schreiber et al. 1999).

### *Mania*

For mania following TBI, the mood stabilizers lithium carbonate (Oyewumi and Lapierre 1981; Stewart and Nemsath 1988), valproic acid (Pope et al. 1988), and carbamazepine (Stewart and Nemsath 1988) all have been used successfully. Clonidine (Bakchine et al. 1989) and electroconvulsive therapy (Clark and Davison 1987) also can be used as second-line modalities. Dikmen et al. (2000)

have shown that valproic acid is well tolerated following TBI, but lithium and carbamazepine have been associated with neurocognitive adverse effects (Hornstein and Seliger 1989; Schiff et al. 1982). Lithium has a narrow therapeutic window and also can lower the seizure threshold; thus, caution is required when lithium is used in TBI patients whose cognitive impairment may lead to poor adherence or inadvertent overdosage. Although serum blood levels of valproic acid and carbamazepine help in monitoring adherence and absorption, dosing should be guided primarily by therapeutic response and side effects. The possible roles for other anticonvulsants in secondary mania are reviewed in Chapter 11 (“Mania, Catatonia, and Psychosis”). Carbamazepine, gabapentin, and clonazepam also can be effective for the treatment of neuropathic pain.

### *Anxiety*

Benzodiazepines are the treatment of choice for acute anxiety in TBI, but they should be used initially at lower doses because of their propensity to exacerbate or cause cognitive impairment and oversedation. The high prevalence of substance abuse in patients with TBI and SCI adds to the risk of benzodiazepine use and precludes their use in some patients. Although few studies exist in TBI patients, antidepressants also appear to be effective for anxiety, particularly in the context of depression. SSRIs also have been found to be effective in decreasing mood lability after brain injury (Nahas et al. 1998; Sloan et al. 1992), although this effect may take as long as their antidepressant effects. Valproic acid and gabapentin may be of benefit, especially in patients with concomitant mood lability or seizures (Pande et al. 1999, 2000). Buspirone is another option for generalized anxiety symptoms; however, it has been associated, albeit rarely, with seizures and movement disorders (Levitt et al. 1993).

### *Sleep Disorders*

Treatment of sleep problems in patients with TBI and SCI ideally should be based on diagnosis of a specific sleep disorder. Sleep apnea is fairly common in TBI (Castriotta and Lai 2001; Masel et al. 2001) and SCI (Burns et al. 2000), and nocturnal periodic leg movements are frequent in SCI (Dickel et al. 1994). Fichtenberg et al. (2000) found that insomnia often appeared to be associated with depression in post-acute TBI patients. No specific data exist on treating insomnia or other sleep disorders in TBI or SCI, but trazodone is widely used in these patients for middle or late insomnia. Trazodone-associated orthostatic hypotension may be particularly problematic in the rehabilitation setting, however. Antihistamines such

as diphenhydramine should be avoided because of their anticholinergic properties (see Chapter 16, “Sleep Disorders,” for general diagnosis and treatment of sleep disorders).

### *Anger, Aggression, and Agitation*

Anger, aggression, and agitation are common following TBI and can occur in isolation or as part of delirium or other psychiatric disorders (see Chapter 8, “Aggression and Violence,” for a full review of agitation and aggression in the medically ill). The published literature regarding their treatment is often not diagnostically specific and consists of largely case reports, case series, and reviews (e.g., Burnett et al. 1999; Krieger et al. 2003; Maryniak et al. 2001; McAllister and Ferrell 2002; Stanislav and Childs 2000).

Treatment can be divided into acute treatment, in which the goal is timely management of behavior to prevent injury to self or others, and chronic treatment, in which the goal is long-term management and prevention (Silver et al. 2002). Many agents take from 2 to 8 weeks to gain full effectiveness. It is important to keep in mind that medications that worsen cognition or sedation can actually worsen confusion and may, therefore, worsen agitation during the confusional state of posttraumatic amnesia after TBI. Because the effects of medications on the patient with TBI can be unpredictable, and their side effects actually may potentiate the behavior problem (e.g., akathisia from antipsychotics), systematically eliminating certain medications, including those that were initially prescribed to treat the behavioral dyscontrol, can prove beneficial. A rationale for such an approach is the clinical observation that some patients have a natural course of recovery and that some medication efficacy may decrease over time.

A survey published in 1997 (Fugate et al. 1997) showed that physiatrist experts in TBI most often treated agitation with carbamazepine, TCAs, trazodone, amantadine, and beta-blockers. Psychiatrists appear more likely than physiatrists to use atypical antipsychotics (Burnett et al. 1999) and SSRIs.

The atypical antipsychotics afford the clinician many more options in the acute setting than were available a decade ago (Battaglia et al. 2003; Currier and Simpson 2001; Lesem et al. 2001). The efficacy of the atypical antipsychotics in treating aggression and agitation in TBI patients is undocumented; however, evidence is mounting to support their efficacy in treating other agitated states associated with neurological syndromes (Lee et al. 2001; Meehan et al. 2002). The typical antipsychotics given orally or intramuscularly also may be useful in the acute setting (Stanislav and Childs 2000), but the elevated risks of extrapyramidal and anticholinergic effects in TBI patients

must be considered. Studies have suggested that haloperidol may impede neuronal recovery in animals (Feeney et al. 1982), but this finding has not been supported in humans with TBI.

Antipsychotic use for chronic agitation should be reserved for situations when aggression occurs in the context of psychotic symptoms. Risperidone (Cohen et al. 1998; De Deyn et al. 1999; I.R. Katz et al. 1999; McDougle et al. 1998) and olanzapine (Street et al. 2000) show promise in neuropsychiatric patients, although efficacy data are lacking in TBI patients for these and the other atypical antipsychotics. Clozapine use in TBI patients is limited by its seizure risk, although it has been found to be effective for chronic aggression (Duffy and Kant 1996; Michals et al. 1993).

The benzodiazepines offer rapid sedation that may be useful in the acute setting; however, they also have a high potential for neurocognitive effects, such as mental slowing, amnesia, disinhibition, and impaired balance, in patients with TBI. As a result, low doses of a short-acting agent, such as lorazepam 1–2 mg orally or parenterally, should be used initially and titrated as needed. If agitation is frequent, a longer-acting agent, such as clonazepam 0.5–1.0 mg two or three times a day, may be used for short durations. The combination of haloperidol and low-dose lorazepam (e.g., 0.5–1.0 mg) may offer a synergistic calming effect for some acutely agitated patients.

Serotonergic antidepressants, such as the SSRIs, trazodone, and amitriptyline, have been used to treat agitation and aggression in TBI populations (Mysiw et al. 1988; Rowland et al. 1992). In 8-week, nonrandomized trials with sertraline, Fann et al. (2000) showed that improved depression was associated with improved anger and aggression scores in patients with mild TBI, whereas Kant et al. (1998) found improved aggression independent of depression scores. One rationale for the use of antidepressants is the observation that serotonin and norepinephrine levels are reduced in the cerebrospinal fluid of agitated patients with brain injury (van Workeom et al. 1977). SSRIs are also effective in treating emotional incontinence, such as pathological crying or laughter (Muller et al. 1999; Nahas et al. 1998; Sloan et al. 1992).

Buspiron also has shown some efficacy for agitation in TBI and other neurological patients (Gualtieri 1991; Silver and Yudofsky 1994a; Stanislav et al. 1994) and can be particularly useful when anxiety also is present. Although one 6-week placebo-controlled trial found that methylphenidate significantly reduced anger an average of 27 months after severe TBI (Mooney and Haas 1993), stimulants should be used with caution in the agitated TBI patient because of the risks of exacerbating agitation and psychosis and of abuse.

Among the anticonvulsants, carbamazepine (Azouvi et al. 1999; Chatham-Showalter 1996) and valproic acid (Chatham Showalter and Kimmel 2000; Lindenmayer and Kotsaftis 2000; Wroblewski et al. 1997) have been studied the most for treatment of behavioral dyscontrol in TBI populations. Although evidence of seizures or epileptiform activity on electroencephalogram is a strong indication for anticonvulsant use in the agitated patient, these agents also have shown efficacy in those without electroencephalographic abnormalities. Oxcarbazepine, gabapentin, lamotrigine, and topiramate also may be efficacious, although data are more limited. Some TBI patients may experience paradoxical agitation with gabapentin (Childers and Holland 1997). Lamotrigine should be monitored for possible exacerbation of aggression, as is seen in some reports in mentally retarded patients with epilepsy (Beran and Gibson 1998; Ettinger et al. 1998). Evidence indicates that cognitive functioning may worsen with topiramate in some cases (Martin et al. 1999; Shorvon 1996; Tatum et al. 2001). Some patients may need to achieve serum levels of anticonvulsants that exceed therapeutic levels used for seizure prophylaxis to ensure adequate behavioral control. Lithium is also an effective mood stabilizer and has antiaggressive properties in TBI patients, according to case reports; however, its narrow therapeutic window and high potential for neurotoxicity limit its routine use, particularly in those with significant cognitive impairment or history of seizures.

When anger, aggression, or agitation occurs without signs of other psychiatric syndromes, beta-blockers such as propranolol, pindolol, and nadolol should be considered. Placebo-controlled studies have shown their efficacy in treating agitation in TBI patients (Brooke et al. 1992a; Greendyke and Kanter 1996; Greendyke et al. 1996). A Cochrane review (Fleminger et al. 2003) concluded that among the drugs used to treat agitation and aggression in TBI, beta-blockers have the best evidence for efficacy. Although dosages of propranolol in the range of 160–320 mg/day have been effective, Yudofsky et al. (1987) proposed titrating the dosage as high as 12 mg/kg or 800 mg/day. Bradycardia and hypotension are potential side effects; contraindications include asthma, chronic obstructive pulmonary disease, type 1 diabetes mellitus, congestive heart failure, persistent angina, significant peripheral vascular disease, and hyperthyroidism (Yudofsky et al. 1987). Pindolol is less likely to cause bradycardia.

### **Psychosis**

Because of the increased susceptibility of patients with TBI to experience anticholinergic and extrapyramidal side effects and patients with SCI to experience problematic anticholinergic sequelae, the newer-generation atyp-

ical antipsychotics are the drugs of first choice for psychotic symptoms that emerge after TBI or SCI (Burnett et al. 1999) (see also earlier discussion of antipsychotics for agitation in “Anger, Aggression, and Agitation” subsection and Chapter 11, “Mania, Catatonia, and Psychosis”). Clozapine carries a risk of seizures and should be used with extreme caution in TBI patients, particularly when compliance is in question.

### *Cognitive Impairment*

Little evidence is available to guide pharmacological treatments to enhance cognitive recovery following TBI; most data are derived from theoretical or animal models or case reports. Medications targeting the dopaminergic, cholinergic, and noradrenergic neurotransmitter systems have been tried (McElligott et al. 2003). Dopaminergic agents include levodopa/carbidopa, bromocriptine, amantadine, pergolide, the newer dopamine agonists (ropinirole, pramipexole), catecholamine-*O*-methyltransferase (COMT) inhibitors (entacapone, tolcapone), and the monoamine oxidase-B (MAO-B) inhibitor selegiline (Meythaler et al. 2002; Zafonte et al. 2001). The SSRI sertraline, which has some dopaminergic activity, may have a cognition-enhancing effect in addition to its antidepressant effect (Fann et al. 2001), although larger, controlled studies are needed to confirm this finding and to determine whether this effect is independent of its influence on depression. Medications that enhance cholinergic activity include cholinergic precursors such as lecithin and acetylcholinesterase inhibitors such as physostigmine (Cardenas et al. 1994) and donepezil (Taverni et al. 1998; Whelan et al. 2000; Whitlock 1999). The noradrenergic agents most commonly used to enhance cognition, perhaps by improving arousal and awareness, are the psychostimulants methylphenidate and dextroamphetamine, which also have dopaminergic effects. Modafinil, a treatment for narcolepsy whose mechanism of action is unclear, also may show some benefit. The opioid antagonist naltrexone helped improve TBI-associated memory impairment in a case series (Tennant and Wild 1987). None of these agents has yet been proven effective in controlled studies in improving cognition in TBI patients, and all would also require further study to better delineate appropriate indications, dosages, and treatment durations.

## Psychological Treatment

### *Traumatic Brain Injury*

A widely accepted model of psychological effects of TBI distinguishes among symptoms that are reactions to the effects of TBI (e.g., depression, anxiety, irritability, anger,

hopelessness, helplessness, social withdrawal, distrust, and phobias), symptoms that are neurologically based (e.g., affective lability, impulsivity, agitation, paranoia, unawareness), and symptoms that reflect long-standing personality traits (e.g., obsessiveness, antisocial behavior, work attitude, social connectedness, dependence, entitlement) (Prigatano 1986). Although the genesis of symptoms can be multifactorial, it is useful to consider the potential contributions of all three factors to observed problem behaviors. Prigatano (1986) argued that reactive problems may be most amenable to psychotherapeutic interventions, whereas neurologically mediated symptoms may require multimodal interventions that also target underlying cognitive impairment. Characterological problems may require making coordinated changes in important environmental contingencies as well as working with families or caregivers.

Although psychotherapy is considered an important aspect of brain injury rehabilitation (National Institutes of Health Consensus Development Panel 1999), there are as yet no controlled studies of psychotherapeutic interventions in persons with TBI and little guidance on the indications for psychotherapeutic interventions. Empirically supported psychotherapies have been adapted for use in brain injured individuals (e.g., modified CBT for anxiety [Hibbard et al. 2000b] and depression [Hibbard et al. 1992]). Psychological interventions are more likely to require involvement of family members or caregivers to help cue follow-through and generalization to real-world situations. Psychotherapy has been used with selected patients to foster insight in comprehensive post-acute neurorehabilitation programs (Prigatano and Ben-Yishay 1999). Insight-focused psychotherapy often begins with providing the patient with a simple model to explain what has happened. These explanations and coping strategies must be rehearsed repeatedly until they are automatic. Group therapy may be used to foster more insight through feedback from peers.

When insight and self-management approaches are not feasible, applied behavioral analysis can be used to manage a wide variety of brain injury-related behavioral deficits or excesses, such as emotional lability, anger management, and impulsivity. Mostly case studies have shown the efficacy of contingency management for enhancing appropriate social behavior, improving participation in rehabilitation, and increasing independent functioning (Horton and Howe 1981). In some cases, such as anger management, both self-control and environmental control strategies can be combined to achieve better outcomes (Uomoto and Brockway 1992).

Therapy for impaired awareness is in its infancy but has included several different strategies. Mildly impaired

patients may benefit from information about the effects of brain injury coupled with test data and observations about the specific ways they have been affected, including limited awareness. Basic cognitive compensatory strategies should be used to help patients attend to, understand, and recall this information. Family, friends, or caregivers should be included in these educational processes. With more severe or persistent problems, treatment may include more comprehensive, coordinated, and real-time feedback about impairments, such as via videotaping. Experiential learning paradigms can be used in which the person is asked to predict how well he or she will perform on a given test and is reinforced for successively improving the accuracy of his or her predictions. Failure experiences may be permitted, although staff should minimize the potential for shame or humiliation that may occur with failures. Improvements may be made in safety behaviors without corresponding changes in verbal awareness, so at times it may be therapeutic to ignore verbal denial and work strictly on the level of behavior. With intractable unawareness, it may be essential to enlist relatives and friends to create a protective environment by ensuring 24-hour supervision, removing access to cars or other dangerous equipment, contacting employers, and providing a written letter signed by the physician that lists all the behavioral restrictions to support caregivers when the restrictions are challenged. When adaptive denial is present, staff may benefit from information about how the denial helps the person psychologically. Staff may be inclined to confront the denial, not realizing the value of defensive denial in managing anxiety and maintaining a sense of self-efficacy.

**Cognitive rehabilitation.** The science of cognitive rehabilitation has grown tremendously in the past 15 years to the point that evidence-based guidelines have been derived from significant efficacy and effectiveness trials (Cicerone et al. 2000). Empirically validated approaches are available for remediation of visuoperceptual deficits, language deficits, and impaired pragmatic communication and for memory compensation in patients with mild memory impairment (Cicerone et al. 2000). Some evidence suggests that attention training, including computer-based training modules, is effective (Park and Ingles 2001). Effective strategies are available to train patients to improve visual scanning, reading comprehension, language formation, and problem solving (Cicerone et al. 2000). Optional rehabilitation strategies that may be effective include the use of memory books for persons with moderate-to-severe impairment, verbal self-instructional training, and self-questioning and self-monitoring to address deficits in executive functioning. Isolated use of

computer-based training procedures is not recommended for any form of impairment (Cicerone et al. 2000).

Controlled trials of comprehensive rehabilitation programs are rare for post-acute rehabilitation and absent for acute rehabilitation, primarily because of cost and ethical issues associated with withholding usual care. In one of the best controlled studies of post-acute rehabilitation, Ruff and colleagues (1989) compared outcomes resulting from an 8-week structured cognitively oriented day treatment program and a less structured psychosocially oriented day treatment program (control condition). The group receiving structured cognitively oriented treatment had improvement that was only marginally better than in the psychosocial group, whereas both groups improved significantly compared with stable pretreatment baselines. The data suggested that treatment in a structured setting that includes professional attention, psychosocial group therapy, TBI-relevant education, or cognitive remediation has positive benefits on neurobehavioral functioning. A current synthesis of the available evidence on comprehensive rehabilitation concludes that the greatest benefits accrue to those patients who receive individualized and integrated treatment oriented toward both cognitive and interpersonal areas of function (Cicerone et al. 2000).

### *Spinal Cord Injury*

Three types of problems may require psychological interventions in the context of SCI: 1) primary psychiatric disorders, 2) problems with adjustment to disability, and 3) problems with adherence to medical and rehabilitation therapies. With the caveat that there may be significant time constraints on implementing psychotherapy during a relatively short rehabilitation stay, abbreviated forms of standard empirically supported psychotherapies can be used in many cases if cognition is intact. Additionally, if a rehabilitation psychologist is on staff, responsibilities for therapeutic interventions can be negotiated between the psychiatrist and the psychologist.

For depression and anxiety disorders, brief CBT is often indicated in conjunction with initiating pharmacotherapy. Rehabilitation activities should afford the patient numerous opportunities to practice CBT skills, such as identification of irrational thoughts and positive reframing within a supportive context. The consultant also can work within the rehabilitation team to accomplish additional therapy goals by proxy. For example, the recreation therapist can carry out graded exposure to being in a motor vehicle for a patient with acute PTSD-related anxiety and avoidance of cars.

Cognitive-behavioral therapies have been adapted to, and studied to a limited degree in, the SCI population.

Craig and colleagues (1997) used a group-based skills-oriented approach to teaching relaxation, cognitive restructuring, social skills, assertiveness, pleasant activity scheduling, and how to begin sexual adjustment. Subjects with high levels of depressed mood before treatment were significantly less depressed than were historical control subjects 1 year after treatment. At 2-year follow-up, those individuals who had received CBT had fewer hospital readmissions, used fewer drugs, and reported higher levels of adjustment compared with subjects in the control group (Craig et al. 1999). Kennedy et al. (2003) tested a “coping effectiveness training” approach that involves teaching cognitive appraisal and coping skills in small groups. Compared with matched historical control subjects, the treated subjects reported reduced depression and anxiety, although improvements were unrelated to changes in coping skills.

Group-based interventions provide unique opportunities to capitalize on the positive coping abilities modeled by participants with better adjustment. Therefore, group-based coping skills training is recommended for people with significant anxiety or depressive symptoms after SCI as an adjunct to or in lieu of individual psychotherapy.

Poor adjustment to disability and management of grief are also common reasons for referrals. As noted earlier, potentially harmful myths exist about the nature and course of grief. Empirically supported approaches to manage grief are lacking (Bonanno et al. 2002), but clinical experience provides guidance. Clinicians should resist the temptation to confront patients with their prognosis when they, for example, insist that they are going to walk again. It should be recognized that statements labeled as *denial* may simply reflect the common, understandable hope or wish for neurological recovery rather than psychopathology. Overly direct confrontation may damage defenses needed by patients, increase resistance, and risk eliciting excessive distress. We recommend tolerance of verbal denial and other adjustment patterns that do not interfere with rehabilitation progress for more than a day or so. For these patients, staff education about the range of normal adjustment may be the main intervention. When verbal denial is accompanied by behavioral denial (e.g., refusing to learn adaptive strategies such as wheelchair use and self-catheterization) or persistently interferes with rehabilitation progress, more directive interventions may be needed. In such cases, the psychiatrist may recommend that patients review information about the nature and extent of their injury (including radiographic evidence), prognosis for recovery, and current SCI research with the attending physician, possibly with the consultant present.

Given the action-oriented behavioral style of many patients with SCI, we believe that much adjustment is behaviorally mediated. That is, rather than verbally processing losses associated with SCI, patients accommodate to their impairments largely through physical and occupational therapy wherein they repeatedly experience their abilities and limitations through activities. To the extent that therapists can set attainable incremental goals and maximize the patients’ sense of mastery, positive adjustment can be facilitated. Therapies also can be organized to help patients resume participation in their most meaningful, rewarding, and pleasant life activities. Prospective descriptive studies of bereavement (Bonanno et al. 2002) and the incipient empirical use of combined interpersonal therapy and CBT for “traumatic grief” (Shear et al. 2001) may lead to more valid approaches to treating adjustment to loss in SCI.

Nonadherence to treatment, and the associated conflicts with staff, often trigger psychiatric consultation. Causes of nonadherence are varied and include depression, amotivational states due to concomitant TBI, antisocial personality traits, ongoing substance abuse, and unrealistic staff expectations. Adherence is a function of the interaction among somatic, psychological, and environmental variables (Trieschmann 1988). Environmental factors may be particularly salient in cases of nonadherence. Once primary psychiatric disorders are ruled out, the consultant should examine how adherence to prescribed therapies may not be as rewarding for the patient as it should be, perhaps because of pain, withdrawal of social contact, or relinquishing a sense of control. In some cases, nonadherence may inadvertently be rewarded by engaging staff in negative social interactions, asserting independence, or avoiding unwanted responsibilities. One example is patients with dependent traits not improving toward independence because staff attention and expressions of support are contingent on dependent behavior. Behavioral principles such as rewarding successive approximations, ignoring disability-inappropriate behaviors, initiating behavioral activation, using quota systems, and explicitly linking progress in rehabilitation to desired outcomes (such as earlier discharge) may improve adherence to treatment (W.E. Fordyce 1976).

## Conclusion

---

As society’s attitudes toward disability continue to evolve and researchers work toward better understanding the potent effects of psychosocial factors in disability, psychiatrists will have an increasing role in the rehabilitation setting. To achieve comprehensive evaluation and treat-

ment of persons with TBI and SCI, psychiatrists must appreciate and address the multiple complex facets of these conditions, from the acute neurological injury and attendant psychological trauma through the chronic neurological, medical, psychiatric, and social sequelae of the injury. The multidisciplinary rehabilitation setting affords an environment in which psychiatrists can utilize their pharmacological and psychotherapeutic skills in psychosomatic medicine to maximize the long-term functional potential of their patients.
