# 36 Pain

---

Michael R. Clark, M.D., M.P.H.

Maciej P. Chodynicki, M.D.

**IN THIS CHAPTER**, we first review definitions, assessment, and epidemiology of pain. We then discuss selected specific acute and chronic pain syndromes, followed by the major psychiatric comorbidities of chronic pain, including somatization, substance use, depression, anxiety, and other emotional states. The chapter closes with a review of treatments, including medications, psychological therapies, and multidisciplinary programs. Some pain topics are covered elsewhere in this book, including arthritis (see Chapter 25, “Rheumatology”), fibromyalgia (see Chapter 26, “Chronic Fatigue and Fibromyalgia Syndromes”), postoperative pain (see Chapter 30, “Surgery”), headache (see Chapter 32, “Neurology and Neurosurgery”), pelvic pain and vulvodynia (see Chapter 33, “Obstetrics and Gynecology”), spinal cord injury (see Chapter 35, “Physical Medicine and Rehabilitation”), and palliative care (see Chapter 40, “Palliative Care”).

## Definition and Assessment

---

Pain has been defined by the International Association for the Study of Pain (IASP) as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (Merskey et al. 1986, p. S217). Other terms relevant to pain are defined in Table 36–1. Pain is the most common reason a patient presents to a physician for evaluation (Kroenke 2003; Kroenke and Mangelsdorff 1989; Kroenke et al. 1990). If the patient suffers from chronic pain, defined as “pain without apparent biological value that has persisted beyond the normal tissue healing time (usually 3 months),” many specialists may be required in the successful care of the patient (Bonica 1990, p. 19). Most diseases associated with chronic pain, including

cancer, peripheral vascular disease, neuropathy, temporal arteritis, arthritis, and postherpetic neuralgia, are disproportionately represented in the elderly (Foley 1994; Gordon 1979). However, chronic pain and its consequences are now recognized complications of many illnesses, such as spinal cord injury, amputations, cerebral palsy, multiple sclerosis, HIV, Parkinson’s disease, stroke, and neuromuscular diseases (Ehde et al. 2003).

Pain is a complex experience that varies demographically; is influenced by affective, cognitive, and behavioral factors; and has an extensive neurobiology (Meldrum 2003; Turk et al. 1983). Women are more sensitive to noxious stimuli and have higher risk for developing chronic pain (Fillingim 2000). African Americans with chronic pain report significantly higher levels of pain unpleasantness, avoidance, fearful thinking, and somatic complaints, that are not explained by their initially higher ratings of pain severity (McCracken et al. 2001; Riley et al. 2002). Elderly patients are often less likely to report pain or take opioids and other analgesics because of fears of addiction, tolerance that would limit pain relief in the future instance of disease progression, side effects, and a belief that pain is an indicator of disease that may distract the doctor from primary and possibly curative treatment (Ferrell 2004).

Pain is difficult to assess, especially in patients with terminal illness or cognitive impairment (Nikolaus 1997; Parmelee 1996). Patients’ compliance with pain diaries is often poor, with only 11% actually following instructions, despite 90% of patients reporting compliance in one recent study (Stone et al. 2002). Pain rating scales attempt to measure the severity of pain. Many factors can influence these ratings, including contextual circumstances, disease states, mental disorders, distress, personality traits, memory of past experiences, and meaningful inter-

**TABLE 36-1. Definitions relating to pain sensations**

Allodynia	Pain from a stimulus that does not normally provoke pain
Deafferentation pain	Pain resulting from loss of sensory input into the central nervous system
Dysesthesia	An unpleasant, abnormal sensation that can be spontaneous or evoked
Hyperalgesia	An increased response to a stimulus that is normally painful
Hyperesthesia	Increased sensitivity to stimulation that excludes the special senses
Hyperpathia	Pain characterized by an increased reaction to a stimulus, especially a repetitive stimulus, and an increased threshold
Hypoesthesia	Diminished sensitivity to stimulation that excludes the special senses
Nociception	Detection of tissue damage by transducers in skin and deeper structures and the central propagation of this information via A delta and C fibers in the peripheral nerves
Paresthesia	An abnormal sensation, spontaneous or evoked, that is not unpleasant
Sensitization	Lowered threshold and prolonged/enhanced response to stimulation

Source. Adapted from Merskey et al. 1986.

pretations based on personal beliefs. Generally, there are poor correlations among pain reporting, tissue pathology, disability, and treatment response (Turk 1999). Drawings by patients of their pain distributions considered “nonorganic” were associated with significantly lower scores of psychological health (Dahl et al. 2001). Scores on simple numerical rating scales reflect the affective or emotional aspects of pain much more than the sensory intensity (Clark et al. 2002).

Even the simplest self-report measures used to record the presence of pain, such as a numeric rating scale or pain thermometer, cannot be effectively used by many individuals (Ferrell et al. 1995). Some patients have deficits in abstraction ability that make it difficult for them to rate pain using a visual analog scale (VAS) or a verbal descriptor scale (VDS). In a comparison study, the VDS was rated as the preferred, easiest, and best assessment tool for rating pain by the elderly (Herr and Mobily 1993). However, the ratings of pain intensity using these scales were poorly correlated with one another. The magnitude of a meaningful decrease on pain rating scales is difficult to define. Outcomes judged as clinically significant and referenced to a 7-point self-report global impression of change scale were associated with an approximately 30%

drop on a numerical rating (0–10) of pain intensity (Farrar et al. 2001). Alternative tools for evaluating pain, such as observations of pain behaviors, are limited by reliance on an outside observer to rate a patient’s pain (Weiner et al. 1996, 1998).

A comprehensive evaluation should be performed for any patient who reports pain (Clark 2000a; Clark and Cox 2002). This evaluation should incorporate simple standardized tools for rating pain severity; observations of pain-related behaviors, including any problems with activities of daily living that would indicate the presence of pain; and a clinical examination to elicit evidence of pain and the signs of possible etiologies.

## Epidemiology

The prevalence of chronic pain reported in the general population ranges from 10% to 55%, with an estimate of severe chronic pain of approximately 11% among adults (noting the lack of standard definitions for “chronic” or “severe”) (Karlsten and Gordh 1997; Nickel and Raspe 2001; Ospina and Harstall 2002; Verhaak et al. 1998). In the most recent World Health Organization (WHO) review from multiple countries, the weighted mean prevalence of chronic pain was 31% in men, 40% in women, 25% in children up to age 18 years, and 50% in the elderly older than 65 years (Ospina and Harstall 2002). During a 2-week period, 13% of the U.S. workforce reported a loss in productivity due to a common pain condition such as headache, back pain, arthritis pain, or other musculoskeletal pain (Stewart et al. 2003).

An 8-year follow-up survey by the U.S. Center for Health Statistics found that 32.8% of the general population experienced chronic pain symptoms (Magni et al. 1993). In another WHO study of more than 25,000 primary care patients in 14 countries, 22% (17% in the United States) of patients suffered from pain that had been present for most of the time for at least 6 months (Gureje et al. 1998). In a study of 6,500 individuals aged 15–74 years in Finland, 14% experienced daily chronic pain that was independently associated with lower (odds ratio [OR]=11.8 for “poor”) self-rated health (Mantyselka et al. 2003). A retrospective analysis of 14,000 primary care patients in Sweden reported that approximately 30% of patients seeking treatment had some kind of defined pain problem, with almost two-thirds diagnosed with musculoskeletal pain (Hasselstrom et al. 2002).

In a 24-year longitudinal study of chest, abdomen, and musculoskeletal pain, symptoms increased with age, and women reported more persistent and severe pain (Brattberg et al. 1997). In people 65 years or older, musculo-

skeletal pain is associated with three times the likelihood of significant difficulty performing three or more physical activities (Scudds and McD Robertson 1998). In persons older than 75 years, over two-thirds reported pain, almost half reported pain in multiple sites, and one-third rated pain as severe in at least one location (Brattberg et al. 1996).

## Acute Pain

---

The Joint Commission on Accreditation of Healthcare Organizations has implemented pain management standards for all patient encounters (Phillips 2000). In the Veterans Affairs medical centers, pain intensity has been defined and tracked as the “5th vital sign.” Acute pain is usually the result of trauma from a surgery, injury, or exacerbation of chronic disease, especially musculoskeletal conditions. Acute pain management will usually be successful with straightforward strategies such as relaxation, immobilization, analgesics (aspirin, acetaminophen, non-steroidal anti-inflammatory drugs [NSAIDs], opioids), massage, and transcutaneous electrical nerve stimulation (TENS) (Acute Pain Management Guideline Panel 1992). Older adults are more likely to undergo surgery for degenerative problems, fractures, and cardiovascular disease (Ferrell 1996). The normal physiology of aging and the presence of chronic diseases must be taken into consideration when using pharmacotherapy for pain so as to avoid delirium, side effects, and toxicity.

In acute pain management, psychiatric consultation is requested when a patient requires more analgesia than expected or has a history of substance abuse. Patients with acute pain most frequently seek analgesic medications to alleviate pain. The absence of signs consistent with acute pain, such as elevated heart rate, blood pressure, and diaphoresis, does not rule out the presence of pain.

Acute pain management should be initiated as early as possible. If the management is focused on preventing occurrence and reemergence of pain, it may allow for lower total doses of analgesics. Analgesics, especially opioids, should be prescribed only for pain relief. Although analgesia may produce other benefits, other symptoms commonly coinciding with acute pain, such as insomnia and anxiety, should be managed separately from pain. Sleep deprivation and anxiety may intensify the sensation of pain and increase requests for more medication. Reducing anxiety and insomnia often reduces analgesic requirements.

Patients with active or recent history of opioid addiction, and those receiving methadone maintenance therapy, have increased tolerance to opioids and may require up to 50% higher doses of opioid analgesics than other

patients. Although it is important to carefully monitor opioid use in these patients, adequate treatment of acute pain is a priority. Inadequate dosing is significantly more common than abuse or diversion in these patients. Dosage should be carefully individualized, rather than based on preconceived expectations.

## Selected Chronic Pain Conditions

---

### Postherpetic Neuralgia

Postherpetic neuralgia is defined as pain persisting or recurring at the site of shingles at least 3 months after the onset of the acute varicella zoster viral rash (Bowsher 1997b). Postherpetic neuralgia occurs in about 10% of patients with acute herpes zoster. More than half of patients over 65 years of age with shingles develop postherpetic neuralgia, and it is more likely to occur in patients with cancer, diabetes mellitus, and immunosuppression. Other risk factors include greater acute pain and rash severity, sensory impairment, and psychological distress (Schmader 2002). Most cases gradually improve over time, with only about 25% of patients with postherpetic neuralgia experiencing pain at 1 year after diagnosis. Approximately 15% of referrals to pain clinics are for the treatment of postherpetic neuralgia.

Although degeneration and destruction of motor and sensory fibers of the mixed dorsal root ganglion characterize acute varicella zoster, other neurological damage may include inflammation of the spinal cord, myelin disruption, axonal damage, and decreases in the number of nerve endings from the affected skin. These injuries persist in postherpetic neuralgia patients, but the actual mechanism of pain is not well understood. Studies have suggested the role of both peripheral and central mechanisms resulting from the loss of large-caliber neurons and subsequent central sensitization or adrenergic receptor activation and alterations in C-fiber activity (Fields et al. 1998). Early treatment of varicella zoster with low-dose amitriptyline reduced the prevalence of pain at 6 months by 50% (Bowsher 1996, 1997a; Johnson 1997). Tricyclic antidepressants (TCAs), anticonvulsants, and opioids are the most common effective treatments for postherpetic neuralgia and may have potential for its prevention (Dworkin and Schmader 2003; Johnson and Dworkin 2003).

### Peripheral Neuropathy Pain

Sensory neurons are damaged by many diseases, both directly and indirectly (Scadding 1994). Approximately 25% of patients with diabetes mellitus will experience painful diabetic neuropathy, with duration of illness and poor gly-

centric control contributing risk factors. If C-fiber input is preserved but large-fiber input is lost, paresthesias and pain are the predominant sensory experiences. The pain of a peripheral neuropathy can range from a constant burning to pain that is episodic, paroxysmal, and lancinating in quality (Mendell and Sahenk 2003). These phenomena are primarily the result of axonal degeneration and segmental demyelination. Sites of ectopic impulse generation can be found at any point along the peripheral nerve, including the dorsal root ganglion, regardless of where the nerve is actually damaged. Other changes can alter the magnitude and frequency of impulse generation, such as sensitivity to mechanical or neurochemical stimuli.

The paroxysms of pain that result from stimulation of hyperexcitable damaged neurons and subsequent recruitment of nearby undamaged sensory afferents may be explained by several forms of nonsynaptic (ephaptic) and prolonged (afterdischarge) impulse transmission described in models of peripheral neuropathic pain. Voltage-dependent sodium channels in the dorsal root ganglion undergo both up- and downregulation depending on the subpopulation (Rizzo 1997). When a peripheral nerve is damaged, central sensitization amplifies and sustains neuronal activity by a variety of mechanisms, such as reduced inhibition of dorsal horn cells.

Pharmacological treatments have been almost identical to those used for postherpetic neuralgia, but the new norepinephrine-serotonin reuptake inhibitor duloxetine has been the first agent to be approved by the U.S. Food and Drug Administration (FDA) for treatment of diabetic peripheral neuropathy pain.

## Parkinson's Disease

Pain is the most common sensory manifestation of Parkinson's disease and reported by half of patients (Goetz et al. 1986; Koller 1984; Starkstein et al. 1991). The pain is typically described as cramping and aching, located in the lower back and extremities, but not associated with muscle contraction or spasm. These pains often decrease when the patient is treated with levodopa, which suggests a central origin. The loss of dopaminergic input could explain how pain is produced, perhaps through a loss of descending inhibition in the spinal cord (Burkey et al. 1996).

## Central Poststroke Pain

Approximately 5% of patients who have suffered a stroke experience intractable pain in addition to other neurological deficits (Bowsher 1995). Patients typically have hemibody sensory deficits and pain associated with dysesthesias, allodynia, and hyperalgesia. Radiographic lesions are present in the thalamus, although other sites are often in-

involved. Excitatory amino acids may be involved in the development of this syndrome. Pharmacological treatment is usually not effective, and even ketamine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, reduced pain in less than 50% of patients (Yamamoto et al. 1997). Fluvoxamine significantly improved pain ratings but only in patients within 1 year after stroke (Shimodozono et al. 2002). In contrast, patients with spinal cord injury experienced reductions in continuous and evoked pain with ketamine and mu opioid receptor agonists, suggesting different mechanisms in different central pain states (Eide et al. 1995).

## Migraine and Chronic Daily Headache

The International Headache Society has published guidelines for the classification of headache (Olesen 1988) (see also Chapter 32, "Neurology and Neurosurgery"). The peak incidence of migraine occurs between the third and sixth decades of life and then decreases with age. Over the life span, 18% of women and 6% of men will suffer from migraine (Lipton et al. 1997). Theories of pathogenesis include the involvement of the trigeminovascular system and plasma protein extravasation, antagonism of serotonin receptors, modulation of central aminergic control mechanisms, stabilizing effects on membranes through action at voltage-sensitive calcium channels, and involvement of substance P (Goadsby 1997; Solomon 1995). Common migraine is defined as a unilateral pulsatile headache, which may be associated with other symptoms such as nausea, vomiting, photophobia, and phonophobia (Szirmai 1997). The classic form of migraine adds visual prodromal symptoms such as scintillating scotomata. Complicated migraine includes focal neurological signs such as cranial nerve palsies and is often described by the name of the primary deficit (e.g., hemiplegic, vestibular, or basilar migraine).

Calcium channel blockers, beta-blockers, antidepressants, and anticonvulsants are the treatments with best-documented efficacy (Mathew 2001). A group-based multidisciplinary treatment consisting of stress management, supervised exercise, dietary education, and massage therapy significantly improved pain characteristics, functional status, quality of life, depression, and pain-related disability in patients with migraine (Lemstra et al. 2002).

Headache is the most common pain condition reported by the U.S. workforce as the reason for lost productive time (Stewart et al. 2003). Chronic daily headache affects about 5% of the population and is composed of constant (transformed) migraine, chronic tension-type headaches, new-onset daily persistent headache, and hemicrania continua (Lake and Saper 2002). Patients with chronic daily

headache are more likely to overuse medication, leading to rebound headache; have psychiatric comorbidity such as depression and anxiety; report functional disability; and experience stress-related headache exacerbations (Lake 2001). Patients with transformed migraine have poor quality of life, having been found to have the worst SF-36 Health Survey profile compared with patients with episodic migraine or chronic tension-type headaches (Wang et al. 2001). Chronic tension-type headaches typically manifest as daily pain that is difficult to manage and unresponsive to many treatments.

A variety of medications have been recommended in addition to the traditional prophylactic agents and include serotonin agonists, serotonin antagonists, and alpha<sub>2</sub>-adrenergic agonists. Olanzapine decreased headache severity and frequency in patients with refractory headaches who had undergone unsuccessful treatment with at least four preventive medications (Silberstein et al. 2002). Topiramate decreased migraine frequency, severity, number of headache days, and use of abortive medications in patients with both episodic and transformed migraine (Mathew et al. 2002). TCAs and stress management therapy significantly reduced headache activity, analgesic medication use, and headache-related disability (Holroyd et al. 2001). Combined medication and cognitive-behavioral psychotherapy are more effective than either treatment alone (Lake 2001; Lipchik and Nash 2002).

## Low Back Pain

Low back pain (LBP) is one of the most common physical symptoms, and the most expensive condition when including lost productivity and health care costs (Stewart et al. 2003). Psychological factors are highly correlated with LBP; these factors include distress, depressed mood, and somatization, which predict the transition from acute to chronic LBP (Linton 2000; Pincus et al. 2002). A minority of patients with acute LBP will develop chronic LBP with disproportionate distress and disability. In one prospective cohort study of 1,246 patients with acute LBP who sought treatment, about 8% had chronic, continuous symptoms for 3 months, and less than 5% had unremitting pain for 22 months (T.S. Carey et al. 2000). Two-thirds of patients with chronic LBP at 3 months exhibited functional disability at 22 months. The most powerful predictor of chronicity was poor functional status 4 weeks after seeking treatment. In a study of secondary gain, both economic and social rewards were associated with higher levels of disability and depression in patients with chronic nonmalignant back pain (Ciccone et al. 1999). Depression has been identified as a presurgical risk factor associated with poor outcome in long-term follow-up of compen-

sated workers who underwent posterolateral lumbar fusion (DeBerard et al. 2001). Specifically, anxiety, depression, and occupational mental stress predicted lower rates of return to work in patients undergoing lumbar surgeries (Schade et al. 1999; Trief et al. 2000). Despite an extensive array of pain scales and functional instruments available to evaluate outcome, patient global assessment has been found a valid and responsive measure of overall treatment effect (Hagg et al. 2002).

The presence of a depressive disorder has been demonstrated to increase the risk of developing chronic musculoskeletal pain 3 years later (Leino and Magni 1993; Magni et al. 1993, 1994; Von Korff et al. 1993). In a 15-year prospective study of workers in an industrial setting, initial depression symptom scores were predictive of LBP and a positive clinical back examination in men but not women (Leino and Magni 1993). In a study of health care workers examined over 3 years with the Zung Depression Index, affective distress contributed to new-onset LBP (Adams et al. 1999). In a community-based sample, depression was associated with a nearly fourfold increase in the likelihood of seeking a consultation for the new complaint of back pain lasting greater than 3 months at follow-up (Waxman et al. 1998). In a 13-year follow-up study that examined the longitudinal relationship between LBP and depressive disorder, using lifetime reports of symptoms, and excluded other forms of affective distress such as demoralization, grief, and adjustment disorders, depressive disorder was a significant risk factor for incident LBP (Larson et al. 2004). While it is understandable that patients with LBP would experience reactive affective distress, a significant relationship between LBP and the subsequent onset of incident depressive disorder was not found. In another prospective analysis, participants who did not have current LBP were followed for 12 months (Croft et al. 1996). Patients with higher levels of distress at baseline were almost twice as likely to report a new episode of back pain. This study concluded that as much as 16% of LBP in the general population may be attributable to psychological distress.

The treatment of chronic LBP has been pursued with multiple modalities alone and in combination (Deyo and Weinstein 2001; Hildebrandt et al. 1996). Patients with chronic LBP exemplify the complexity of chronic pain treatment. Their symptoms may represent numerous diagnoses and require multimodal treatment plans. Although treatments often produce symptom reductions, there is conflicting evidence about their ability to improve functional status, particularly with respect to returning to work (Pfungsten et al. 1997; Saur et al. 1996; Staiger et al. 2003). Conservative interventions such as education, exercise, massage, and TENS produce incon-

sistent results (Furlan et al. 2002; Pengel et al. 2002). Studies of behavior therapies support their effectiveness in comparison with wait-list or no-treatment control conditions, but the efficacy data are less convincing for these therapies compared with usual treatment for chronic LBP (van Tulder et al. 2001). There is evidence that surgery may be effective for a carefully selected group of patients with chronic LBP (Fritzell et al. 2001). Multidisciplinary rehabilitation programs usually offer the best outcomes, but such programs are the most expensive approach, and high-quality randomized, controlled trials are still needed to document their efficacy (Huppe and Raspe 2003; Karjalainen et al. 2003; Lang et al. 2003). The patient's perception of disability is a critical factor that must be addressed for treatment to succeed.

### Complex Regional Pain Syndrome (Causalgia and Reflex Sympathetic Dystrophy)

The term *complex regional pain syndrome* (CRPS)) now replaces reflex sympathetic dystrophy (CRPS type I) and causalgia (CRPS type II) (Stanton-Hicks et al. 1995). Type I involves ongoing spontaneous burning pain that is precipitated by a specific noxious trauma or cause of immobilization and is usually associated with hyperalgesia or allodynia to cutaneous stimuli. The symptoms are not limited to a single peripheral nerve, and there is often evidence of edema, blood flow abnormalities, or sudomotor dysfunction in the region of pain, usually an extremity. Motor changes such as tremor, weakness, and limitations in movement are common. If nerve injury is present, CRPS type II is appropriately diagnosed. Although the natural history varies, three clinical stages are classically described. Stage 1 (acute, early) is characterized by an inflammatory onset with constant aching or burning pain. Stage 2 (dystrophic, intermediate) is notable for cool, pale, and cyanotic skin. Stage 3 (atrophic, late) manifests as atrophy and wasting of multiple soft tissues, fixed joint contractures, and osteoporosis. When pain is relieved by blockade of the efferent sympathetic nervous system, the modifier, sympathetically maintained pain, is added (Wesselmann and Raja 1997). Patients with sympathetically maintained pain often report hyperalgesia to cold stimuli.

Patients with CRPS often exhibit emotional distress and psychological dysfunction. The reported prevalence of psychiatric disorders in patients with CRPS ranges from 18% to 64% (Bruehl and Carlson 1992). Examination using the Structured Clinical Interview for DSM-IV (SCID) demonstrated a high frequency of affective (46%), anxiety

(27%), and substance abuse disorders (14%) in patients with CRPS (Rommel et al. 2001). Some patients with CRPS may exhibit signs of conversion disorder, such as the normalization of hypoesthesia by nerve blocks. Non-anatomic and expansive areas of hypoesthesia or hyperalgesia with normal peripheral sensory nerve conduction or somatosensory evoked potentials in patients with CRPS type I are probably psychogenic in origin. Neurophysiological investigation suggests that certain positive motor signs (dystonia, tremors, spasms, irregular jerks) identified in patients with CRPS type I represent pseudoneurological illness (Verdugo and Ochoa 2000). A review of studies that used the Minnesota Multiphasic Personality Inventory (MMPI) concluded that patients with CRPS, like other patients with chronic pain, are somatically preoccupied, are depressed, and use repression as a psychological defense mechanism (Bruehl and Carlson 1992). However, there are no consistent differences in psychological characteristics or psychiatric diagnoses between CRPS and non-CRPS pain patients (Bruehl et al. 1996; Ciccone et al. 1997; DeGood et al. 1993; Fishbain 1999a; Geertzen et al. 1998; Monti et al. 1998; Nelson and Novy 1996; van der Laan et al. 1999; Zucchini et al. 1989).

Several literature reviews have examined whether psychological dysfunction was the cause or effect of CRPS (Bruehl and Carlson 1992; Haddox 1990; Lynch 1992). The majority of studies suffered flaws in methodology such as a lack of homogenous diagnostic groups, lack of control groups, and incorrect use of psychiatric or psychological terminology. Depression, anxiety, and fear of movement are common, but no unique personality traits or profile predisposes one to develop CRPS. In patients with CRPS, a recent study of daily diaries demonstrated that the prior day's depressed mood contributed to the present day's increased pain and that yesterday's pain also contributed to today's depression, anxiety, and anger (Feldman et al. 1999).

In summary, most authors have concluded that comorbid psychopathology in patients with CRPS is a consequence of the chronic pain rather than its cause. However, psychiatric conditions should be treated as primary barriers to functional rehabilitation. In addition, treatment for CRPS usually combines a variety of anesthetic blocks, typically regional sympathetic blocks, with oral sympatholytics, reactivating physical therapies, adjuvant analgesic medications, electrical stimulation, and possibly even surgical sympathectomy (Lee and Benzon 1999).

### Orofacial Pain

*Trigeminal neuralgia* (tic douloureux) is a chronic pain syndrome with severe, paroxysmal, recurrent, lancinating

pain in the distribution of cranial nerve V that is unilateral and most commonly involves the mandibular division (Elias and Burchiel 2002; Loeser 2001). Sensory or motor deficits are not usually present. Episodes of pain can be spontaneous or evoked by nonpainful stimuli to trigger zones, activities such as talking or chewing, or environmental conditions. Between episodes, patients are typically pain-free. Less common syndromes involving the intermedius branch of the facial nerve or the glossopharyngeal nerve present with pain that can involve the ear, posterior pharynx, tongue, or larynx (Zakrzewska 2002). Other related conditions include cluster headache, which occurs predominantly in men with an onset before age 25 and presents with pain that is episodic, unilaterally surrounding the eye, excruciating, lasts minutes to hours, and is associated with autonomic symptoms. Short-lasting, unilateral, neuralgiform pain with conjunctival injection and tearing (SUNCT) syndrome is a rare condition that more commonly affects older males. Tolosa-Hunt syndrome manifests as pain in the ocular area accompanied by ipsilateral paresis of oculomotor nerves and the first branch of the trigeminal nerve that is associated with compromise of ophthalmic venous circulation, and improves with steroids. The residual category of atypical facial pain is more commonly associated with psychopathology or other psychological factors that amplify the patient's pain, distress, and disability (Kapur et al. 2003).

The majority of patients with classical trigeminal neuralgia show evidence of trigeminal nerve root compression by blood vessels (85%), mass lesions, or other diseases that cause demyelination and hyperactivity of the trigeminal nucleus (multiple sclerosis, herpes zoster, postherpetic neuralgia) (Joffroy et al. 2001; Love and Coakham 2001). The ignition hypothesis postulates that afferent fibers become hyperexcitable as a result of injury and that paroxysms of pain are the manifestation of synchronized afterdischarge activity (Devor et al. 2002). Uncontrolled pain with frequent or severe prolonged attacks increases the risk of insomnia, weight loss, social withdrawal, anxiety, and depression, including suicide. Pharmacological treatment includes anticonvulsants, antidepressants, baclofen, mexiletine, lidocaine, and opioids (Cheshire 2002; Fisher et al. 2002; Sindrup and Jensen 2002). When pharmacological treatments fail, a variety of surgical procedures, such as microvascular decompression via suboccipital craniectomy, percutaneous gangliolysis, and stereotactic radiosurgery, may be undertaken.

*Temporomandibular disorder* (TMD) is a general term referring to complaints that involve the temporomandibular joint, muscles of mastication, and other orofacial musculoskeletal structures. Pain most commonly arises from the muscles of mastication and is precipitated by jaw

function, such as opening the mouth or chewing. Associated symptoms include feelings of muscle fatigue, weakness, and tightness as well as changes in bite (malocclusion) or the ability to open/close the jaw. In contrast to the vague, diffuse pain of myalgia, temporomandibular joint dysfunction causes sharp, sudden, and intense pain with joint movement that is often localized to the preauricular area. Joint sounds such as clicking, popping, and crepitation are common. Patients may experience limitations in jaw movements, such as catching sensations or actual locking of the jaw. Joint problems are classified as relating to the condyle-disk complex, structural incompatibility of the articular surfaces, and inflammatory joint disorders.

Psychological distress is common in patients with TMD (McCreary et al. 1991). Patients with pain of muscular origin are usually more distressed and depressed, with greater levels of disability, than those with TM joint pain. These factors are responsive to treatment (Auerbach et al. 2001). Longitudinal data suggest that negative affect in patients with orofacial pain is more likely than pain to cause poor sleep quality (Riley et al. 2001). Patients with TMD classified as either "dysfunctional" or "interpersonally distressed" were at higher risk to develop chronic pain without treatment, suggesting a role for proactive prevention programs during the initial acute stages of illness or injury (Epker and Gatchel 2000). In treatment trials for patients with TMD, the dysfunctional group showed the best response to multidisciplinary treatment, with greater improvements in pain intensity, interference, catastrophizing, depression, and negative thoughts when compared with the other groups (Rudy et al. 1995; Sherman and Turk 2001). Patients with low levels of psychosocial dysfunction experienced significantly decreased pain, pain-related interference, numbers of painful muscles, and visits for TMD treatment when they received a less intensive self-care treatment program (Dworkin et al. 2002).

*Burning mouth syndrome* (BMS) is characterized as pain in oral and pharyngeal cavities, especially the tongue, often associated with dryness and taste alterations. Most cases are idiopathic, but BMS may coincide with a plethora of conditions such as bruxism, poorly fitting dentures, oral candidiasis, xerostomia, malnutrition, food allergies and contact dermatitis, gastroesophageal reflux disease, diabetes mellitus, hypothyroidism, neoplasia, menopause, and psychiatric conditions such as depression, anxiety, and somatoform disorders (Drage and Rogers 2003; Formaker and Frank 2000; Grushka et al. 2002). The condition mainly affects middle-aged and postmenopausal women, and the oral mucosa is usually normal. Psychological factors such as severe life events have been associ-

ated with the condition (Bergdahl and Bergdahl 1999; Bogetto et al. 1998).

Theories of etiology and pathogenesis include brain stem pathology, hyperactivity of sensory and motor components of the trigeminal nerve following loss of central inhibition that resulted from damage to the chorda tympani or glossopharyngeal nerves, disorders of the dopaminergic system, and small sensory fiber dysfunction (Forsell et al. 2002; Grushka et al. 2003; Scala et al. 2003). Potential underlying etiologies—such as depression/anxiety, nutritional deficiencies (iron, folate, B<sub>12</sub>, and other B vitamins), maladaptive oral habits, and iatrogenic causes such as medications—should be identified and treated (Bogetto et al. 1998; Pinto et al. 2003). Treatment with TCAs or anticonvulsants has brought pain relief in some patients with BMS. Other treatments include benzodiazepines, topical analgesics, soft desensitizing oral appliances, serotonin reuptake inhibitors, vitamin and hormonal supplements, and habit awareness counseling (Formaker et al. 1998; Maina et al. 2002; Pinto et al. 2003; Zakrzewska et al. 2001).

## Psychiatric Comorbidity

Patients' experiences of suffering, their language and behaviors, and the neurobiological conception of nociception all support a psychological component of pain (Hunt and Mantyh 2001; Price 2000). Cross-sectional studies have consistently found an association between chronic pain and psychological distress (Wilson et al. 2001). In a sample of more than 3,000 individuals, psychiatric disorder was a significant predictor of new-onset physical symptoms such as back, chest, and abdominal pain 7 years after evaluation (Hotopf et al. 1998). In a population-based case-control study, the prevalence of a mental disorder was more than three times higher in patients with chronic widespread pain than in those without such pain (Benjamin et al. 2000).

## Pain Disorder and Somatization

Pain "caused" by emotional factors was first operationalized in DSM-II under psychophysiological disorders (American Psychiatric Association 1968). DSM-III introduced *psychogenic pain disorder*, in which pathophysiology was either absent or insufficient to explain the severity and duration of pain (American Psychiatric Association 1980). In DSM-III-R *somatoform pain disorder*, psychological factors were no longer required as an etiology of pain (American Psychiatric Association 1987). A preoccupation with pain, instead of the pain itself, was established as

the core criterion in conjunction with the absence of adequate physical findings. DSM-IV refined this diagnosis as *pain disorder* (American Psychiatric Association 1994; see also King and Strain 1992). The primary criteria require that pain be the chief complaint and that the pain cause significant distress or functional impairment. Psychological factors are recognized as having an important role in the pain. Unfortunately, the concept of psychological and physical dualism is still inherent in this diagnosis, undermining its validity and utility (Aronoff et al. 2000; King 2000; Sullivan 2000).

The lifetime prevalence of somatoform pain disorder (DSM-III-R) in the general population was 34% with a 6-month prevalence of 17% (Grabe et al. 2003). However, when the DSM-IV requirement of significant distress or psychosocial impairment was added to make the diagnosis, the lifetime prevalence was only 12% and the 6-month prevalence decreased to 5%, with the female:male ratio remaining 2:1. In a sample of more than 13,000 psychiatric consultations, a diagnosis of a somatoform pain disorder was made in 84% (Thomassen et al. 2003). Injured workers who developed somatoform pain disorder, compared with those injured workers who did not develop the condition, were characterized by more sites of pain, spread of pain beyond the area of the original injury, more opioid and benzodiazepine use, and greater involvement with compensation and with litigation (Streltzer et al. 2000).

Characterizing somatization as a psychophysiological process or a multidimensional construct such as somatic style rather than a categorical psychiatric diagnosis or a psychological trait is probably most appropriate (Barsky and Borus 1999; Mayou et al. 2003; Rief and Hiller 1999; Sullivan and Katon 1993). Symptoms, rather than specific diseases, are the most common reason for seeking medical care (Brown et al. 1971; Koch 1978; Kroenke 2003; Kroenke et al. 1990). Women report more severe, numerous, and frequent physical symptoms (including pain) than men (Barsky et al. 2001). Usually, a medical cause is never found for these "somatization" symptoms (Kroenke and Mangelsdorff 1989). As the number of medically unexplained symptoms increases, so does associated morbidity, such as functional disability, increased health care utilization, inappropriate treatment with medications, excessive evaluations, and higher rates of psychiatric disorders (Andersson et al. 1999; Katon et al. 1991; Kouyanou et al. 1998).

Although the actual diagnosis of somatization disorder is rare in patients with chronic pain, multiple pain complaints are present in somatization disorder by definition. Most patients with multiple unexplained symptoms have subsyndromal forms of somatization disorder, such

as multisomatoform disorder, which has a prevalence in primary care of 4%–18% (Dickinson et al. 2003; Kroenke et al. 1997; Simon and Gureje 1999). Such patients are more likely to exhibit catastrophic thinking, believe the cause of their pain to be a mystery, have feelings of losing control, and think that physicians believe their pain is imaginary. Patients with chronic pain and medically unexplained symptoms also are at risk for iatrogenic consequences of excessive diagnostic tests, inappropriate medications, and unneeded surgery.

## Substance Use

The prevalence of substance use disorders in patients with chronic pain is higher than in the general population (Dersh et al. 2002; Weaver and Schnoll 2002). In a study of primary care outpatients with chronic noncancer pain who received at least 6 months of opioid prescriptions during 1 year, behaviors consistent with opioid abuse were recorded in approximately 25% of patients (Reid et al. 2002). Almost 90% of patients attending a pain management clinic were taking medications and 70% were prescribed opioid analgesics (Kouyanou et al. 1997). In this population, 12% met DSM-III-R criteria for substance abuse or dependence. In another study of 414 chronic pain patients, 23% met criteria for active alcohol, opioid, or sedative misuse or dependence; 9% met criteria for a remission diagnosis; and current dependency was most common for opioid use (13%) (Hoffman et al. 1995). In reviews of substance dependence or addiction in patients with chronic pain, the prevalence ranges from 3% to 19% in high-quality studies (Fishbain et al. 1992; Nicholson 2003).

Recent efforts have attempted to standardize diagnostic criteria and definitions for problematic medication use behaviors and substance use disorders across professional disciplines (American Academy of Pain Medicine et al. 2001; Chabal et al. 1997; Greenwald et al. 1999; Savage 2003). The core criteria for a substance use disorder in patients with chronic pain include the loss of control in the use of the medication, excessive preoccupation with it despite adequate analgesia, and adverse consequences associated with its use (Compton et al. 1998). Items from the Prescription Drug Use Questionnaire that best predicted the presence of addiction in a sample of patients with problematic medication use were 1) the patient believing they were addicted, 2) increasing analgesic dose/frequency, and 3) a preferred route of administration. It must be emphasized that the presence of maladaptive behaviors must be demonstrated to diagnose addiction, because physical dependence and tolerance alone are normal physiological phenomena. In other words, depen-

dence and tolerance are necessary but not sufficient for a diagnosis of addiction in the patient with chronic pain receiving treatment with opioids. Access to opioids may not be an issue because a physician has been prescribing them. If addiction is present, however, the patient may fear that opioid access will be limited and therefore try to conceal any problematic use of the medication.

Determining whether patients with chronic pain are abusing prescribed controlled substances is a routine but challenging issue in care (Compton et al. 1998; Miotto et al. 1996; Robinson et al. 2001; Savage 2002). In one survey of approximately 12,000 medical inpatients treated with opioids for a variety of conditions drawn from the Boston Collaborative Drug Surveillance Program, only four patients without a history of substance abuse were reported to have developed dependence on the medication (Porter and Jick 1980). While this report was based on a large sample and extensive medication database, the methods were not detailed and specifically did not describe the criteria for addiction or the extent of follow-up performed. Other studies of opioid therapy have found that patients who developed problems with their medication all had a history of substance abuse (Portenoy and Foley 1986; Taub 1982). However, inaccurate reporting and underreporting of medication use by patients complicate assessment (Fishbain et al. 1999b; Ready et al. 1982). Not infrequently, prior substance abuse history emerges only after current misuse has been identified, thus requiring physicians to be vigilant over the course of treatment. In patients with chronic pain who did develop new substance use disorders, the problem most commonly involved the medications prescribed by their physicians (Long et al. 1988; Maruta et al. 1979).

The causes and onset of substance use disorders have been difficult to characterize in relationship to chronic pain. During the first 5 years after the onset of chronic pain, patients are at increased risk for developing new substance use disorders and additional physical injuries (Brown et al. 1996; Savage 1993). This risk is highest in patients with a history of substance abuse or dependence, childhood physical or sexual abuse, and psychiatric comorbidity (Aronoff 2000; Fishbain et al. 1998; Miotto et al. 1996). In a study of chronic LBP patients, 34% had a substance use disorder, yet in 77% of cases the substance abuse was present before the onset of the chronic pain (Brown et al. 1996; Polatin et al. 1993). The mechanisms of relapse into substance abuse are not well understood and probably involve multiple factors. A cycle of pain followed by relief *after* taking medications is a classic example of operant reinforcement of *future* medication use that eventually becomes abuse (Fordyce et al. 1973). Research in patients with substance abuse has also demonstrated

abnormalities in pain perception and tolerance. An increased sensitivity to pain and the reinforcing effects of relieving pain with substance use suggest a combined mechanism for the development of substance abuse in patients with chronic pain.

Careful monitoring of patients is essential to prevent this complication of the treatment of chronic pain. Increased function and opioid analgesia without side effects, not the avoidance of particular doses of opioids, are the goals of treatment (K.B. Carey et al. 2000; Hamilton 1999; Hathaway 2001; Marlatt 1996; Pappagallo and Heinberg 1997; Savage 1999). The evaluation of a patient suspected of misusing medications should be thorough and include an assessment of the pain syndrome as well as other medical disorders, patterns of medication use, social and family factors, patient and family history of substance abuse, and a psychiatric history (Miotto et al. 1996; Portenoy 1990). Reliance on medications that provide pain relief can result in a number of stereotyped patient behaviors that can either represent or be mistaken for addiction. Persistent pain can lead to increased focus on opioid medications. Patients may take extraordinary measures to ensure an adequate medication supply even in the absence of addiction. This may be manifested as requests for premature refills, higher doses, or extra quantities of medication or seeking medication from additional sources. Patients understandably fear the reemergence of pain and withdrawal symptoms if they run out of medication. Drug-seeking behavior may be the result of an anxious patient trying to maintain a previous level of pain control. In this situation, the patient's actions may represent pseudoaddiction that results from therapeutic dependence and current or potential undertreatment but not addiction (Kirsh et al. 2002; Weaver and Schnoll 2002). Since these behaviors occur in both pseudo- and true addiction, the distinction is based in part on whether the behaviors are infrequent and isolated vs. repetitive and persistent, and whether they abate with adequate opioid therapy. However, these are not distinct categories; overuse of analgesics occurs along a continuum.

In patients with higher risk of addiction, prevention should begin with a treatment contract to clarify the conditions under which opioids will be provided. The contract emphasizes a single physician being responsible for prescriptions, and explicitly describes all the conditions under which use of opioids will be considered inappropriate and may lead to discontinuation. Under optimal circumstances, opioid contracts attempt to improve compliance by distributing information and using a mutually agreed upon treatment plan that includes consequences for aberrant behaviors and incorporates the primary care physician to form a "trilateral" agreement with the patient

and pain specialist (Fishman et al. 1999, 2000, 2002). When there is concern that a patient will have difficulty taking medications as directed, a policy of prescribing small quantities, performing random pill counts, and not refilling lost supplies should be explicitly discussed and then followed. External sources of information such as urine toxicology testing, interviews with significant others, direct contact with pharmacists, data from prescription monitoring programs, and review of medical records can improve detection of substance use disorders. In one study, patients who denied using illicit substances that were detected on urine toxicology were more likely to be younger, receiving worker's compensation benefits, and have a previous diagnosis of polysubstance abuse (Katz and Fanciullo 2002).

The occurrence of any aberrant medication-related behaviors should prompt evaluation for addiction. Even when the diagnosis of a substance use disorder is suspected in patients taking opioids for chronic pain, behaviors such as stealing or forging prescriptions are relatively uncommon (Fishbain et al. 1992; Longo et al. 2000; Sees and Clark 1993). These more serious aberrant behaviors consistent with addiction also include selling medications, losing prescriptions, buying medications on the Internet, diverting medications from other patients, using oral medications intravenously, concurrently abusing alcohol or illicit drugs, repeatedly being noncompliant with the prescribed use of medications, and the patient's experiencing deterioration in the ability to function in family, social, or occupational roles. Concerns by family or friends about the patient's pattern of medication use, an appearance suggesting intoxication, or the patient's having other difficulties with functional abilities requires in-depth evaluation. Any unwillingness to discuss the possibility of addiction or changes in chronic opioid therapy is a red flag underlining the need for a full substance abuse evaluation.

Patients with substance use disorders have increased rates of chronic pain and are at the greatest risk for stigmatization and undertreatment with appropriate medications by health care practitioners (Gilson and Joranson 2002; Rosenblum et al. 2003). Ironically, this places them at additional risk of drug-seeking behaviors, including self-medication with illicit drugs. Almost one-quarter of patients admitted to inpatient residential substance abuse treatment and more than one-third of patients in methadone maintenance treatment programs reported severe chronic pain, with almost half of the inpatients and two-thirds of the methadone maintenance patients experiencing pain-related interference in functioning (Rosenblum et al. 2003). In another study of methadone maintenance therapy, patients with pain were more likely to overuse

both prescribed and nonprescribed medications (Jamison et al. 2000). Patients with substance abuse and back pain were less likely to complete a substance abuse treatment program compared with those without pain (Stack et al. 2000). Ethical principles such as beneficence, quality of life, and autonomy can provide particularly useful guidance for the use of chronic opioid therapy (Cohen et al. 2002; Drug Enforcement Administration 2002; Nicholson 2003). Benefits of treatment should be optimized for each patient, recognizing a continuum of severity for both pain and addiction, within a context of risk management.

## Depression and Distress

### *Pain in Patients With Depression*

Physical symptoms are common in patients with major depression (Lipowski 1990). Approximately 60% of patients with depression report pain symptoms at the time of diagnosis (Magni et al. 1985; Von Knorring et al. 1983). In WHO data from 14 countries on five continents, 69% (range = 45%–95%) of patients with depression presented with only somatic symptoms, of which pain complaints were most common (Simon et al. 1999). Half the depressed patients reported multiple unexplained somatic symptoms, and 11% actively denied the psychological symptoms of depression. A survey of almost 19,000 Europeans found a fourfold increase in the prevalence of chronic painful conditions in respondents with major depression (Ohayon and Schatzberg 2003).

The presence of a depressive disorder has been demonstrated to increase the risk of developing chronic musculoskeletal pain, headache, and chest pain up to 3 years later (Leino and Magni 1993; Magni et al. 1993, 1994; Von Korff et al. 1993). Even after 8 years, the previously depressed patients remained twice as likely as the nondepressed subjects to develop chronic pain. In a 15-year prospective study of workers in an industrial setting, the presence of initial depression symptoms predicted LBP and a positive clinical back examination in men but not in women (Leino and Magni 1993). Five years later, self-assessed depression at baseline was a significant predictor in the 25% of at-risk women who developed fibromyalgia (Forseth et al. 1999).

### *Depression in Patients With Chronic Pain*

In 1,016 health maintenance organization (HMO) members, the prevalence of depression was 12% in individuals with three or more pain complaints, compared with only 1% in those with one or no pain complaints (Dworkin et al. 1990). Depression was significantly more common in patients with rheumatoid arthritis, and the level of de-

pression increased with greater levels of pain (Dickens et al. 2002). The Canadian National Population Health Survey found that the incidence of major depression was approximately doubled in subjects who reported a long-term medical condition such as back problems, migraine, and sinusitis (Patten 2001). In a community survey of people over age 65 who had activity limitations but no psychiatric morbidity, the incidence of depression three years later was highest in people with an acute illness and experienced pain (Livingston et al. 2000). In a similar study of late-onset depression in the elderly, joint pain was one of the most important predictors of incident depression 5 years later (Hein et al. 2003).

One-third to over half of patients presenting to clinics specializing in the evaluation of chronic pain have a current major depression (Dersh et al. 2002; Fishbain et al. 1997a; Reich et al. 1983; Smith 1992). In one study, 65% of patients hospitalized for rehabilitation for a musculoskeletal disease had a lifetime history of a psychiatric disorder (Harter et al. 2002). More than 30% of patients met criteria for a current mental disorder (11% major depression), with half having two or more psychiatric conditions. In groups of patients with medically unexplained symptoms such as back pain, orofacial pain, and dizziness, two-thirds of patients have a history of recurrent major depression, compared with less than 20% of medically ill control groups (Atkinson et al. 1991; Katon and Sullivan 1990; Sullivan and Katon 1993; Yap et al. 2002). Patients with higher levels of baseline affective distress on the General Health Questionnaire (GHQ) were 1.8 times more likely to seek consultation for a new episode of back pain 12 months later (Croft et al. 1996).

### *Affective Distress Versus Affective Disorder*

The determination whether negative affect represents a diagnosis of major depression as opposed to psychological distress varies widely. Diagnostic criteria, structured interviews, and self-report questionnaires might lack validity or measure different concepts when applied to patients with chronic pain (Lebovits 2000). Self-report measures of depression are generally reliable and have predictive validity in patients with chronic pain (Turk and Okifuji 1994). Principal-components analyses of the responses of patients with chronic pain on the Beck Depression Inventory find three factors consistent with the core criteria of major depression: low mood, impaired self attitude, poor vital sense. One study described these factors as sadness, self-reproach, and somatic symptoms, and another described them in the similar terms of negative attitudes/suicide, physiological manifestations, and performance difficulty (Novy et al. 1995; Williams and Richardson 1993).

In a study comparing separate measures of affective distress, self-reported depressive symptoms, and major depression in patients with chronic pain at a pain clinic, the relationship between pain and depression remained significant even when the somatic items of depressive symptoms were excluded (Geisser et al. 2000). Self-reported depressive symptoms were also highly related to the evaluative or cognitive component of pain. In contrast, more general symptoms of affective distress were uniquely related to the sensory or emotional component of pain. Self-reported symptoms of affective distress and depressive symptoms were independently associated with increased pain, greater disability, and more negative thoughts about pain. A diagnosis of major depression was found only to make unique contributions to measures of negative thoughts about pain and self-reported disability. A diagnosis of major depression was determined to be a less sensitive indicator and less important predictor of the chronic pain experience than self-reported depressive symptoms. Therefore, practitioners should recognize the presence of depressive symptoms, even without the categorical diagnosis of major depression, as an important comorbidity for patients with chronic pain.

### *Consequences of Depression*

The presence of depression has been shown to worsen other medical illnesses, interfere with their ongoing management, and amplify their detrimental effects on health-related quality of life (Cassano and Fava 2002; Gaynes et al. 2002). Depression in patients with chronic pain is associated with greater pain intensity, more pain persistence, less life control, more use of passive-avoidant coping strategies, noncompliance with treatment, application for early retirement, and greater interference from pain, including more pain behaviors observed by others (Hasenbring et al. 1994; Haythornthwaite et al. 1991; Kerns and Haythornthwaite 1988; Magni et al. 1985, 1993; Weickgenant et al. 1993). Primary care patients with musculoskeletal pain complicated by depression are significantly more likely than nondepressed patients with musculoskeletal pain to use medications daily, including sedative-hypnotics, and in combinations (Mantyselka et al. 2002). In a study of more than 15,000 employees who filed health claims, the cost of managing chronic conditions such as back problems was multiplied by 1.7 when comorbid depression was present (Druss et al. 2000). Depressed patients with chronic facial pain were more likely than nondepressed chronic facial pain patients to be noncompliant with medication changes, therapeutic injections, and splint therapy (Riley et al. 1999b).

Depression is a better predictor of disability than pain intensity and duration (Rudy et al. 1988). For example, fi-

bromyalgia patients with depression compared with those without were significantly more likely to live alone, report functional disability, and describe maladaptive thoughts (Okifuji et al. 2000). A naturalistic follow-up study of patients with chronic pain who had substantial numbers of sick days found that a diagnosis of major depression predicted disability an average of 3.7 years later (Ericsson et al. 2002). The presence of depression in whiplash patients reduced the insurance claim closure rate by 37% (Cote et al. 2001). This rate was unaffected even after the insurance system eliminated compensation for pain and suffering. Preoperative major depression in patients undergoing surgery for thoracic outlet syndrome increased the rate of self-reported disability by over 15 times (Axelrod et al. 2001). The presence of preoperative depression in patients undergoing lumbar discectomy predicted poorer surgical outcome at 1-year follow-up (Junge et al. 1995). In patients with rheumatoid arthritis, depressive symptoms were significantly associated with negative health and functional outcomes, as well as increased health services utilization (Katz and Yelin 1993). Depression consistently predicted level of functioning, pain severity, pain-related disability, less use of active coping, and more use of passive coping in patients on a university chronic pain inpatient unit (Fisher et al. 2001). In a clinical trial of 1,001 depressed patients older than 60 years with arthritis, antidepressants and/or problem-solving-oriented psychotherapy not only reduced depressive symptoms but also improved pain, functional status, and quality of life (Lin et al. 2003).

Patients suffering from chronic pain syndromes, including migraine, chronic abdominal pain, and orthopedic pain syndromes, report increased rates of suicidal ideation, suicide attempts, and suicide completion (Fishbain 1999b; Fishbain et al. 1991; Magni et al. 1998). In one study of patients who attempted suicide, 52% suffered from a chronic somatic disease and 21% were taking analgesics on a daily basis for pain (Stenager et al. 1994). Patients with chronic pain completed suicide at two to three times the rate in the general population (Fishbain et al. 1991). Cancer patients with pain and depression, but not pain alone, were significantly more likely to request assistance in committing suicide as well as actively to take steps to end their lives (Emanuel et al. 1996).

### *Relationship Between Pain and Depression*

In addition to the epidemiology of pain and depression, as well as the effects of comorbidity on diagnosis, treatment, and outcome reviewed in the preceding subsections, the existing models of the relationship between pain and depression were recently detailed (Bair et al. 2003; Pincus and Williams 1999). Cognitive conceptualizations of de-

pression have included the role of negative schemata, leading to processing biases, distorted perceptions, negative thoughts, and depressed mood; the role of learned helplessness in a context of having no control over adverse events; the focus on hopelessness that emerges as a result of the desired outcomes being improbable and undesired outcomes being inevitable; and a problem-solving mechanism that persuades others to interact with the ill person (Abramson et al. 1978, 1989; Beck 1976; Seligman 1974; Watson and Andrews 2002).

The rates of affective disorders in family members of patients with depression occurring after the onset of chronic pain are similar to those in the general population and significantly lower than those in family members of patients with major depression (Banks and Kerns 1996; Dworkin et al. 1999; Gallagher and Verma 1999). For example, major depression and depressive spectrum disorders were not more common in the first-degree relatives of patients with myofascial facial pain regardless of whether they had personal histories of early- or late-onset major depression (Dohrenwend et al. 1999). These results do not support the characterization of chronic nonmalignant pain as a variant of depression (“masked depression”), but they do support the hypothesis that depression emerges out of the stress of living with chronic pain.

In addition to depression as a consequence of chronic pain, there are mediating biopsychosocial factors in the interaction between depression and chronic pain (Banks and Kerns 1996; Fishbain et al. 1997a; Pincus and Williams 1999; Sheftell and Atlas 2002). The diathesis–stress model postulates an interaction between personal pre-morbid vulnerabilities activated and exacerbated by life stressors such as chronic pain and the subsequent outcome of depression or other psychopathology. In a study of patients with chronic LBP, regression models that included all cognitive-behavioral variables (self-control, cognitive distortion, interference with instrumental activities of daily living) produced the strongest association with self-reported depression (Maxwell et al. 1998). Without these cognitive factors, there was no significant association of pain and disability with depression—a finding consistent with the diathesis–stress model. Other intervening factors have also been identified. A study of nearly 4,000 twin pairs found that genetic factors accounted for 60% of the covariation in the best-fitting model for the association between back and neck pain and symptoms of depression and anxiety (Reichborn-Kjennerud et al. 2002).

More sophisticated models add the component of illness behaviors/disability, which functions both as a response of the vulnerable individual to a significant stressor

and, later, as a stressor itself (Revenson and Felton 1989). The severity of depression has been found to be unaffected by pain intensity when pain-related disability is controlled for (Von Korff et al. 1992). If pain causes disability—such as loss of independence or mobility—that decreases an individual’s participation in activities, the risk of depression is significantly increased (Williamson and Schulz 1992). In a clinical trial involving patients with chronic LBP, the association between pain and depression was found to be attributable to disability and illness attitudes (Dickens et al. 2000). A study of patients in primary care found that after a variety of factors, such as disability and perceived health, were controlled for, anxiety and depression were no longer associated with the diagnoses of headache, osteoarthritis, and abdominal pain (Wu et al. 2002).

The neurobiology of pain and depression overlap (Bair et al. 2003; Bolay and Moskowitz 2002; Hunt and Mantyh 2001; Price 2000; Riedel and Neeck 2001). In particular, the descending pathways of pain modulation in the central nervous system that utilize monoamine neurotransmitters in the limbic system, periaqueductal gray, rostral-ventromedial medulla, and dorsolateral pontine tegmentum influence aspects of affect and attention (Millan 2002). Pain can be decreased by descending inhibition as first postulated by the gate theory of Melzack and Wall (1965). Increased levels of serotonin and norepinephrine diminish peripheral nociceptive inputs and augment descending central inhibition. The functional deficiency of monoamine neurotransmitters or related neurochemical dysfunctions in affective disorder could partially explain the linkages between pain and depression. Similar associations between pain, depression, and sleep disturbance have been described (Moldofsky 2001). Reduced sleep quantity and quality have been correlated with pain, depression, and negative affectivity. Current models postulate that pain increases negative affect over time, with subsequent detrimental effects on sleep quality, although bidirectional relationships have also been proposed (McCracken and Iverson 2002; Riley et al. 2001). Physical functioning, duration of pain, and age have been implicated in mediation of the decreased sleep quality and latency in patients with chronic pain (Menefee et al. 2000).

### Anxiety, Fear, Catastrophizing, and Anger

Patients with a variety of chronic pain syndromes, such as headache, LBP, neck pain after whiplash injury, and chronic pain from prostate cancer, have increased rates of both anxiety symptoms and current anxiety disorders (Dersh et al. 2002; Fishbain et al. 1986; Heim and Oei 1993; Juang et al. 2000; Lee et al. 1993; Polatin et al.

1993; Weissman and Merikangas 1986). Almost 50% of patients with chronic pain report anxiety symptoms, and up to 30% of patients have an anxiety disorder such as panic disorder and generalized anxiety disorder (Devlen 1994; Fishbain et al. 1998; Katon et al. 1985; Reich et al. 1983). One prospective study of 1,007 young adults found that a baseline history of migraine was significantly associated with an increased risk (OR=12.8) of first-incident panic disorder (Breslau and Davis 1993). In a study of patients with fibromyalgia, more than half of the patients reported clinically relevant posttraumatic stress disorder (PTSD)-like symptoms that were significantly associated with greater levels of pain, emotional distress, interference, and disability (Sherman et al. 2000). Patients with chronic pain classified as Dysfunctional according to the Multidimensional Pain Inventory are almost twice as likely to complain of PTSD-like symptoms as patients classified as Interpersonally Distressed and more than three times as likely as Adaptive Copers (Asmundson et al. 2000, 2002).

Conversely, anxiety symptoms and disorders are associated with high levels of somatic preoccupation and physical symptoms. Pain intensity in rheumatoid arthritis patients was found to be significantly influenced by the presence of anxiety and depression even after disease activity had been controlled for (Smedstad et al. 1995). Men with high levels of anxiety were shown to experience greater pain severity, interference from pain, and limitations in daily activities (Edwards et al. 2000). Almost two-thirds of patients with panic disorder reported at least one current pain symptom, with chest pain and headache being the most common (Schmidt et al. 2002). Pain was related to higher levels of anxiety symptoms, panic frequency, and cognitive features of anxiety, but not to treatment response.

The fear-avoidance model and expectancy model of fear provide explanations for the initiation and maintenance of chronic pain disability, proposing that anxiety sensitivity amplifies reactions such as avoidance of specific activities (Greenberg and Burns 2003; Lethem et al. 1983; Reis 1991; Vlaeyen and Linton 2000). Anxiety sensitivity is a significant predictor of fear of, and anxiety about, pain (Zvolensky et al. 2001). Fear of pain, movement, reinjury, and other negative consequences that result in the avoidance of activities promote the transition to and sustaining of chronic pain and its associated disabilities such as muscular reactivity, deconditioning, and guarded movement (Asmundson et al. 1999). In one study, patients with chronic LBP who restricted their activities developed physiological changes (muscle atrophy, osteoporosis, weight gain) and functional deterioration attributed to deconditioning (Verbunt et al. 2003). This

process is reinforced by negative cognitions such as low self-efficacy, catastrophic interpretations, and increased expectations of failure regarding attempts to engage in rehabilitation. Higher levels of pain anxiety were shown to correlate with lower amounts of weight lifted and carried by men with chronic pain referred for work rehabilitation (Burns et al. 2000).

Fear-avoidance beliefs have been found to be one of the most significant predictors of failure to return to work in patients with chronic LBP (Waddell et al. 1993). Operant conditioning reinforces disability if the avoidance provides any short-term benefits, such as reducing anticipatory anxiety or relieving the individual of unwanted responsibilities. In a study of patients with chronic LBP, improvements in disability following physical therapy were associated with decreases in pain, psychological distress, and fear-avoidance beliefs but not in specific physical deficits (Mannion et al. 1999, 2001). Decreasing work-specific fears was a more important outcome than addressing general fears of physical activity in predicting improved physical capability for work among patients participating in an interdisciplinary treatment program (Vowles and Gross 2003).

Catastrophic thinking about pain has been attributed to the amplification of threatening information, and it interferes with the focus needed to facilitate patients' remaining involved with productive instead of pain-related activities (Crombez et al. 1998). Catastrophizing intensifies the experience of pain and increases emotional distress as well as self-perceived disability (Severeijns et al. 2001; Sullivan et al. 2001). This multidimensional construct includes elements of cognitive rumination, symptom magnification, and feelings of helplessness (Van Damme et al. 2002). Early treatment catastrophizing and helplessness of patients in a 4-week multidisciplinary pain program predicted late-treatment outcomes such as pain-related interference and activity level (Burns et al. 2003). These changes persisted despite changes in depression over the course of treatment being controlled for, supporting the model that changing negative cognitions improves treatment outcome.

Pain-related cognitions such as catastrophizing and fear-avoidance beliefs are considered some of the strongest psychological variables mediating the transition from acute to chronic pain and usually have more predictive power of poor adjustment to chronic pain than objective factors such as disease status, physical impairment, or occupational descriptions (Hasenbring et al. 2001). In a population-based study of individuals without LBP, high levels of catastrophizing and fear of injury prospectively predicted disability due to new-onset LBP 6 months later (Picavet et al. 2002). In a study of patients with pain after

spinal cord injury, catastrophizing was the only form of coping significantly associated with poor adjustment (Turner et al. 2002).

Anger is characterized by a specific cognitive appraisal and action tendency (Fernandez and Turk 1995). This emotional state is distinguished from the trait of hostility and the goal-oriented behavior of aggression. In a sample of patients with chronic pain referred for comprehensive evaluation, 70% reported anger that was most commonly directed at themselves (74%) and health care professionals (62%) (Okifuji et al. 1999). Patients have different anger management styles that range from suppression (anger-in) to expression or engagement (anger-out). Women with chronic pain who were low in hostility and high on anger expression were more likely to report lower pain intensity and higher levels of activity (Burns et al. 1996). In contrast, patients who reported the highest levels of pain and associated interference were men with high hostility and suppression of anger. In men, anger suppression is associated with depression and limitations in performing general activities (Burns et al. 1998). In women with chronic headache, anger suppression was associated with depression, but expression was associated with anxiety (Venable et al. 2001).

## Pharmacological Treatment

---

While medications are often prescribed for all types of chronic pain, research has consistently shown that several classes have proven efficacy for the treatment of neuropathic pain (Nitu et al. 2003). Ideally, pharmacotherapy of pain would be specifically selected on the basis of considerations of etiology (e.g., ischemic, neuropathic), pathophysiology (e.g., demyelination, central pain), and anatomy (e.g., C fibers, sympathetic nerves) (Woolf and Decosterd 1999; Woolf and Mannion 1999; Woolf et al. 1998). No experimental data exist to support or refute this clinical approach, and a number of drug classes have been found to improve many different kinds of pain. Unfortunately, medications are often underutilized and underdosed. In one study of patients with neuropathic pain, 73% complained of inadequate pain control, but 72% had never received anticonvulsants, 60% TCAs, or 41% opioids, and 25% had never received any of the above (Gilron et al. 2002). Physicians still attempt to alleviate pain with simple analgesics and fail to appreciate the subtleties of the "adjuvant" medications, which possess multiple pharmacological actions. These medications offer a sophisticated and multifaceted approach to antinociception that is usually required in the treatment of patients with chronic pain.

## Opioids

Comprehensive reviews describe opioid pharmacology and opioid peptide systems (Ballantyne and Mao 2003; Bodnar and Hadjimarkou 2002; Drolet et al. 2001; Inturrisi 2002; Kieffer and Gaveriaux-Ruff 2002; O'Callaghan 2001; Przewlocki and Przewlocka 2001; Riedel and Neeck 2001; Vaccarino and Kastin 2001). The analgesic effects of opioids typically decrease the distressing affective component of pain more than the sensation of pain. This effect may be more pronounced in women who reported lower levels of affective distress despite higher levels of pain compared with men while being treated with opioids (Fillingim et al. 2003). The treatment of nonmalignant chronic pain with opioids remains a subject of considerable debate, with fears of regulatory pressure, medication abuse, and the development of tolerance creating reluctance to prescribe opioids (Chabal et al. 1992a; Maruta et al. 1979; Morgan 1985; Potter et al. 2001; Schug et al. 1991). Nevertheless, the prescription of long-term opioids for the treatment of chronic nonmalignant pain has increased (Clark 2002; Fanciullo et al. 2002; Moulin et al. 2002; Turk et al. 1994).

Opioids are effective in the treatment of chronic nonmalignant pain, as demonstrated in randomized, placebo-controlled trials, in reducing pain, pain-related disability, depression, insomnia, and physical dysfunction (Arkin-stall et al. 1995; Caldwell et al. 2002; Maier et al. 2002; Moulin et al. 1996; Roth et al. 2000; Sittl et al. 2003). Studies of neuropathic pain show that opioids provide direct analgesic benefits and do not just counteract the unpleasantness of pain (Dellemijn and Vanneste 1997; Watt et al. 1996). Levorphanol reduced pain, affective distress, interference with function, and sleep difficulties in adults with neuropathic pain (Rowbotham et al. 2003). Continuous-release morphine decreased pain in patients with postherpetic neuralgia significantly more than did TCAs or placebo (Raja et al. 2002).

Successful treatment with opioids requires the assessment and documentation of improvements in function and analgesia without accompanying adverse side effects and aberrant behaviors (Mendelson and Mendelson 1991; Nedeljkovic et al. 2002; Passik and Weinreb 2000; Schug et al. 1991). The Federation of State Medical Boards, American Academy of Pain Medicine, American Pain Society, and American Geriatrics Society have all produced guidelines for the treatment of chronic pain (American Geriatrics Society Panel on Chronic Pain in Older Persons 1998). These efforts, combined with legislation to support these educational and governmental initiatives, are improving attitudes toward, acceptance of, and access to chronic opioid therapy (Gilson and Joranson 2001;

Joranson et al. 2002). If opioid therapy is unsuccessful, the medication should be gradually tapered and discontinued. Acute opioid withdrawal is not dangerous except in patients at risk from increased sympathetic tone, such as those with increased intracranial pressure or unstable angina. Intermittent discontinuation or tapering of opioids often results in exacerbation of the patient's pain (opioid-abstinence hyperalgesia, opioid-induced hyperalgesia), probably involving spinal sensitization (Li and Clark 2002; Li et al. 2001).

Generally, a constant rather than intermittent "as needed" schedule for pharmacotherapy should be followed, with the time between dosages and the individual dose amounts kept consistent. In particular, opioids with slow onset and longer duration of action are preferred so as to minimize the initial euphoria and interdose withdrawal symptoms of traditional short-acting opioids, which should be reserved for the treatment of breakthrough pain. Extended-release oral medications and transdermal routes of administration decrease these qualities of opioids that place patients at risk of inadequate treatment and abuse. In the United States, controlled-release formulations of morphine, oxycodone, fentanyl, and potentially hydromorphone and oxymorphone, as well as newer alternatives such as dihydroetorphine, transdermal buprenorphine, slow-release tramadol, and slow-release dihydrocodeine, are now available but still represent the minority of opioid prescriptions (Ohmori and Morimoto 2002; Portenoy et al. 2002; Tzschentke 2002; Wilder-Smith et al. 2001). Mixed agonist-antagonist opioids should be avoided because of their propensity to precipitate withdrawal symptoms in patients undergoing chronic opioid therapy.

Most long-acting opioids are expensive. Methadone offers a low-cost alternative with the unique advantage of suppressing withdrawal symptoms for more than 24 hours. Unfortunately, the analgesic properties of methadone are similar to those of immediate-release morphine, necessitating a 6-hour dosing schedule for the treatment of chronic pain. Generic formulations of continuous-release morphine and oxycodone offer affordable options. In a randomized, open-label, crossover trial in patients with chronic noncancer pain treated with opioids, transdermal fentanyl was preferred to sustained-release oral morphine (65% vs. 28%), with the greater preference attributed to better pain relief, an enhanced quality of life, and less constipation (Allan et al. 2001). Transdermal fentanyl produced significantly better cost-utility ratios than continuous-release formulations of morphine and oxycodone for each quality-adjusted life year gained despite higher costs of therapy (Neighbors et al. 2001).

The most common side effect of chronic opioid therapy is decreased gastrointestinal motility, potentially leading to constipation, vomiting, and abdominal pain. In some patients with chronic abdominal pain, the problem of "narcotic bowel" results from the vicious cycle of opioid treatment causing painful constipation, followed by the escalation of opioid dose, resulting in even more pain. This process is further complicated by rebound pain with attempts to taper the opioids, which leads to additional dose increases with no subsequent benefits, as well as the persistence of colonic dysmotility after opioid discontinuation. Oral opioids differ in their propensity to cause symptoms of gastrointestinal dysmotility (Heiskanen and Kalso 1997). Transdermal fentanyl is an effective analgesic with fewer gastrointestinal side effects than oral medications, with over 90% of patients choosing to continue the medication after completion of a study trial (Donner et al. 1996; Grond et al. 2000). Newer experimental opioid antagonists that do not cross the blood-brain barrier may offer relief of constipation without compromising analgesia or precipitating withdrawal (Kurz and Sessler 2003; Portenoy and Foley 1987).

Opioids induce centrally mediated hypogonadism with lower production of testosterone, manifested in fatigue, loss of libido, and impaired sexual function (Daniell 2002). Concerns about cognitive impairment are more often the reason opioids are not prescribed. Studies comparing patients taking opioids with those who are not or patients before and during treatment with opioids have not demonstrated deleterious effects on neuropsychological testing, computerized testing of performance, or electroencephalography (EEG), except in patients prescribed multiple medications, especially sedatives and hypnotics (Chapman et al. 2002; Hendler et al. 1980; Lomardo et al. 1976; McNairy et al. 1984; Sabatowski et al. 2003; Zielger 1994). Although no studies have examined the risk of delirium in chronic pain syndromes treated with opioids, meperidine poses a unique risk for causing an agitated hyperactive delirium.

Long-term administration of opioids predisposes one to tolerance, but chronic pain may actually facilitate its development (Christensen and Kayser 2000). While several physiological mechanisms have been described to explain this phenomenon, tolerance is uncommon in clinical practice (Borgland 2001; Cahill et al. 2001; Dogrul et al. 2002; France et al. 1984; Freye and Latasch 2003; Katz 2000; Mao et al. 2002; Portenoy 1990). The incidence of analgesic tolerance is lower with more potent opioids such as fentanyl, presumably because they are more receptor-specific and fewer receptors are needed to induce an analgesic effect. Although constipation is likely to persist, tolerance to most opioid side effects usually occurs.

The loss of preexisting analgesia can have many causes besides tolerance and should be carefully evaluated so as to determine its etiology. Disease progression or other changes in the patient's chronic pain condition should be considered before this loss is attributed to tolerance. A return of, or even an increase in, pain can be the result of new injury, worsening neurological damage, comorbid psychiatric disorders, or medication effects such as toxicity, withdrawal, or opioid-induced hyperalgesia (Liu and Anand 2001).

When tolerance to an analgesic agent develops, suggested strategies have included simultaneous administration of other agents (opioid agonists with differing receptor affinities; ultra-low-dose opioid antagonists; calcium channel blockers;  $\alpha_2$ -adrenergic agonists; COX-2 inhibitors; NMDA receptor antagonists such as ketamine, dextromethorphan, memantine, and amantadine); opioid rotation to a more potent agonist; and intermittent cessation of certain agents (e.g., opioids, benzodiazepines) (Bolan et al. 2002; Pasternak 2001). Augmentation of analgesia may occur by using opioids that possess NMDA antagonist action, such as methadone, dextropropoxyphene, and ketobemidone, or those that inhibit monoamine reuptake, such as methadone, tramadol, and levorphanol (Rojas-Corrales et al. 2002; Sang 2000). Incomplete cross-tolerance of the analgesic effects of opioids probably accounts for the improved pain relief gained through rotating between different long-acting opioids or switching from short-acting to long-acting opioids (Quang-Cantagrel et al. 2000; Thomsen et al. 1999). Opioid rotation may also improve analgesia if morphine or hydromorphone is discontinued, because these agents' 3-glucuronide metabolites can accumulate within the cerebrospinal fluid and produce neuroexcitatory effects such as allodynia, myoclonus, delirium, and seizures (Forman 1996; Smith 2000).

## Antidepressants

The neurobiology of pain suggests potential efficacy for all antidepressants in the treatment of chronic pain (Ansari 2000; Lynch 2001; Mattia et al. 2002). The analgesic effect of antidepressants is thought to be primarily mediated by the blockade of reuptake of norepinephrine and serotonin, increasing their levels to enhance the activation of descending inhibitory neurons (King 1981; Magni 1987; Ollat and Cesaro 1995). However, antidepressants may produce antinociceptive effects through a variety of other pharmacological mechanisms (Ansari 2000; Carter and Sullivan 2002; Feighner 1999; Kiefer et al. 1999). (See Chapter 37, "Psychopharmacology," for a discussion of the pharmacology of antidepressants.)

## *Tricyclic Antidepressants*

The effectiveness of antidepressants for the treatment of major depression is well documented, but their analgesic properties are underappreciated (Barkin and Fawcett 2000). In 1960, the first report of imipramine use for trigeminal neuralgia was published (Paoli et al. 1960). Since then, antidepressants, particularly the TCAs, have been commonly prescribed for many chronic pain syndromes, including diabetic neuropathy, postherpetic neuralgia, central pain, poststroke pain, tension-type headache, migraine, and orofacial pain (Ansari 2000; Clark 2000b; Collins et al. 2000; Lynch 2001). TCAs have been most effective in relieving neuropathic pain and headache syndromes (Gruber et al. 1996; MacFarlane et al. 1997; Magni 1991; Max et al. 1987; McQuay et al. 1996; Volmink et al. 1996; Vrethem et al. 1997; Wesselmann and Reich 1996). A meta-analysis showed that TCAs were more effective than placebo for the treatment of chronic back pain in reducing pain severity but not functional disability (Salerno et al. 2002). Meta-analyses of randomized, controlled trials concluded that TCAs are the most effective agents for the treatment of postherpetic neuralgia and that nortriptyline is better tolerated than amitriptyline with equivalent efficacy (Dworkin and Schmader 2003; Lynch 2001; Roose et al. 1981; Volmink et al. 1996; Watson et al. 1988). Protriptyline, compared with placebo, decreased chronic tension-type headache frequency by 86% in a study of women with this condition (Cohen 1997).

Only 25% of patients in one multidisciplinary pain center were prescribed TCAs, and 73% of treated patients were prescribed only the equivalent of 50 mg or less of amitriptyline, suggesting the potential for additional pain relief (Richeimer et al. 1997). The cost of TCAs for pain treatment is much lower (often less than \$5.00/month) than the cost of other antidepressants and most analgesics (Adelman and Von Seggern 1995). A number of treatment studies of postherpetic neuralgia and painful diabetic peripheral neuropathy have used TCAs, with mean daily doses ranging from 100 to 250 mg (Max 1994; Onghena and Van Houdenhove 1992). Over 60% of patients reported improvement, usually beginning in the third week of treatment, with serum levels at the low end of the therapeutic range for the treatment of depression. Typically, the analgesic effects of antidepressants are independent of the presence of depression or improvement in mood. Analgesia usually occurs at lower doses and with earlier onset of action than expected for the treatment of depression. The results of investigations to determine drug concentrations needed for pain relief support higher serum levels but remain contradictory (Kishore-Kumar et al. 1990; Sindrup et al. 1989).

Noradrenergic activity is often associated with better analgesic effects than serotonergic activity alone. The relatively noradrenergic antidepressants (i.e., with a serotonin/norepinephrine ratio of less than 1.0) include amitriptyline, imipramine, doxepin, nortriptyline, desipramine, and maprotiline (Feighner 1999; Richelson 1994). Generally, the tertiary TCAs with balanced effects on serotonin and norepinephrine reuptake (imipramine, amitriptyline, doxepin) are considered more effective analgesic agents than the secondary TCAs with more selective norepinephrine reuptake inhibition (desipramine, nortriptyline, maprotiline). While tertiary amines have been used most commonly, the secondary amines have fewer side effects and are less likely to be discontinued. Randomized, controlled trials have not demonstrated consistent differences in efficacy between the TCAs (Bryson and Wilde 1996; Collins et al. 2000; Sindrup and Jensen 1999, 2000).

### **Selective Serotonin Reuptake Inhibitors**

The selective serotonin reuptake inhibitors (SSRIs) produce weak antinociceptive effects in animal models of acute pain (Gatch et al. 1998; Paul and Hornby 1995; Schreiber et al. 1996). This antinociception is blocked by serotonin receptor antagonists and is enhanced by opioid receptor agonists. In human clinical trials, the efficacy of SSRIs in chronic pain syndromes has been variable and inconsistent (Belcheva et al. 1995; Jung et al. 1997; Tokunaga et al. 1998). In patients with chronic LBP without depression, nortriptyline or maprotiline, but not paroxetine, significantly reduced pain intensity (Atkinson et al. 1998, 1999). Desipramine was superior to fluoxetine in the treatment of painful diabetic peripheral neuropathy (Max et al. 1992). On the other hand, paroxetine and citalopram were beneficial in studies of patients with diabetic neuropathy (Sindrup et al. 1990, 1992). Fluoxetine significantly reduced pain in patients with rheumatoid arthritis and was comparable in efficacy to amitriptyline (Rani et al. 1996). A 12-week course of fluoxetine also improved outcome measures in women with fibromyalgia (Arnold et al. 2002). The SSRIs may be effective in the treatment of some headaches, especially migraine, and are well tolerated by patients (Bank 1994; Foster and Bafaloukos 1994; Saper et al. 1994). However, citalopram did not significantly reduce the duration of chronic tension headache, headache frequency, and the intake of analgesics (Bendtsen et al. 1996). In depressed patients with neuropathic pain, improvements in pain were dependent on improvements in depressive symptoms if patients were treated with fluoxetine but not fluvoxamine, which improved pain independently of antidepressant effects (Ciarrella et al. 2000).

### **Other Antidepressants**

Venlafaxine and duloxetine inhibit the presynaptic reuptake of both serotonin and norepinephrine. Duloxetine more potently blocks serotonin and norepinephrine transporters both in vitro and in vivo when compared with venlafaxine (Bymaster et al. 2001). There is evidence of its analgesic efficacy in preclinical models and in clinical populations (Enggaard et al. 2001; Lang et al. 1996). Duloxetine is an effective treatment for major depression and significantly reduced pain complaints and time in pain while awake in these patients (Detke et al. 2002). Duloxetine has just been approved (September 2004) by the FDA for treatment of diabetic peripheral neuropathy pain. Controlled trials have shown duloxetine to be effective in fibromyalgia and diabetic neuropathy. A small controlled trial of venlafaxine in patients with neuropathic pain following treatment of breast cancer showed pain relief, with improved response at higher doses of venlafaxine that may be attributable to increased reuptake inhibition of norepinephrine (Tasmuth et al. 2002). In patients with neuropathic pain but without depression, bupropion decreased pain intensity and interference of pain with quality of life (Semenchuk et al. 2001). In a small open-label trial of diabetic neuropathy, nefazodone significantly reduced pain, paresthesias, and numbness (Goodnick et al. 2000). Monoamine oxidase inhibitors decrease the frequency and severity of migraine headaches (Merikangas and Merikangas 1995). Trazodone is commonly prescribed for insomnia, and several reports suggested efficacy for chronic pain. However, in higher-quality studies, trazodone was ineffective in decreasing pain in a double-blind, placebo-controlled study of patients with chronic LBP (Goodkin et al. 1990; Marek et al. 1992).

### **Comparing Relative Efficacy of Antidepressants and Other Agents**

Comparing the relative efficacy of antidepressants and other pharmacological agents used in the treatment of pain can be calculated with the *number needed to treat* (NNT). NNT is defined as the number of patients who would need to receive the specific treatment for one patient to achieve at least 50% pain relief (Cook and Sackett 1995). Antidepressants, especially TCAs with optimized serum levels, are the most effective in the treatment of neuropathic pain, with the majority of clinical trials enrolling patients with postherpetic neuralgia and diabetic peripheral neuropathy (Collins et al. 2000; McQuay et al. 1996; Sindrup and Jensen 1999, 2000, 2002; Watson 2000). An NNT of 2.5 for TCAs, compared with an NNT of 6.7 for SSRIs, indicates that the difference in response between the active drug treatment and placebo is approximately 40%

versus only 15%, respectively. Subsequent meta-analyses of the treatment of functional gastrointestinal disorders, fibromyalgia, and chronic headache, including both migraine and tension headaches, found no differences in outcome between types of antidepressants with a pooled NNT of 3.2–4.0 (Jackson et al. 2000; O'Malley et al. 2000; Tomkins et al. 2001).

## Anticonvulsants

Phenytoin was first reported as a successful treatment for trigeminal neuralgia in 1942 (Bergouignan 1942). Carbamazepine is the most widely studied anticonvulsant effective for neuropathic pain (Tanelian and Victory 1995). Anticonvulsants are effective for trigeminal neuralgia, diabetic neuropathy, postherpetic neuralgia, and migraine recurrence (McQuay et al. 1995; Tremont-Lukats et al. 2000; Wiffen et al. 2000). The NNT ranges from less than 2 to approximately 4 for anticonvulsants, with better compliance when compared with TCAs because of fewer adverse effects (Collins et al. 2000; Sindrup and Jensen 1999, 2000, 2002; Wiffen et al. 2000). Therapeutic serum levels have not been clearly established, but some evidence suggests lower levels than for seizures may be effective in decreasing pain (Moosa et al. 1993). (See Chapter 37, "Psychopharmacology," for a discussion of the anticonvulsants.)

Valproic acid is most commonly used in the prophylaxis of migraine but is also effective in the treatment of neuropathic pain (R. Jensen et al. 1994). Valproate was an effective prophylactic treatment in over two-thirds of patients with migraine and almost three-quarters of those with cluster headache (Gallagher et al. 2002; Mathew et al. 1995). Improvement occurred in frequency of headache, duration or headache days per month, intensity of headache, use of other medications for acute treatment of headache, the patient's opinion of treatment, and ratings of depression and anxiety (Kaniecki 1997; Klapper 1997; Rothrock 1997).

Gabapentin has been reported to reduce neuropathic pain in multiple sclerosis, migraine, postherpetic neuralgia, spinal cord injury, HIV-related neuropathy, and reflex sympathetic dystrophy (Houtchens et al. 1997; La Spina et al. 2001; To et al. 2002; Wetzel and Connelly 1997). Randomized, double-blind, placebo-controlled clinical trials have confirmed the efficacy of gabapentin in the treatment of diabetic peripheral neuropathy, postherpetic neuralgia, and postamputation phantom limb pain (Backonja et al. 1998; Bone et al. 2002; Mellegers et al. 2001; Rice et al. 2001; Rowbotham et al. 1998; Serpell 2002). A retrospective analysis found that patients were more likely to benefit from gabapentin if they had experienced allo-

dynia as a feature of their neuropathic pain (Gustorff et al. 2002). Gabapentin significantly decreased the pain associated with Guillain-Barré syndrome as well as the concomitant consumption of fentanyl (Pandey et al. 2002).

Lamotrigine may be effective in reducing the pain of phantom limbs, neuroma hypersensitivity, trigeminal neuralgia, causalgia, poststroke pain, and postherpetic neuralgia (Canavero and Bonicalzi 1996; Harbinson et al. 1997; T.S. Jensen 2002). Lamotrigine decreased the pain of diabetic neuropathy without associated improvements in mood or pain-related disability (Eisenberg et al. 2001). Lamotrigine produced analgesia that was correlated with serum drug concentrations and comparable to that obtained with phenytoin and dihydrocodeine (Webb and Kamali 1998).

Combinations of anticonvulsants with complementary mechanisms of action may increase effectiveness and decrease adverse effects of treatment. Patients with multiple sclerosis or trigeminal neuralgia who had failed treatment with carbamazepine or lamotrigine at therapeutic doses because of intolerable side effects were given gabapentin as an augmentation agent (Solaro et al. 2000). Gabapentin was titrated to pain relief, with no new side effects up to a maximum dosage of 1,200 mg/day, at which time either carbamazepine or lamotrigine was tapered until side effects were no longer present. Ten of 11 patients achieved pain control with no side effects.

Topiramate, tiagabine, pregabalin, vigabatrin, retigabine, levetiracetam, and zonisamide are new anticonvulsants with a spectrum of pharmacological actions and antinociceptive effects in animal models, but few clinical studies exist to support their use as a first-line therapy for patients with chronic pain (Cutrer 2001; Marson et al. 1997). Pregabalin is similar to gabapentin but with greater potency (Bryans and Wustrow 1999; Chen et al. 2001). Topiramate offers the advantages of low protein binding, minimal hepatic metabolism and unchanged renal excretion, few drug interactions, long half-life, and the unusual side effect of weight loss. A pilot study found that tiagabine improved pain symptoms and neuronal function assessed with quantitative sensory testing in patients with painful neuropathy (Novak et al. 2001).

## Local Anesthetics

Topical lidocaine has been approved for the treatment of postherpetic neuralgia and does not produce significant serum levels (Argoff 2000). Oral mexiletine has been an effective treatment for neuropathic pain in painful diabetic neuropathy, peripheral nerve injury, alcoholic neuropathy, and phantom limb, but not cancer-related pain (Boulton 1993; Chabal et al. 1992b; Davis 1993; Kalso et

al. 1998; Nishiyama and Sakuta 1995). Mexiletine not only decreased reports of pain but also the accompanying paresthesias and dysesthesias (Dejgard et al. 1988). Mexiletine also has been shown to decrease pain and sleep disturbances associated with painful diabetic neuropathy (Oskarsson et al. 1997). No significant correlations were found with plasma concentrations of mexiletine. Its effectiveness in widespread clinical use has been disappointing despite relatively few adverse effects.

## Calcium Channel Blockers

Verapamil is the most commonly prescribed calcium channel blocker for chronic pain and has proven to be effective in the treatment of migraine and cluster headaches (Lewis and Solomon 1996; Markley 1991). The calcium channel blockers diltiazem and verapamil have also been found to potentiate morphine analgesia, but the results have been inconsistent (Hodogluligil et al. 1996; Taniguchi et al. 1995). Now in clinical trials, the experimental neuron-specific calcium channel blockers ziconotide and related omega-conopeptides possess potent analgesic, antihyperesthetic, and antiallodynic activity, as well as synergistic analgesic effects with morphine without producing tolerance (Bowersox et al. 1996; Brose et al. 1997; Jain 2000; M. T. Smith et al. 2002; Wang et al. 2000; Xiao and Bennett 1995).

## Benzodiazepines

Benzodiazepines are commonly prescribed for insomnia and anxiety in patients with chronic pain (see Chapter 37, "Psychopharmacology"); however, there is little evidence of their utility for relief of pain, and they may even be counterproductive (Holister et al. 1981; King and Strain 1990). Only a limited number of chronic pain conditions, such as trigeminal neuralgia, tension headache, and temporomandibular disorder, were found to improve when treated with benzodiazepines (Dellemijn and Fields 1994). Clonazepam has been reported to provide long-term relief of the episodic lancinating variety of phantom limb pain (Bartusch et al. 1996). A recent extensive review failed to conclude that benzodiazepines significantly improve spasticity following spinal cord injury (Taricco et al. 2000).

Benzodiazepines also cause cognitive impairment (Buffett-Jerrott and Stewart 2002; Hendler et al. 1980). In patients with chronic pain, benzodiazepines, but not opioids, were associated with decreased activity levels, higher rates of health care visits, increased domestic instability, depression, and more disability days (Ciccone et al. 2000). Combining benzodiazepines with opioids may

cause several problems. In methadone-related mortality, almost 75% of deaths were attributable to a combination of drug effects, and benzodiazepines were present in 74% of the deceased (Caplehorn and Drummer 2002; Ernst et al. 2002). Benzodiazepines have been associated with exacerbation of pain and interference with opioid analgesia (Nemmani and Mogil 2003; Sawynok 1985). They also increase the rate of developing tolerance to opioids (Freye and Latach 2003).

## Psychological Treatment

---

### Patient Classifications

The biopsychosocial model of chronic pain recognizes the importance of a large number of factors, their interrelationships, and their contributions to ongoing suffering and eventually successful treatment (Keefe et al. 1996; Turk and Okifuji 2002). Controversy persists over which type of psychological treatment is most effective in the treatment of chronic pain. No differences were found between the treatment effects of cognitive versus behavioral therapies in patients mildly disabled by chronic LBP (Turner and Jensen 1993). Cognitive-behavioral therapy (CBT) provided as part of an individual therapy program offered no advantage over a group-based multidisciplinary program over 1 year (Turner-Stokes et al. 2003). Patients who are oriented toward self-management, with decreased perceptions of disability and less negative emotional responses to pain, are those most likely to improve (McCracken and Turk 2002). If treatment effects are to be optimized, more specific psychotherapies need to be designed for different types of pain patients.

Attempts to define more homogeneous subgroups of patients with chronic pain for the purpose of matching them with treatments have led to several empirical categorical or graded classifications based on different levels of psychosocial and functional impairment (Deardorff et al. 1993; Pfingsten et al. 2000; Riley et al. 1999a; Riley and Robinson 1998; Sanders and Brena 1993; Williams et al. 1995). Three groups have consistently been described across patient populations based on the Multidimensional Pain Inventory (Cook and Chastain 2001; Greco et al. 2003; Kerns et al. 1985; Turk and Rudy 1990; Weiner et al. 2001). The Dysfunctional group scores higher on pain severity, life interference due to pain, and psychological distress. This group also scores lower on perceptions of control and performance of daily activities. The Interpersonally Distressed group is characterized by the perception of poor support from others. The Adaptive Copers have lower ratings of pain severity, pain interference,

affective distress, physical disability, and perceptions of being out of control. However, this subgroup classification did not predict the magnitude of positive treatment response for patients with chronic pain treated in a comprehensive interdisciplinary program (Gatchel et al. 2002). Tailoring psychological interventions to patient profiles based on psychosocial characteristics can result in greater and more prolonged improvement compared with usual care. In patients with early rheumatoid arthritis, tailoring or customizing CBT by assigning specific modules matched to patient priorities optimized the effectiveness of treatment (Evers et al. 2002).

### *Cognitive-Behavioral Therapy*

Psychological treatment for chronic pain was pioneered by Fordyce, who used an operant conditioning behavioral model (Fordyce et al. 1973). The behavioral approach is based on an understanding of pain in a social context. The behaviors of the patient with chronic pain not only reinforce the behaviors of others but also are reinforced by others. Pain behaviors such as grimacing, guarding, and taking pain medication are indicators of perceived pain severity and functional disability, and such behaviors predict whether patients receive opioids (Chapman et al. 1985; Fordyce et al. 1984; Keefe et al. 1986; Romano et al. 1988; Turk and Matyas 1992; Turk and Okifuji 1997). In treatment, productive behaviors are targeted for reinforcement and pain behaviors are targeted for extinction. In practice, it remains unclear what type of patient benefits most from what type of behavioral treatment. For patients with chronic LBP, behavioral treatment decreased pain intensity and improved behavioral outcomes, including functional status, when compared with wait-listed control condition or no treatment, but not when it was added to usual treatment (van Tulder et al. 2001).

The cognitive-behavioral model of chronic pain assumes individual perceptions and evaluations of life experiences affect emotional and behavioral reactions to these experiences. If patients believe pain, depression, and disability are inevitable and uncontrollable, they will experience more negative affective responses, increased pain, and even more impaired physical and psychosocial functioning. The components of CBT, such as relaxation, cognitive restructuring, and coping self-statement training, interrupt this cycle of disability and enhance operant-behavioral treatment (Turner 1982a, 1982b; Turner and Chapman 1982). Patients are taught to become active participants in the management of their pain by using methods that minimize distressing thoughts and feelings.

Outcome studies of CBT in patients with syndromes ranging from specific painful diseases to vague functional somatoform symptoms have demonstrated significant im-

provements in pain intensity, pain behaviors, physical symptoms, affective distress, depression, coping, physical functioning, treatment-related and indirect socioeconomic costs, and return to work (Hiller et al. 2003; Keefe et al. 1990a; Kroenke and Swindle 2000; McCracken and Turk 2002; Turner 1982a; Turner and Romano 1990). The effectiveness of CBTs in adults with chronic pain has been documented in a meta-analysis across numerous outcome domains (Morley et al. 1999). The NNT was 2.3 in a meta-analysis of psychological treatment (relaxation, CBT) effectiveness for reducing the severity and frequency of chronic headache in children and adolescents (Eccleston et al. 2003). Pain reduction and improved physical function have been found to continue up to 12 months after the completion of active CBT (Gardea et al. 2001; Keefe et al. 1990b; Nielson and Weir 2001).

In a large HMO-based primary care study of back pain, a self-care intervention designed to provide education, reduce fear, promote attitudes favorable to self-management, and develop problem-solving skills to decrease pain and increase function significantly reduced back-related worry and fear-avoidance beliefs (Moore et al. 2000). Women, but not men, on sick leave for chronic spinal pain were at lower risk of taking early retirement at 18 months follow-up if they had been treated with physical therapy, CBT, or a combination of treatments compared with those in usual care (M.P. Jensen et al. 2001). Regardless of whether the women received CBT alone or in combination with physical therapy, CBT resulted in significant improvements in health-related quality of life. Elderly patients with chronic pain benefit more from CBT that presents information in concrete, well-organized, and brief formats (Kerns et al. 2001; Manetto and McPherson 1996; Middaugh and Pawlick 2002).

Patients on sick leave with nonspecific LBP treated with the addition of problem-solving therapy to behavioral graded activity had significantly fewer future sick leave days, higher rates of returning to work, and lower rates of receiving disability pensions (van den Hout et al. 2003). The risk for long-term sick absence of patients with spinal pain at risk for developing chronic pain was lowered by a factor of 9.3 at 1-year follow-up with a 6-session CBT group intervention (Linton and Andersson 2000). Pain-related fear and catastrophizing of patients were more likely to improve when the patients were exposed in vivo to individually tailored, fear-eliciting, and hierarchically ordered physical movements instead of following a general graded activity treatment program for back pain (Vlaeyen et al. 2002). A CBT program in a military population with nonmalignant chronic pain conditions reduced outpatient clinic visits by 87% in the first 3 months after treatment (Peters et al. 2000).

## Mediators of Treatment Effects

The success of CBT has focused attention on many elements of the chronic pain experience to improve outcome. Adjustment is defined as the ability to carry out normal physical and psychosocial activities. The three dimensions of adjustment are social functioning (e.g., employment, functional ability), morale (e.g., depression, anxiety), and somatic health (e.g., pain intensity, medication use, health care utilization) (M.P. Jensen et al. 1991a; Lazarus and Folkman 1984). These concepts address resilience to the effects of chronic illness, the alleviation of suffering, and the development of a more positive concept of self or identity for the patient (Buchi et al. 2002).

Acceptance of chronic pain is a factor reported to influence patient adjustment. An analysis of patient accounts of their acceptance of chronic pain involved themes such as taking control, living day to day, acknowledging limitations, being empowered, accepting loss of self, believing that there is more to life than pain, not fighting battles that cannot be won, and relying on spiritual strength (Risdon et al. 2003). Therefore, acceptance is a realistic approach to living with pain that incorporates both disengagement from struggling against pain and engagement in productive everyday activities with achievable goals. Acceptance of pain is associated with reports of lower pain intensity, less pain-related anxiety and avoidance, less depression, less physical and psychosocial disability, more daily uptime, and better work status (McCracken 1998).

A *self-efficacy* expectancy is a belief about one's ability to perform a specific behavior, while an *outcome* expectancy is a belief about the consequences of performing a behavior. These variables have been derived from social learning theory and overlap with constructs such as locus of control and optimism (Anderson et al. 1995; Haugli et al. 2000; M.P. Jensen et al. 1991b; Keefe et al. 1992). Individuals are considered to be more likely to engage in coping efforts they believe are both within their capabilities and likely to result in a positive outcome. Patients with a variety of chronic pain syndromes who score higher on measures of self-efficacy or have an internal locus of control report lower levels of pain, higher pain thresholds, increased exercise performance, and more positive coping efforts (Asghari and Nicholas 2001; Barry et al. 2003; Berkke et al. 2001; Lackner and Carosella 1999). Evidence supports self-efficacy as a mediator of the relationship between pain intensity and disability (Arnstein 2000; Rudy et al. 2003).

The effectiveness of particular coping strategies is dependent on many aspects of a patient's experience. In a 6-month follow-up study of patients completing an inpatient pain program, improvement was associated with de-

creases in the use of passive coping strategies such as taking medications or hoping pain will decrease (M.P. Jensen et al. 1994). "Reinterpreting pain sensations as not being signs of ongoing injury" has been typically formulated as an active coping strategy. However, in a study of amputees with phantom limb pain, it was associated not with reduced pain levels but instead with greater psychosocial dysfunction. This coping strategy may not be appropriate for these patients because it requires greater amounts of time spent focusing on pain and disability, preventing them from engaging in social activities (Hill et al. 1995). Similarly, some types of emotion-focused coping are adaptive for some patients. For example, patients with myofascial pain were significantly more likely to report pain, impairment, and depression if they used passive coping strategies in contrast to emotion-focused coping, which was associated with significantly better adjustment (J.A. Smith et al. 2002). The coping strategies concept is consistent with the cognitive-behavioral model of chronic pain, although it still remains unclear how many unique coping strategies exist and whether changes in coping lead to or are the result of changes in patient adjustment (Hadjistavropoulos et al. 1999; M.P. Jensen et al. 1991a; Tan et al. 2001).

## Placebo Response

Placebo effects are complex phenomena but similar to the effects of active treatments (Kleinman et al. 1994; Turner et al. 1994). The literature supporting the placebo effect has been criticized as flawed, misinterpreted, and overrated (Kienle and Kienle 1997). In a clinical setting it is difficult to separate "true" improvements from placebo responses to treatment as well as other factors such as regression to the mean and the natural history of the condition. Multiple patient and practitioner characteristics, such as expectancy, conditioning, and learning, affect the placebo response, and most are almost impossible to control for (Ploghaus et al. 2003; Price et al. 1999). Evidence supports a role of the endogenous opioid and sympathetic nervous systems in placebo-induced analgesia that can be reversed with opioid antagonists (Pollo et al. 2003; ter Riet et al. 1998).

Historically based on Beecher's original article, placebo interventions were a part of paternalistic medicine's treatment armamentarium (Kaptchuk 1998). In the era of randomized, controlled trials, placebos may be employed if cooperation of informed patients is secured. The magnitude of placebo analgesic effects was found to be significantly higher in studies that specifically investigated placebo analgesic mechanisms compared with those controlled trials that simply used a placebo for comparison

(Vase et al. 2002). However, there is controversy about the evidence of clinically important effects to justify the use of placebo interventions (Hrobjartsson and Gotzsche 2003). Using placebo to determine if the patient's pain is "real," or to "cure" a psychogenic condition by replacing an analgesic with a "neutral" substance, is dishonest, misleading, and counterproductive. A positive placebo response neither proves that the patient's pain is psychogenic nor shows that the patient would not benefit from an active treatment. Such an intervention can also result in loss of the patient's trust and render future treatment less effective.

## Multidisciplinary Treatment

---

### Methodology

Patients with chronic pain suffer dramatic reductions in physical, psychological, and social well-being with lower-rated health-related quality of life than those with almost all other medical conditions (Becker et al. 1997; Skevington 1998). The multidisciplinary pain center offers the full range of treatments for the most difficult pain syndromes in a setting that encourages patients to take an active role in improving their functional status and reinforces positive changes in behavior (Gibson et al. 1996; Helme et al. 1996). Specifically, interventions are designed to change maladaptive behavior such as inactivity and social withdrawal; alter maladaptive cognitions such as somatization, catastrophizing, and passive expectations of medical care; adopt active and positive coping skills; identify and stop operant conditioned behavior; and increase emotional control and stability while decreasing affective distress and depression.

Early failure of a single-modality treatment for chronic pain can have devastating consequences for future treatment attempts (Davies et al. 1997). A study of sequential trials of different treatment modalities found that the success of nerve blocks was diminished when used later in the treatment sequence.

A multidisciplinary approach starts with a serial evaluation by multiple specialists (Turk and Stieg 1987). Usually, this process implies a hierarchy of diagnostic importance. Psychiatry is often the last specialty to evaluate the patient, which may be perceived as signifying that psychological understanding is a low priority or that the other clinicians have decided the patient's pain is psychogenic. Even attempts at simultaneous evaluation by multiple specialists, including a psychiatrist or psychologist, can be misconstrued as trying to determine if symptoms are "real."

Interdisciplinary approaches combine areas of expertise to form a comprehensive formulation of chronic pain. The representatives of different fields of study recognize all symptoms can have a multiplicity of causes. These etiologies and diagnoses are all "real" and can be made by any number of specialists, if they are properly trained. When a specific diagnosis cannot be made, an etiology for the patient's symptoms has simply not yet been discovered. The patient no longer is stigmatized as having a "false" condition but instead is recognized as having a legitimate problem with understandable distress. The patient can remain in treatment to receive symptomatic interventions, functional rehabilitation, and the coordination of future evaluations.

### Effectiveness

Multidisciplinary pain programs are often mistakenly equated with detoxification programs. It is true that most multidisciplinary programs pursue the goal of reducing inappropriate medication use. In one program, opioid use decreased from 83% to 58% of patients (Nissen et al. 2001). While reducing inappropriate medication use is necessary, it is almost never sufficient in achieving treatment goals. There is evidence that multidisciplinary pain programs improve patient functioning globally and in a number of specific areas, especially pain intensity, depression, disability, pain-related cognitions, and coping responses (Cutler et al. 1994; Fishbain et al. 1993; Flavell et al. 1996; M.P. Jensen et al. 2001). Multidisciplinary rehabilitation programs that include psychological and cognitive treatment are known to be effective for the treatment of chronic pain (Cutler et al. 1994; Fishbain et al. 1993; Flavell et al. 1996; Flor et al. 1992). Quality of life improves with multidisciplinary pain treatment, and good quality of life is associated with low levels of pain, distress, and interference with performing daily activities (Skevington et al. 2001). A meta-analysis of 65 studies evaluated the efficacy of treatments in patients who attended multidisciplinary pain clinics (Flor et al. 1992). Combination treatments were superior to unimodal treatments, treatment effects were maintained over a period of up to 7 years, and improvements were found not only on subjective but also on objective measures such as return to work and decreased health care utilization. Although more study is needed, the data support the conclusion that multidisciplinary pain clinic approaches are efficacious.

Ultimately, the goal of treating patients with chronic pain is to end disability and return them to work or other productive activities. Patients with chronic pain encounter many obstacles to returning to work, including their own negative perceptions and beliefs about work, such as poor

self-efficacy and use of maladaptive coping strategies (Grossi et al. 1999; Marhold et al. 2002; Schult et al. 2000). In a longitudinal follow-up study of chronic back pain, patients who were not working and involved in litigation had the highest scores on measures of pain, depression, and disability (Suter 2002). One of the most important predictors is the patient's own intention of returning to work, which is less likely to be a function of pain than of job characteristics (Fishbain et al. 1997b). For example, job availability, satisfaction, dangerousness, physical demands, and litigation status are more likely to influence a patient's return to work (Fishbain et al. 1995, 1999a; Hildebrandt et al. 1997). In the longest follow-up study (13 years) of an inpatient pain management program, only half of the patients were unemployed, compared with almost 90% of the patients at the time of their admission (Maruta et al. 1998).

## Psychopharmacology

---

Michael J. Robinson, M.D., F.R.C.P.C.

James A. Owen, Ph.D.

**PSYCHOPHARMACOLOGICAL** interventions are an essential part of the management of the medically ill; at least 35% of psychiatric consultations include recommendations for medication (Bronheim et al. 1998). Appropriate use of psychopharmacology in the medically ill requires careful consideration of the underlying medical illness, potential alterations to pharmacokinetics, drug–drug interactions, and contraindications. In this chapter, we review basic psychopharmacological concepts, including pharmacokinetics and pharmacodynamics in the medically ill, side effects, toxicity, drug interactions, and alternative routes of administration for each psychotropic drug class, as well as safety in pregnancy and lactation. Important considerations are critically examined for the use of psychotropic drugs in patients with major organ disorders. We also briefly review the use of complementary medicines, including herbal medicines and nonherbal dietary supplements.

### Pharmacokinetics in the Medically Ill

---

*Pharmacokinetics* describes the absorption, distribution, metabolism, and excretion of drugs, whereas *pharmacodynamics* refers to the effects of drugs, primarily in the brain.

#### Absorption

Absorption of a drug is influenced by the characteristics of the absorption site and the physiochemical properties of a drug. Specific site properties that may affect absorption include surface area, ambient pH, mucosal integrity and function, and local blood flow. Orally administered drugs absorbed through the gastrointestinal tract may be extensively altered by “first-pass” hepatic metabolism before entering the systemic circulation. Sublingual and

topical administration of drugs minimizes this first-pass effect, and rectal administration may reduce the first-pass effect by 50%. Drug formulation, drug interactions, gastric motility, and the characteristics of the absorptive surface all influence the *rate* of absorption, a key factor when rapid onset is desired. The *extent* of drug absorption, however, is more important with chronic administration. The *bioavailability* of a drug describes the rate and extent to which the drug ingredient is absorbed from the drug product and available for drug action. Intravenous drug delivery has 100% bioavailability.

#### Distribution

Systemic drug distribution is influenced by serum pH, blood flow, protein binding, lipid solubility, and the degree of ionization. Most drugs bind to proteins, either albumin or  $\alpha_1$  acid glycoprotein (AAGP), to a greater or lesser extent. Disease may alter the concentrations of serum proteins as well as binding affinities. For example, albumin binding is decreased in a number of illnesses (e.g., cirrhosis, bacterial pneumonia, acute pancreatitis, renal failure, surgery, and trauma), resulting in increased systemic toxicity with low therapeutic index drugs. In contrast, some disease states, such as hypothyroidism, may increase protein binding. AAGP concentrations may increase in Crohn’s disease, myocardial infarction, stress, surgery, and trauma.

In general, acidic drugs (e.g., valproic acid, barbiturates) bind mostly to albumin, and more basic drugs (e.g., phenothiazines, tricyclic antidepressants [TCAs], amphetamines, most benzodiazepines) bind to globulins. In general, only free (unbound to plasma proteins) drug is pharmacologically active. Decreases in protein binding increase availability of the “free” drug to pharmacological

action, metabolism, and excretion. When metabolic and excretory processes are unchanged by disease, changes to protein binding of a drug have little effect on steady-state plasma concentrations of pharmacologically active free drug. However, total plasma levels (free + bound drug) may be lowered; for this reason, clinical response to the drug, rather than laboratory-determined drug levels, should guide dosage. Most diseases that affect protein binding also affect metabolism and excretion. Therefore, disease-induced changes in free drug availability may have clinically significant consequences, especially for drugs with a low therapeutic index.

*Volume of distribution* is a function of a drug's lipid solubility and plasma- and tissue-binding properties. Most psychotropic drugs are lipophilic but are also extensively bound to plasma proteins. Volume of distribution is unpredictably altered by disease and is not useful in guiding dosage adjustments for medically ill patients.

## Metabolism (or Biotransformation) and Elimination

Biotransformation occurs throughout the body, with the greatest activity in the liver and gut wall. Most psychotropic drugs are eliminated by hepatic metabolism and renal excretion. Hepatic biotransformation consists mostly of two types: phase I and phase II metabolism. Phase I metabolism consists of oxidation (i.e., cytochrome P450 monooxygenase system), reduction, or hydrolysis, which prepares medications for excretion or further metabolism by phase II pathways. The monoamine oxidases (MAOs) are also considered part of phase I. Phase II metabolism consists of many conjugation pathways, the most common being glucuronidation, acetylation, and sulfation. The hepatic clearance of drugs may be limited by either the rate of delivery (i.e., hepatic blood flow) of the drug to the hepatic metabolizing enzymes or the intrinsic capacity of the enzymes to metabolize the substrate. Clinically significant decreases in hepatic blood flow occur only in severe cirrhosis, and when possible, parenteral administration of drugs is preferred. Hepatic disease may preferentially affect anatomic regions of the liver, thereby altering specific metabolic processes. For example, oxidative metabolic reactions are more concentrated in the pericentral regions affected by acute viral hepatitis or alcoholic liver disease. Disease affecting the periportal regions, such as chronic hepatitis (in the absence of cirrhosis), may spare some hepatic oxidative function. In addition, acute and chronic liver diseases generally spare glucuronide conjugation reactions. Metabolic reactions altering the intrinsic capacity of the enzymes through inhibition and induction are discussed in the next section ("Drug-Drug Interactions").

The kidney's primary pharmacokinetic role is drug elimination. However, renal disease may affect absorption, distribution, and metabolism of drugs. Creatinine clearance is a more useful indicator of renal function than serum creatinine. Specific drugs and their use in renal failure are covered later in this chapter. In general, despite the complexity of pharmacokinetic changes in renal failure, few psychotropic agents other than lithium and gabapentin mandate dosage adjustment.

Disease processes, particularly those involving the gastrointestinal tract, liver, heart, and kidneys, can alter absorption, distribution, metabolism, and elimination. Table 37-1 summarizes how disease in these organ systems may alter the pharmacokinetics of psychotropic medications.

## Drug-Drug Interactions

---

Drug-drug interactions are pharmacodynamic or pharmacokinetic in nature. Pharmacodynamic interactions involve alterations in the pharmacological response to a drug, which may be additive, synergistic or antagonistic. These interactions may occur directly, by altering the drug binding to the receptor site, or indirectly through other mechanisms. Pharmacokinetic interactions include altered absorption, distribution, metabolism, or excretion and can result in changing the drug concentration in tissues.

A *substrate* is an agent or a drug that is metabolized by an enzyme. An *inducer* is an agent or a drug that increases the activity of the metabolic enzyme, allowing for an increased rate of metabolism. Induction may lead to decreases in the amount of circulating parent drug and increases in the number and amount of metabolites produced. The clinical effect may be a loss or decrease in therapeutic efficacy or an increase in toxicity from metabolites. An *inhibitor* has the opposite effect, decreasing or blocking enzyme activity needed for the metabolism of other drugs. This results in increased levels of any drug dependent on that enzyme for biotransformation, thereby producing prolonged pharmacological effect or increased toxicity.

The hepatic cytochrome P450 enzyme system catalyzes phase I reactions and is responsible for most metabolic drug interactions. There are 11 cytochrome P450 enzyme families, of which 3 are important in humans: CYP1, CYP2, and CYP3. The families are divided into subfamilies that are identified by a capital letter (i.e., CYP3A). The subfamilies are further divided into isozymes based on the homology between the subfamily proteins and are denoted by a number following the capital letter (i.e., CYP3A4).

**TABLE 37–1. Pharmacokinetics in the medically ill**

<b>Pharmacokinetic parameter</b>	<b>Potential factors</b>	<b>Clinical significance</b>
<b>Liver disease</b>		
Absorption	Gastric acidity Gastric and intestinal motility Small intestine surface area (e.g., short gut) Enteric blood flow Reduced hepatic blood flow Portosystemic shunting	Minimize gastrointestinal side effects of psychotropics Liquid formulations may be better or more quickly absorbed than solid drug formulations Motility, secretory, and enteric blood flow changes in gastrointestinal disease usually do not require dosage change Consider parenteral administration
Distribution	Alterations in liver blood flow Changes in plasma proteins Albumin may fall AAGP may rise Decreases in binding affinities Fluid shifts (e.g., ascites)	Reduce dose Serum levels of drugs (bound + free) may be misleading
Metabolism and excretion	Reduced hepatic blood flow Intrinsic capacity of the enzymes	Clinically significant reductions only occur in severe cirrhosis
<b>Renal disease</b>		
Absorption	Ammonia buffering may raise gastric pH	Rarely clinically significant changes in pharmacokinetics Major exceptions—lithium and gabapentin
Distribution	Altered body water volume Reduced protein binding	Exact prediction of pharmacokinetic changes in the context of renal disease is impractical clinically Monitor drug levels more frequently but interpretation of blood levels difficult Serum levels of drugs (bound + free) may be misleading
Metabolism and excretion	Reduced renal blood flow Glomerular function	Creatinine clearance is a useful indicator of renal function to guide dose adjustments Serum creatinine may be confounded by some diseases that affect creatinine metabolism Dialysis alters pharmacokinetics
<b>Cardiac disease</b>		
Absorption	Decreased perfusion of drug absorption sites Intestinal wall edema may reduce absorption Changes in autonomic activity may affect GI motility and cause vasoconstriction	Congestive heart failure may decrease absorption of drugs through the gastrointestinal tract Intramuscular drug absorption may be decreased by vasoconstriction
Distribution	Changes in plasma proteins AAGP may rise Albumin may fall Volume of distribution is reduced Regional blood flow redistributions	Acute doses should be reduced by approximately 50% Intravenous infusions should be given at a slower rate to avoid toxicity
Metabolism and excretion	Reduced renal and hepatic blood flow	A 50% reduction of dosage for chronic drug administration should be considered

*Note.* AAGP=alpha<sub>1</sub> acid glycoprotein; GI=gastrointestinal.

Cytochrome P450 enzymes exist in a variety of body tissues, including the gastrointestinal tract, liver, and brain. The most important cytochrome P450 enzymes in drug metabolism in humans are 1A2, 2C9, 2C19, 2D6, and 3A4. Because some of these enzymes exist in a polymorphic form, a small percentage of the population has one or more cytochrome P450 enzymes with significantly altered activity.

Phase II reactions are conjugation reactions in which water-soluble molecules are coupled to a drug to make it easily excreted. The most abundant phase II enzymes belong to the superfamily of uridine glucuronosyltransferases (UGTs). A classification system similar to the cytochrome P450 system has been developed to characterize the UGT superfamily of enzymes. There are two clinically significant UGT subfamilies: 1A and 2B. As with the cytochrome P450 system, there can be substrates, inhibitors, and inducers of UGT enzymes. For example, the benzodiazepines primarily metabolized by conjugation (oxazepam, lorazepam, and temazepam) are glucuronidated by UGT2B7. A number of nonsteroidal anti-inflammatory drugs (NSAIDs) are competitive inhibitors of UGT2B7. Phenobarbital, rifampin, and oral contraceptives appear to be inducers of UGT2B7. The role of UGTs in clinical pharmacology is being increasingly recognized.

Another system receiving increasing attention in clinical pharmacology is P-glycoproteins (P-gp). Human P-gps are divided into P-gp1 and P-gp3 (and they were renamed P<sub>1</sub> and P<sub>3</sub>). P<sub>3</sub> functions in phospholipid transport, whereas P<sub>1</sub> (we use *P-gp* to refer to P<sub>1</sub>) is an efflux transporter. P-gps are present in the gut, liver and biliary systems, gonads, kidneys, brain, and other organs. They appear to be important for protecting the body from harmful substances and are involved in transporting certain hydrophobic substances into the gut, out of the brain, into urine, into bile, out of gonads, and out of other organs. They seem to play a large role in the distribution and elimination of many clinically important therapeutic substances.

As with the cytochrome P450 and UGT enzyme systems, there are substrates, inhibitors, and/or inducers of the P-gp transporters. Because intestinal P-gps are located in antecedent proximity to CYP3A4 and block absorption in the gut, they should be thought of as part of the first-pass effect, functioning as “gatekeepers” for later CYP3A4 actions. The effect of inhibiting P-gp is to “open the gates.” For example, loperamide (an over-the-counter antidiarrheal) is a P-gp substrate and is normally transported out of the brain and therefore has no central opiate effects. When this drug is given with quinidine (a P-gp inhibitor), loperamide concentrations in the brain increase, and signs of respiratory depression can ensue (Sadeque et

al. 2000). Many factors can alter P-gp function and influence P-gp-based interactions; these include genetic differences, gender, herbal supplements, foods, and hormones (Cozza et al. 2003). Future understanding of the physiological regulation of these transporters may be key in designing and improving therapeutic actions of drugs.

## General Principles

In medically ill patients, polypharmacy is usually the norm and requires vigilance regarding the many potential drug–drug interactions. To commit to memory all of the potential drug–drug interactions associated with psychotropic medications is practically impossible; these interactions are constantly changing as our knowledge increases and new medications are developed. Knowing the metabolic pathways of a drug and whether a drug to be combined has inhibitory or inductive effects on that enzyme provides a rough screen for predicting potential interactions. However, it should be remembered that drug concentration changes do not necessarily translate into clinically meaningful interactions. Cozza et al. (2003) advised that physicians prescribing in a polypharmacy environment should, whenever possible, avoid medications that significantly inhibit or induce cytochrome P450 enzymes and prefer those that are eliminated by multiple pathways and have a wide safety margin.

## Identification of Potential Pharmacokinetic Interactions

Most pharmacokinetic drug–drug interactions involve the effects of an interacting drug on the cytochrome P450-mediated metabolism of a substrate drug. The interacting drug may be either an inhibitor or an inducer of the critical P450 isozymes involved in the substrate drug’s metabolism. However, not all combinations of interacting drug with substrate will result in clinically significant drug–drug interactions. For these interactions to be clinically relevant, the substrate must have certain characteristics. A critical drug substrate is a drug with a narrow therapeutic index and one primary P450 isozyme mediating its elimination. For example, nifedipine, like all calcium-channel blockers, is primarily metabolized by the CYP3A4 isozyme. The addition of a drug that is a potent CYP3A4 inhibitor, such as fluvoxamine, will inhibit nifedipine’s metabolism. Without a compensatory reduction in nifedipine dose, nifedipine levels will rise and toxicity may result. On the other hand, the addition of an inhibitor or inducer that interacts with a cytochrome P450 isozyme other than CYP3A4 will have no significant effect on nifedipine levels. Table 37–2 lists those drugs that are sig-

nificant cytochrome P450 isozyme inhibitors, inducers, and critical substrates.

Metabolic drug interactions are most likely to occur in three situations: addition of an interacting drug (inhibitor or inducer) to an existing critical substrate drug; withdrawal of an interacting drug from a dosing regimen containing a substrate drug; or addition of a substrate drug to an existing regimen containing an interacting drug.

The addition of an interacting drug to a medication regimen containing a substrate drug at steady-state levels will dramatically alter the concentration of the substrate drug. If the interacting drug is an inhibitor, substrate drug concentrations will rise as its elimination is reduced. This rise in substrate levels may result in toxicity because of the drug's narrow therapeutic index. Conversely, addition of an enzyme inducer will increase elimination of the substrate, thereby lowering its concentration and therapeutic effect.

Withdrawal of an interacting drug from a drug regimen containing a critical substrate drug can also result in a drug interaction. The dosage of substrate drug will have been titrated, in the presence of the interacting drug, to optimize therapeutic effect and minimize adverse effects. Withdrawal of an enzyme inhibitor will allow metabolism to return (increase) to normal levels. This increased metabolism of the substrate drug will lower its levels and decrease therapeutic effect. In contrast, removal of an enzyme inducer will result in an increase in substrate drug levels and drug toxicity as metabolism of the substrate decreases to a normal rate.

The addition of a critical substrate drug to a drug regimen containing an interacting drug can result in a clinically significant interaction if the substrate is dosed according to established guidelines. Dosing guidelines do not account for the presence of a metabolic inhibitor or inducer and thus may lead to substrate concentrations that are, respectively, toxic or subtherapeutic.

Metabolic drug interactions can be minimized by avoiding drugs that are known critical substrates or potent inhibitors or inducers. Unfortunately, this is not always possible. However, by identifying medications that are critical substrates or potent inhibitors or inducers, making appropriate dosage adjustments, and monitoring drug levels (where possible), the adverse effects of these metabolic interactions will be reduced.

Drug interactions that affect renal drug elimination are clinically significant only if the parent drug or its active metabolite undergoes appreciable renal elimination. Changes in urine pH can modify the elimination of those compounds whose ratio of ionized/un-ionized forms is dramatically altered across the physiological range of urine pH (4.6 to 8.2) (i.e., the compound has a pKa within this

pH range). Common drugs that alkalinize urine include antacids and carbonic anhydrase inhibitor diuretics. Un-ionized forms of drugs undergo greater glomerular resorption, whereas ionized drug forms are resorbed less and so have greater urinary excretion. For a basic drug such as amphetamine, alkalization of urine increases the un-ionized fraction, enhancing resorption and so prolonging activity. Other basic psychotropic drugs, such as amitriptyline, imipramine, and meperidine, may be similarly affected (Cadwallader 1983).

## Antidepressants

---

Antidepressant drugs are used to treat affective, anxiety, eating, and some somatoform disorders as well as insomnia, enuresis, incontinence, headaches, and chronic pain.

### Side Effects and Toxicity

#### *Selective Serotonin Reuptake Inhibitors and Novel/Mixed-Action Agents*

Adverse effects of selective serotonin reuptake inhibitors (SSRIs) and novel/mixed-action agents are common, but they are usually mild, dose related, and abate over time. However, serotonergic agents, especially when used in combination, can induce the potentially fatal serotonin syndrome (see "Serotonin Syndrome" subsection later in this section).

Common short-term side effects with SSRIs and venlafaxine include nausea, vomiting, anxiety, headache, sedation, tremors, and anorexia. Common long-term side effects include sexual dysfunction, dry mouth, sweating, impaired sleep, and potential weight gain. Trazodone and nefazodone do not disrupt sexual function or sleep. Trazodone causes sedation in 20%–50% of patients and is often used for its sedating properties. It also infrequently causes priapism. Trazodone and nefazodone can cause orthostatic hypotension.

Frequent duloxetine side effects are nausea, dry mouth, fatigue, dizziness, constipation, somnolence, decreased appetite, and increased sweating (Nemeroff et al. 2002). Patients treated with reboxetine (used only in Europe) often report dry mouth, insomnia, constipation, sweating, and hypotension (Andreoli et al. 2002). Mirtazapine is associated with a high incidence of sedation, increased appetite, and weight gain (Nelson 1997). Common adverse effects of bupropion include agitation, insomnia, anxiety, dry mouth, constipation, postural hypotension, tachycardia, and cardiac arrhythmias. Nausea and vomiting are much less common with bupropion than with SSRIs (Vanderkooy et al. 2002).

**Central nervous system.** An association between SSRI use and increased suicidal ideation was proposed by Teicher in 1990 on the basis of case reports (Teicher et al. 1990). Unfortunately, because of lack of definitive data, the existence of an association and the magnitude of effect remain unanswered. In a review of U.S. Food and Drug Administration (FDA) summary controlled clinical trial reports for nine modern antidepressants in 48,277 patients, Khan et al. (2003) concluded that there was no difference in suicide risk between antidepressant- and placebo-treated depressed patients or between treatment with SSRIs and with other antidepressants. In contrast, Healy (2003), from his review of randomized clinical trials, suggested that SSRIs possibly double the risk of suicide and suicide attempts in comparison with older antidepressants or no treatment. In June 2003, the United Kingdom Department of Health concluded that the rate of self-harm and potentially suicidal behavior is increased in children and adolescents receiving paroxetine for treatment of depression. Both the U.K. Department of Health and the FDA have issued recommendations that paroxetine not be used in this population. In March of 2004, the FDA asked manufacturers of antidepressant drugs (including fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, escitalopram, bupropion, venlafaxine, nefazodone, and mirtazapine) to include in their labeling a warning statement that recommends close observation of adult and pediatric patients treated with these agents for worsening depression or the emergence of suicidality. The FDA has not concluded that these drugs cause worsening depression or suicidality.

Bupropion causes a dose-related lowering of the seizure threshold and may precipitate seizures in susceptible patients receiving dosages above 450 mg/day. The incidence of seizure rises with increasing dosage, from 0.1% at 100–300 mg/day, through 0.4% at 300–450 mg/day, to 2.3% at dosages over 600 mg/day (McEvoy 2003). The seizure risk reported for other antidepressants ranges from 0.04% for mirtazapine to 15.6% ( $n=32$ ) for maprotiline (Harden and Goldstein 2002; Jabbari et al. 1985). Given that the annual incidence of first unprovoked seizure is 0.06% in the general population, seizure risk for patients taking most antidepressants is not elevated. However, it is clear that certain antidepressants, including bupropion, clomipramine, and maprotiline, especially in higher doses, are associated with a greater seizure risk than are other antidepressants (Harden and Goldstein 2002).

Potential side effects of SSRIs include SSRI-induced extrapyramidal symptoms (EPS), likely resulting from serotonergic antagonism of dopaminergic pathways in the central nervous system (CNS). Akathisia, dystonia, par-

kinsonism, and tardive dyskinesia-like states have been reported, with akathisia being the most common effect and tardive dyskinesia-like states being the least common. Certain patients appear to be at increased risk, such as the elderly, patients with Parkinson's disease, and patients concurrently treated with dopamine antagonists (Leo 1996).

**Serotonin syndrome.** Serotonin syndrome is an uncommon but potentially life-threatening complication of treatment with serotonergic agents. Overall, there is considerable heterogeneity in the reported clinical features of serotonin syndrome (Table 37–3), likely reflecting the variation in the degree of severity of the syndrome. The incidence of the syndrome is unknown, partly due to the lack of uniform diagnostic criteria. Virtually all medications that potentiate serotonergic neurotransmission in the CNS have been reported in association with serotonin syndrome. The antidepressant combinations most commonly implicated have been monoamine oxidase inhibitors (MAOIs; reversible and irreversible) and TCAs, MAOIs and SSRIs, and MAOIs and venlafaxine. Table 37–4 lists selected other serotonergic drugs.

Currently there is no formal consensus regarding diagnostic criteria for serotonin syndrome. The first operationalized criteria were proposed in 1991 by Sternbach. Recently revised criteria are listed in Table 37–5 (Birmes et al. 2003; Keck and Arnold 2000). Laboratory findings have not been commonly reported in cases of serotonin syndrome, but some reports have noted leukocytosis, rhabdomyolysis with elevated creatine phosphokinase

**TABLE 37–3. Clinical features of serotonin syndrome**

Category	Clinical features
Mental status and behavioral	Delirium, confusion, agitation, anxiety, irritability, euphoria, dysphoria, restlessness
Neurological and motor	Ataxia/incoordination, tremor, muscle rigidity, myoclonus, hyperreflexia, clonus, seizures, trismus, teeth chattering
Gastrointestinal	Nausea, vomiting, diarrhea, incontinence
Autonomic nervous system	Hypertension, hypotension, tachycardia, diaphoresis, shivering, sialorrhea, mydriasis, tachypnea, pupillary dilation
Hyperthermia	

*Source.* Compiled in part from Keck and Arnold 2000.

**TABLE 37-4. Drugs that potentiate serotonin in the central nervous system**

Mechanism	Drug
Enhance serotonin synthesis	L-Tryptophan
Increase serotonin release	Cocaine Amphetamine Sibutramine Dextromethorphan, meperidine Methylene dioxymethamphetamine (MDMA, Ecstasy)
Serotonin agonist	Buspirone Lithium Triptans Ergots Trazodone, nefazodone
Inhibit serotonin catabolism	Antidepressant MAOIs Moclobemide Selegiline
Inhibit serotonin reuptake	SSRIs Mirtazapine Trazodone, nefazodone Venlafaxine, duloxetine Tricyclic antidepressants Dextromethorphan, meperidine Pethidine Tramadol

*Note.* MAOIs=monoamine oxidase inhibitors; SSRIs=selective serotonin reuptake inhibitors.

(CPK), serum hepatic transaminase elevations, electrolyte abnormalities (hyponatremia, hypomagnesemia, hypercalcemia), and disseminated intravascular coagulopathy. The differential diagnosis includes other disorders producing cognitive and behavioral, neuromuscular, and autonomic nervous system dysfunction, with or without hyperthermia. Thus, the differential diagnosis for serotonin syndrome is similar to that for neuroleptic malignant syndrome (NMS) (see “Neuroleptic Malignant Syndrome” subsection later in the chapter). Differentiating serotonin syndrome from NMS can be very difficult in patients receiving both serotonergic and antipsychotic medications.

Serotonin syndrome is often self-limited and usually resolves quickly after discontinuation of serotonergic agents. Management includes the following basic principles: 1) provide necessary supportive care, 2) discontinue all serotonergic agents, 3) anticipate potential complications, 4) consider administering antiserotonergic agents, and 5) reassess the need for psychopharmacological ther-

**TABLE 37-5. Revised diagnostic criteria for serotonin syndrome**

1. Addition of a serotonergic agent to an already established treatment (or increase in dosage) and manifestation of at least four major symptoms or three major symptoms plus two minor ones

**Mental (cognitive and behavioral) symptoms**

*Major symptoms:* confusion, elevated mood, coma, or semicoma

*Minor symptoms:* agitation and nervousness, insomnia

**Autonomic symptoms**

*Major symptoms:* fever, hyperhidrosis

*Minor symptoms:* tachycardia, tachypnea and dyspnea, diarrhea, low or high blood pressure

**Neurological symptoms**

*Major symptoms:* myoclonus, tremors, chills, rigidity, hyperreflexia

*Minor symptoms:* impaired coordination, mydriasis, akathisia

2. These symptoms must not correspond to a psychiatric disorder, or its aggravation, that occurred before the patient took the serotonergic agent.
3. Infectious, metabolic, endocrine, or toxic causes must be excluded.
4. A neuroleptic treatment must not have been introduced, nor its dose increased, before the symptoms appeared.

apy before reinstating drug therapy (Keck and Arnold 2000). Some patients will require admission to an intensive care unit, but most will show some improvement within 24 hours with supportive care alone. There are no specific antidotes available for the treatment of serotonin syndrome. The antihistamine cyproheptadine is the most consistently effective serotonin antagonist reported. The recommended adult dose is 4–8 mg and may be repeated every 1–4 hours up to a maximum daily dose of 32 mg. There is limited information on drug rechallenge in patients who have developed serotonin syndrome. General guidelines include reevaluating the necessity for drug therapy, considering a switch to a nonserotonergic medication, using single-drug therapy when serotonergic medications are required, and considering an extended (6-week) serotonin “drug-free” period before restarting a serotonergic agent (Mills 1997).

**Autonomic and cardiovascular.** The SSRIs and the novel/mixed-action antidepressants have a much safer cardiovascular profile than the TCAs and MAOIs. In general,

the SSRIs have little effect on blood pressure or cardiac conduction (Glassman et al. 2002). Fluoxetine has been reported to rarely cause mild bradycardia in elderly patients with preexisting cardiac arrhythmias (Upward et al. 1988), and this may occur with other SSRIs as well.

The novel/mixed-action agents venlafaxine, duloxetine, bupropion, nefazodone, mirtazapine, and reboxetine have no effect on cardiac conduction but may affect blood pressure or heart rate (Khawaja and Feinstein 2003). Venlafaxine exhibits dose-related increases in heart rate (mean increase of 4 beats/minute over placebo) and blood pressure. Placebo-controlled clinical trials of venlafaxine observed an average diastolic pressure increase of 7 mm Hg at dosages of more than 300 mg/day and clinically significant diastolic pressure increases ( $\geq 15$  mm Hg) in 5.5% of patients taking the drug at dosages of more than 200 mg/day (Feighner 1995). Bupropion is reported to cause hypertension without affecting heart rate in some patients. In patients using transdermal nicotine, bupropion is associated with a 6.1% incidence of hypertension (Khawaja and Feinstein 2003). Reboxetine has also been associated with an increase in heart rate of 8–11 beats/minute (Fleishaker et al. 2001), but without any significant effect on electrocardiography (Andreoli et al. 2002). Trazodone lacks significant effects on cardiac conduction but in rare cases was reported to cause ventricular ectopy and ventricular tachycardia. The most frequent cardiovascular adverse effect of trazodone is postural hypotension, which may be associated with syncope. Nefazodone is structurally related to trazodone but has a lower incidence of postural hypotension (3%). Mirtazapine does not have significant effects on cardiac conduction, but because of its moderate  $\alpha_1$ -antagonist activity, it has a 7% incidence of orthostatic hypotension (Khawaja and Feinstein 2003). Hypotension is observed in 10% of patients receiving reboxetine. Duloxetine appears to be without significant cardiovascular effects (Nemeroff et al. 2002).

**Gastrointestinal.** Nausea is the most common adverse effect associated with the serotonergic antidepressants. Nausea is most likely to occur in patients receiving fluvoxamine (36%), venlafaxine (37%), and duloxetine at a starting dose of 60 mg qd (35%–40%) (Detke et al. 2002a, 2002b). Other serotonergic antidepressants have a lower incidence (20%–26%) of nausea, but these incidences are still much higher than those seen with placebo (9.3%–11.8%) (Nelson 1997; Repchinsky 2003). SSRIs and venlafaxine may also cause loose stools.

Although most adverse gastrointestinal effects of serotonergic antidepressants are dose related and generally decrease with continued treatment, sometimes severe side effects require antidepressant discontinuation. Potential

severe hepatotoxicity with nefazodone has led to its removal from the market in a number of countries, and it should not be used in patients with preexisting liver disease (Stewart 2002). Pancreatitis has also rarely been reported with mirtazapine (Lankisch and Werner 2003; Sommer et al. 2001).

**Weight gain/loss.** Weight gain is a relatively common problem during both acute and long-term treatment with antidepressants. TCAs and MAOIs are more likely to cause weight gain than other antidepressants, with the exception of mirtazapine. Paroxetine may be more likely than other SSRIs to cause weight gain during long-term treatment. Bupropion rarely causes weight gain (Fava 2000).

**Sexual dysfunction.** Please refer to Chapter 17, “Sexual Disorders,” for a discussion of the sexual side effects of psychotropic medications.

**Drug interactions.** Many SSRIs and novel/mixed-action antidepressants are potent inhibitors of cytochrome P450 isozymes and may significantly increase the blood levels, and the potential for toxic effects, of other co-administered narrow therapeutic index medications metabolized by these enzymes. See Table 37–2 for a listing of critical narrow therapeutic index drug substrates for these enzymes.

The use of multiple serotonergic drugs can induce serotonin syndrome (see “Serotonin Syndrome” subsection earlier in the chapter).

Abrupt discontinuation of SSRIs, especially those with short half-lives, may give rise to a discontinuation syndrome characterized by a wide variety of symptoms, including gastrointestinal, psychiatric, neurological, and flu-like symptoms; sleep disturbances; and headache (Haddad 1998), usually resolving within 3 weeks. Antidepressants, like all psychoactive medications, should be gradually withdrawn. Discontinuation symptoms can cause misdiagnosis and inappropriate treatment, particularly in a patient with an active medical illness, as well as erode future compliance.

### *Tricyclic Antidepressants*

TCAs are now viewed as second-line treatments for depression because their adverse effect profile is less benign than that of SSRIs. Death from TCA-induced cardiac conduction abnormalities was not uncommon in overdose.

Many adverse effects of TCAs are due not to their effects on serotonin (5-HT) or norepinephrine reuptake inhibition but rather to secondary pharmacological ac-

tivities. TCAs are antagonists at histamine H<sub>1</sub>, adrenergic alpha<sub>1</sub>, and muscarinic receptors and have type-1A antiarrhythmic (quinidine-like) effects as a result of their blockade of voltage-dependent Na<sup>+</sup>-channels. Adverse effects of the TCAs include sedation, anticholinergic effects (dry mouth, dry eyes, constipation, urinary retention, decreased sweating, confusion, memory impairment, tachycardia, blurred vision), and postural hypotension. Tolerance to these effects usually develops over time. TCAs at or just above therapeutic plasma levels frequently prolong PR, QRS, and QTc intervals, but rarely to a clinically significant degree in patients without preexisting cardiac disease or conduction defects (Glassman 1984). TCAs can cause heart block, arrhythmias, palpitations, tachycardia, syncope, and heart failure and should be used with caution in patients with preexisting cardiovascular disease or at risk of suicide. Following the discovery that class I antiarrhythmic drugs can increase mortality in patients with ischemic heart disease, it is prudent to assume that TCAs may carry the same risk in these patients (Cardiac Arrhythmia Suppression Trial [CAST] Investigators 1989; Glassman et al. 1993).

**Drug interactions.** The combination of TCAs and other drugs with sedating, hypotensive, antiarrhythmic, or seizure threshold-lowering properties may lead to additive toxicity.

Concomitant use of TCAs and drugs with anticholinergic properties may cause an anticholinergic crisis characterized by delirium, hyperthermia (especially in hot environments), tachycardia, and paralytic ileus.

Coadministration of TCAs with direct-acting (e.g., isoproterenol, phenylephrine) or indirect-acting (MAOIs and other drugs with MAOI activity) sympathomimetics may precipitate a potentially fatal reaction, with symptoms of hyperpyrexia, sweating, confusion, myoclonus, seizures, hypertension, and tachycardia.

The combination of serotonergic effects from co-therapy with some TCAs and SSRIs may precipitate serotonin syndrome (see "Serotonin Syndrome" subsection earlier in this chapter).

TCAs are narrow therapeutic index drugs, each metabolized predominantly by either CYP2D6 or CYP3A4. Inhibitors of these enzymes can cause TCA toxicity by dramatically increasing TCA serum levels. Many agents, including several SSRIs and novel/mixed-action antidepressants, are potent inhibitors of these cytochromes (see Table 37-2). Plasma levels of TCAs should be monitored if they are coadministered with such inhibitors.

**Toxicity/overdose.** TCA overdose carries a risk of death from cardiac conduction abnormalities that result in ma-

lignant ventricular arrhythmias. Initial symptoms of overdose involve CNS stimulation, in part due to anticholinergic effects, and include hyperpyrexia, delirium, hypertension, hallucinations, seizure, agitation, hyperreflexia, and parkinsonian symptoms. The initial stimulation phase is typically followed by CNS depression with drowsiness, areflexia, hypothermia, respiratory depression, severe hypotension, and coma. Risk of cardiotoxicity is high if the QRS interval is 100 msec or more (Boehnert and Lovejoy 1985) or if the total TCA plasma concentration is greater than 1,000 ng/mL; concentrations greater than 2,500 ng/mL are often fatal (Foulke and Albertson 1987).

Treatment for overdose includes removal of any unabsorbed medication from the stomach (gastric lavage or emesis with aspiration precautions and then activated charcoal to reduce absorption), followed by supportive therapy and close monitoring. Cardiac conduction abnormalities, arrhythmias, and hypotension may be treated with administration of intravenous sodium bicarbonate to produce a serum pH of 7.4-7.5. Life-threatening anticholinergic effects may be managed with physostigmine. Because of their large volumes of distribution and extensive protein binding, TCAs are not removed by dialysis.

Abrupt discontinuation of TCAs may give rise to a discontinuation syndrome characterized by dizziness, lethargy, headache, nightmares, and symptoms of anticholinergic rebound, including gastrointestinal upset, nausea, vomiting, diarrhea, excessive salivation, sweating, anxiety, restlessness, piloerection, and delirium (Dilsaver and Greden 1984). This syndrome can be avoided by gradual withdrawal.

### ***Monoamine Oxidase Inhibitors***

Monoamine oxidase inhibitors (MAOIs), with the possible exception of moclobemide (not available in the United States), are seen as third-line antidepressants because of their significant drug interactions and the dietary restrictions that accompany their use. Moclobemide, a short-half-life reversible inhibitor of monoamine oxidase type A (MAO-A), is less susceptible to dietary interactions providing it is taken after meals. Common adverse effects of MAOIs include orthostatic hypotension, dizziness, headache, sedation, insomnia or hypersomnia, tremor, and hyperreflexia. Interactions between MAOIs and direct- or indirect-acting sympathomimetics or dopaminergic agonists may cause a hypertensive crisis. MAOIs may trigger serotonin syndrome when combined with other medications (see "Serotonin Syndrome" subsection earlier in the chapter). Moclobemide shares the potential to cause hypertensive crises and serotonin syndrome with the irreversible agents. MAOIs may greatly potentiate the hypo-

tensive effects of antihypertensive agents, including diuretics (British Medical Association 2003a).

Selegiline, a semiselective monoamine oxidase type B (MAO-B) inhibitor used to treat Parkinson's disease, may also contribute to serotonin syndrome. At dosages greater than 10 mg/day, selegiline also inhibits MAO-A and thus shares many of the adverse effects and drug/food interactions, including hypertensive crisis, of the antidepressant MAOIs.

**Toxicity/overdose.** Symptoms of MAOI overdose are an extension of the normal adverse-effect profile. Treatment for overdose includes removal of any unabsorbed medication from the stomach and supportive measures.

Treatment for hypertensive crisis involves discontinuing the MAOI and slowly administering intravenous phenolamine (typical adult dose = 5 mg). *Beta-blockers should never be used*; beta-blockade allows unrestrained alpha-adrenergic stimulation, which further exacerbates the hypertension.

## Mood Stabilizers

Mood stabilizers are used in the medically ill to treat primary and secondary mood disorders as well as for symptoms such as headache and chronic pain. Many but not all anticonvulsants appear to have mood-stabilizing properties. Valproic acid, carbamazepine, and oxcarbazepine are the most commonly used anticonvulsant mood stabilizers. Controlled studies do not support the use of gabapentin as a mood stabilizer (Evins 2003).

### Side Effects and Toxicity

#### *Lithium*

Most patients using lithium experience some side effects, both acute (gastrointestinal distress and tremor) and long-term (polyuria and polydipsia, hypothyroidism, weight gain, impaired cognition, sedation, impaired coordination, edema, acne, and hair loss), most of which are mild and dose related (Peet and Pratt 1993). Adverse effects of lithium can be minimized by reducing the dose or decreasing the rate of absorption from the gut by administering the drug either in divided doses with meals or in a slow-release form.

**Central nervous system.** Headache, fatigue, hand tremor, and mild cognitive impairment are reported by up to 50% of patients beginning lithium treatment. Hand tremor is usually a benign, fine, rapid intention tremor that resolves over time or can be managed by dose reduction or low-

dose beta-blockers. The tremor does not respond to antiparkinsonian drugs. Muscle weakness, fatigue, and ataxia are also common initial adverse effects that usually resolve (McEvoy 2003). Mild cognitive impairment may be experienced during the first 6–8 months of treatment; although rarely progressive, this impairment is the most common reason for noncompliance (Gitlin et al. 1989).

**Autonomic and cardiovascular.** Lithium causes benign reversible repolarization electrocardiographic changes in 20%–30% of patients (Mitchell and Mackenzie 1982), including T-wave depression and inversion. Other cardiovascular effects of lithium include decreased heart rate and, rarely, cardiac conduction abnormalities and arrhythmias (Burggraf 1997).

**Renal.** Lithium reduces renal response to antidiuretic hormone, resulting in polyuria and/or polydipsia initially in 30%–50% of patients and persisting in 10%–25%. Stopping lithium usually reverses this nephrogenic diabetes insipidus (McEvoy 2003). Apart from dry mouth, patients do not generally exhibit signs of dehydration. Management of polyuria may include changing to a single daily bedtime dose of lithium, decreasing dosage, and/or administering thiazide diuretics or amiloride. If thiazide diuretics are added, lithium dosage typically will have to be reduced by 50% to compensate for thiazide-induced reduction of lithium excretion (Jefferson et al. 1987). Use of amiloride does not require a reduction in lithium dosage (Bendz and Aurell 1999). Edema has been reported in patients with a high sodium intake (>170 mEq/day), responsive to reduction in sodium intake or spironolactone (Stancer and Kivi 1971).

Both functional and morphological changes of the kidneys have been reported in lithium-poisoned patients. Whether renal impairment is a direct effect of lithium on the kidneys or a secondary effect of systemic toxicity is not resolved. Chronic use of lithium may result in altered kidney morphology in 10%–20% of patients, including interstitial fibrosis, tubular atrophy, urinary casts, and, occasionally, glomerular sclerosis (Bendz et al. 1996). These changes are not generally associated with impaired renal function. In 1979, the World Psychiatric Association convened a meeting in Copenhagen to discuss lithium and renal effects. The consensus was that the risk of lithium nephropathy in the absence of lithium toxicity is small. Most investigators continue to agree that the risk of renal dysfunction during chronic use is far less than the risk of psychiatric morbidity (Perry 1996).

**Endocrine and metabolic.** The prevalence of overt hypothyroidism has been reported to be as high as 8%–19% for

patients taking lithium, compared with a prevalence of 0.5%–1.8% in the general population. Subclinical hypothyroidism has been reported in up to 23% of patients receiving lithium therapy, compared with rates of up to 10.4% in the general population. Elevated thyroid-stimulating hormone is present in approximately 30% of patients taking lithium for 6 months or more, and progression to overt hypothyroidism (elevated thyroid-stimulating hormone and low free T<sub>4</sub>) may occur in as many as 5%–10% of patients per year (Kleiner et al. 1999). Thyroid function should be assessed before lithium is started and periodically during therapy. Hypothyroidism can be treated with L-thyroxine and is not a contraindication to continuing lithium (Bauer and Whybrow 1990) (see also Chapter 23, “Endocrine and Metabolic Disorders”).

Weight gain is the second most common reason cited by patients for lithium noncompliance (Gitlin et al. 1989). Weight gain is a consequence of increased caloric intake in part due to consumption of high-calorie fluids in response to increased thirst (McEvoy 2003).

**Dermatological.** Dermatological adverse effects include dry skin and acne. Occurring in about 1% of patients taking lithium (Jefferson et al. 1987), these effects usually respond to standard treatment and rarely require lithium discontinuation. Alopecia and exacerbation of psoriasis occur less frequently (Chan et al. 2000) (see also Chapter 29, “Dermatology”).

**Drug interactions.** Lithium is almost entirely renally excreted, and most lithium filtered by the glomeruli is reabsorbed with sodium in the proximal tubule. Serum lithium levels are increased by thiazide diuretics, NSAIDs, angiotensin-converting enzyme inhibitors, sodium depletion, and dehydration (Dunner 2003). Verapamil, and possibly other calcium channel blockers, may also cause an increase in serum lithium levels (Wright and Jarrett 1991). For a more complete review, see the article by Thomsen and Schou (1999).

Lithium may potentiate the neurological adverse effects of other drugs, for example, EPS and tremor (Dunner 2000).

**Toxicity/overdose.** Toxicity increases markedly as serum lithium levels exceed 1.5 mEq/L, and serum levels greater than 2.0 mEq/L are dangerous. However, some patients experience toxicity at “therapeutic” levels. Initial symptoms of toxicity include marked tremor, nausea, diarrhea, blurred vision, vertigo, confusion, and increased deep tendon reflexes, progressing to seizures, coma, cardiac arrhythmia, and possibly permanent neurological impairment as lithium levels increase.

Treatment for lithium toxicity includes gastric lavage or emesis followed by supportive measures. These measures include volume resuscitation with isotonic or one-half isotonic sodium chloride solution to enhance renal elimination of lithium in individuals with mild-to-moderate toxicity, or hemodialysis for patients with severe toxicity and/or lithium levels of 3.5 mEq/L or higher (Jaeger et al. 1993; Menghini and Albright 2000).

### *Anticonvulsants*

**Central nervous system.** The anticonvulsants valproate, carbamazepine, gabapentin, lamotrigine, oxcarbazepine, topiramate, tiagabine, zonisamide, and levetiracetam share a similar profile of CNS adverse effects. Sedation, ataxia, dizziness, muscle weakness, fatigue, and vision disturbances such as nystagmus and diplopia are common and often resolve with time, dosage reduction, or discontinuation. Studies of oxcarbazepine in epilepsy suggest a lower rate of adverse effects than carbamazepine (Dam et al. 1989). Psychotic symptoms are an infrequent adverse effect but reportedly occur more frequently with topiramate (Crawford 1998). Cognitive impairment is a common complication of anticonvulsant use. Among anticonvulsants used in psychiatry, the ranking of cognitive profile is (best to worst) gabapentin, lamotrigine, valproate and carbamazepine, and topiramate (Goldberg and Burdick 2001). There are insufficient data to rank oxcarbazepine and levetiracetam.

**Gastrointestinal.** Symptoms of gastrointestinal distress, including nausea, vomiting, dyspepsia, diarrhea, and anorexia, are the most frequent adverse effects experienced with most anticonvulsants. These effects are often dose related and transient, and can be minimized by giving the drug in divided doses, with meals, or with slow titration.

Gastrointestinal effects appear less often with divalproex sodium than with valproic acid or sodium valproate. There are fewer gastrointestinal complaints with oxcarbazepine than with carbamazepine.

**Hematological.** Carbamazepine is frequently associated with transient leukopenia and rarely may cause aplastic anemia. Carbamazepine should be discontinued in patients with white blood cell counts less than  $3.0 \times 10^9/L$  or neutrophil counts less than  $1.0 \times 10^9/L$ , and patients must be educated to report early signs of anemia, infection, or bleeding (Sobotka et al. 1990).

Mild, asymptomatic leukopenia and thrombocytopenia have been observed with valproate and are generally reversible with dosage reduction or discontinuation. More severe cases of thrombocytopenia and agranulocytosis have also been reported (Finsterer et al. 2001).

**Renal.** Carbamazepine and oxcarbazepine frequently cause the syndrome of inappropriate antidiuretic hormone secretion (SIADH), leading to hyponatremia and water intoxication. Carbamazepine-induced hyponatremia has been reported in as many as 6%–36% of patients, more commonly in the elderly (McEvoy 2003; van Amelsvoort et al. 1994). Hyponatremia may be more common with oxcarbazepine than with carbamazepine (Asconape 2002). (For a further discussion of SIADH, see “Antipsychotics” subsection later in this chapter.)

**Endocrine and metabolic.** Transient elevations in liver enzymes occur commonly with anticonvulsants. Significant changes in hepatic function are usually reversible with dosage reduction or discontinuation. However, fatal hepatotoxicity has been reported with valproate. The risk of hepatic failure may be increased by combination therapy and comorbid hepatic disorders (Konig et al. 1999).

Weight gain is a common factor in noncompliance (Mendlewicz et al. 1999). Weight gain is especially a problem with valproate, with 25% of patients gaining up to 20 kg (Pijl and Meinders 1996). Gabapentin is reported to result in about 10% gain of body weight in 25% of patients (DeToledo et al. 1997). Although carbamazepine is also reported to cause weight gain, the incidence is less than with valproate (Corman et al. 1997). Lamotrigine has little effect on weight, whereas topiramate causes a weight loss of about 3–5 kg (Chengappa et al. 1999; McElroy et al. 2000). Topiramate can cause hyperchloremic, non-anion gap metabolic acidosis; in clinical trials, persistent reductions in serum bicarbonate occurred in 23%–67% of patients, and levels were markedly low (<17 mEq/L) in 3%–11% (Ortho-McNeil, general letter, December 2003).

Polycystic ovarian syndrome occurs in women with epilepsy, with a prevalence 3.8 times greater than that in the general population. This increase has been variously attributed to either epilepsy (Joffe et al. 2001) or anticonvulsant medications, especially valproate. Whether valproate presents a similar risk when used as a mood stabilizer remains uncertain (see Chapter 23, “Endocrine and Metabolic Disorders”).

**Immune system.** Benign skin rashes occur in 5%–20% of patients receiving anticonvulsants, including valproate, carbamazepine, and lamotrigine. However, serious and potentially fatal immune reactions to anticonvulsants are not uncommon. Anticonvulsant hypersensitivity syndrome has been observed in up to 1% of patients, with initial signs of rash, fever, malaise, and pharyngitis progressing to internal organ involvement. Severe and often fatal hypersensitivity cutaneous reactions include Stevens-

Johnson syndrome and toxic epidermal necrolysis. Mortality occurs in about 5%–10% of patients with Stevens-Johnson syndrome and in up to 45% of those with toxic epidermal necrolysis. In comparison with general medical patients, the risk of developing Stevens-Johnson syndrome or toxic epidermal necrolysis during the first 2 months of anticonvulsant therapy is increased by 120-fold for carbamazepine, 25-fold for lamotrigine, and 24-fold for valproate (Rzany et al. 1999). Clinical trials suggest that 25% of patients with hypersensitivity reactions to carbamazepine will also cross-react to oxcarbazepine (USP DI Editorial Board 2003). The presence of an anticonvulsant-induced rash should prompt drug discontinuation (Hebert and Ralston 2001).

**Drug interactions.** Significant cytochrome P450 enzyme induction occurs with carbamazepine (CYP1A2, CYP2C, and CYP3A4), oxcarbazepine (CYP3A4), and valproate (CYP2C) (see Table 37–2). Because valproate is highly bound to plasma proteins, it can significantly displace other highly protein-bound drugs. Valproate can also compete for hepatic glucuronidation and so inhibit the elimination of drugs primarily using this route of metabolism, such as lamotrigine and morphine.

**Toxicity/overdose.** Symptoms of anticonvulsant overdose are often an extension of the normal adverse effects, including stupor, conduction disturbances, and hypotension. Treatment for overdose includes gastric lavage or emesis followed by supportive therapy. Hemodialysis is an effective means of enhancing drug elimination for valproate, gabapentin, topiramate, and levetiracetam.

## Antipsychotics

---

Antipsychotic drugs are used in the medically ill to treat nearly all forms of psychosis, including psychosis secondary to general medical conditions, delirium, and dementia, and less frequently for nonspecific sedation and as analgesic adjuvants.

### Side Effects and Toxicity

#### *Central Nervous System*

**Acute extrapyramidal symptoms.** Acute EPS—akathisia, akinesia, and dystonia—occur in as many as 50%–75% of patients who take typical antipsychotics (Collaborative Working Group on Clinical Trial Evaluations 1998). High-potency typical antipsychotics are associated with higher rates of EPS than are low-potency agents. Among the currently available atypical antipsychotics, the hierarchy of

EPS risk (greater to lesser) is risperidone > olanzapine = ziprasidone = aripiprazole (estimated) > quetiapine > clozapine (Tandon 2002).

Most akathisia and acute dystonic reactions in the medically ill are caused by phenothiazine antiemetics or metoclopramide, especially at high intravenous doses. When agitated medically ill patients are being treated with haloperidol, it can be very difficult to distinguish akathisia from the original target symptoms. It is also important to exclude other causes of restlessness that may mimic akathisia in medically ill patients, such as hypoglycemia, hypoxia, drug withdrawal, pain, electrolyte disturbances, iron deficiency, and restless legs syndrome. Severe dystonic reactions (e.g., opisthotonus) may be misdiagnosed in the medically ill as status epilepticus.

**Chronic extrapyramidal symptoms.** Parkinsonian signs and tardive dyskinesia may result from chronic use of antipsychotics, phenothiazine antiemetics, or metoclopramide. Bradykinesia may easily be missed in the elderly or disabled medical patients. Tardive dyskinesias may be difficult to distinguish from other dyskinesias in elderly patients (e.g., "senile dyskinesias," ill-fitting dentures).

**Seizures.** At higher doses, there appears to be an increased risk of seizures associated with antipsychotics. Various reports suggest a dose-dependent seizure risk with phenothiazines from 0.3%–1.2% compared with a rate of first unprovoked seizure in the general population of about 0.1%. Most of the early case reports were of seizures with chlorpromazine. Although there are no controlled comparative studies to allow an accurate assessment of relative seizure risk, it appears that high-potency typical antipsychotics and risperidone have the lowest rate of seizures; olanzapine, quetiapine, and low-potency typical antipsychotics have an intermediate risk; and clozapine has the highest risk (Allredge 1999).

**Sedation.** Sedation is the most common single side effect, especially with the low-potency typical antipsychotics. Among the atypical antipsychotics, the hierarchy of potential for sedation (greater to lesser) is clozapine > quetiapine > olanzapine > risperidone > ziprasidone = aripiprazole (estimated) (Tandon 2002). Sedation is most prominent in the early stages of therapy, with some degree of tolerance developing over time.

**Thermoregulation.** Antipsychotics may interfere with temperature regulation, especially low-potency typical and anticholinergic atypical agents. Medically ill patients, especially elderly ones, are at particular risk because of other anticholinergic drugs and comorbidities impairing thermo-

regulation (e.g., congestive heart failure, cerebrovascular disease). Depending on environmental exposure, either hyperthermia or hypothermia may result (Mann et al. 2003).

**Neuroleptic malignant syndrome.** NMS is a rare, potentially fatal, idiosyncratic reaction to antipsychotics. NMS (or a similar syndrome) is also reported among patients with extrapyramidal disorders such as Wilson's disease, striatonigral degeneration, and Parkinson's disease who have received antipsychotics or dopamine-depleting agents or who have had dopamine agonists abruptly withdrawn (Friedman et al. 1985; Gibb 1988; Gibb and Griffith 1986; Kontaxakis et al. 1988). However, NMS is not specific to any neuropsychiatric diagnosis and has been reported in non-psychiatrically ill individuals who were treated with other dopamine antagonists such as metoclopramide and prochlorperazine (Nonino and Campomori 1999; Pesola and Quinto 1996). Estimates of the incidence of NMS have ranged from 0.02%–3.23%, reflecting differences in diagnostic criteria, survey techniques, patient populations, and treatment settings and practices (Lazarus et al. 1989). Malnutrition, dehydration, and iron deficiency all appear to increase risk for NMS.

NMS generally develops over a 1–3 day period and lasts for 5–10 days after a nondepot antipsychotic is discontinued. Mortality is high, often quoted at 20%–30% but probably lower now because of earlier recognition. The main clinical features of NMS include hyperthermia (>37°C), generalized muscle rigidity, mental status changes and autonomic instability. Temperature in hyperthermia is greater than 38°C in the majority of cases and can exceed 40°C, which predisposes the patient to severe complications, including irreversible CNS and other organ damage. Muscle rigidity is often heterogeneous and can be "lead-pipe" or cogwheeling. Autonomic dysfunction in NMS may include hypertension, orthostatic hypotension, labile blood pressure, tachycardia, tachypnea, sialorrhea, diaphoresis, skin pallor, and urinary incontinence. Neurological dysfunction may consist of tremor, myoclonus, focal dystonias, dysphagia, dysarthria, opisthotonus, oculogyric crisis, and dyskinesias. Altered level of consciousness may range from decreased awareness to coma. CPK levels are often elevated in NMS secondary to muscle necrosis from rigidity, hyperthermia, and ischemia. Elevated CPK levels are not proof of NMS, because they may result from agitation, use of physical restraints, and intramuscular injections. Extreme elevation of CPK (>100,000 U/L) constitutes rhabdomyolysis, which may be a consequence of NMS and/or other causes in the medically ill (e.g., sepsis, shock, alcohol). Serial CPK monitoring in NMS will typically show declining levels with the resolution of the syndrome. Leukocytosis with

or without a left shift is common. Complications may include respiratory or renal failure, pulmonary embolus, electrolyte disturbances, and coagulopathy (Caroff and Mann 1993; Pelonero et al. 1998).

The differential diagnosis of NMS is large (Table 37–6). Although the vast majority of patients receiving antipsychotics who develop fever and rigidity will be found to have other conditions, the possibility of NMS should be considered because of the importance of promptly withholding antipsychotics. Basic and optional examinations for the clinical evaluation of possible NMS include those listed in Table 37–7.

The main interventions in NMS are early diagnosis, rapid cessation of the antipsychotic treatment, and inten-

sive supportive care. Lithium, antipsychotics, and all other dopamine-blocking agents (including antiemetics and droperidol) should be discontinued. No specific therapy (e.g., dantrolene or bromocriptine) has been proven superior to other measures (for a detailed review, see Mann et al. 2003). Most cases of NMS require initial treatment in a medical intensive care unit and should be transferred back to a psychiatric service only after the patient is medically stable. Among patients who recover from NMS, there may be a 30% risk of recurrent episodes following subsequent antipsychotic rechallenge, but the majority of patients who require antipsychotic therapy can be cautiously re-treated.

**TABLE 37–6. Differential diagnosis of neuroleptic malignant syndrome**

Competing diagnosis	Distinguishing clinical features of the competing diagnosis
Malignant hyperthermia	Occurs after general anesthesia
Lethal catatonia	Similar symptoms before neuroleptic exposure
Heat stroke	Hot, dry skin; absence of rigidity; prior neuroleptic exposure may increase risk for heat stroke
Severe extrapyramidal symptoms or Parkinson's disease	Absence of fever, leukocytosis, autonomic changes
Central nervous system infection	Seizures more likely; significant abnormalities in cerebrospinal fluid
Allergic drug reaction	Rash, urticaria, wheezing, eosinophilia
Toxic encephalopathy, lithium toxicity	Absence of fever; low CPK
Anticholinergic delirium	Absence of rigidity; low CPK
Systemic infection plus severe EPS	May appear identical to neuroleptic malignant syndrome

*Note.* CPK = creatine phosphokinase; EPS = extrapyramidal symptoms.

**TABLE 37–7. Examinations for possible neuroleptic malignant syndrome**

Basic	Optional
Physical examination	Arterial blood gases
Electrolytes, including calcium and magnesium	Coagulation studies Blood cultures
Renal and hepatic function tests	Toxicology screen
Complete blood count	Lithium level
Serial tests of CPK levels	Iron deficiency test
Urinalysis	
Lumbar puncture	
CT or MRI of the head	

*Note.* CPK=creatine phosphokinase; CT=computed tomography; MRI=magnetic resonance imaging.

**Autonomic and cardiovascular.** Autonomic side effects result from cholinergic and  $\alpha_1$ -adrenergic blockade, seen more frequently with low-potency typical antipsychotics. Among the atypical agents, the hierarchy for producing hypotension (from greatest risk to least risk) is clozapine > quetiapine > risperidone > olanzapine = ziprasidone = aripiprazole (estimated) (Tandon 2002).

**QTc prolongation and torsades de pointes.** A number of antipsychotics may be associated with QTc interval prolongation and risk for torsades de pointes. Sertindole was never marketed in the United States for this reason, but it is available in Europe with a restrictive label. Thioridazine, mesoridazine, and droperidol carry a "black box" warning regarding dose-related QTc prolongation and risk for sudden death. One study found that almost 30% of patients taking thioridazine had a change in QTc of 60 msec or more, followed by 21% for ziprasidone, 11% for quetiapine, and 4% each for risperidone, olanzapine, and haloperidol. A few subjects receiving thioridazine

(10%) and ziprasidone (3%) had a QTc prolongation of 75 msec or greater (Pfizer 2000). Case reports have also associated droperidol and pimozide with QTc prolongation. Controlled trials confirm QTc prolongation with droperidol (Carroll et al. 2002).

**Other cardiac side effects.** Potentially fatal myocarditis, cardiomyopathy, and heart failure have been reported with clozapine. Estimated rates of clozapine-associated myocarditis range from 1 in 10,000 to 1 in 500. Eighty-five percent of these cases develop during the first 2 months of therapy and may be accompanied by eosinophilia. Clozapine-associated cardiomyopathy has most often occurred in patients under 50 years of age, with dilated cardiomyopathy accounting for two-thirds of the cases and one-third of the deaths. Withdrawal of the drug might result in improvement of the cardiomyopathy (Wooltorton 2002). Myocarditis and cardiomyopathy have also been reported in association with chlorpromazine, fluphenazine, risperidone, and haloperidol, but a causal link has not been demonstrated (Coulter et al. 2001).

### ***Endocrinological and Metabolic***

**Glucose tolerance.** Pharmacoepidemiological studies and case reports reveal an association between the use of various atypical antipsychotics with hyperglycemia, new-onset type 2 diabetes, and occasional ketoacidosis. These effects are not fully understood and are not solely explained by weight gain; schizophrenia is itself a risk factor for type 2 diabetes regardless of treatment. New-onset diabetes has been reported more frequently with olanzapine and clozapine, but there have not been any systematic prospective studies. Current limited data report that hyperglycemia has been associated with all marketed atypical antipsychotics. To date, however, the only report of hyperglycemia associated with ziprasidone has been in the context of possible NMS with rhabdomyolysis and pancreatitis (Yang and McNeely 2002). Diabetic ketoacidosis has been reported in association with all atypical antipsychotics except for ziprasidone (see also Chapter 23, "Endocrine and Metabolic Disorders").

**Lipids.** Phenothiazines, but not butyrophenones (Meyer 2001a), were long ago noted to elevate serum levels of cholesterol and triglycerides (Clark et al. 1967; Mefferd et al. 1958). More recent studies with atypical antipsychotics have demonstrated elevated serum triglyceride levels in patients taking clozapine, olanzapine, and quetiapine (Domon and Cargile 2002; Gaulin et al. 1999; Meyer 2001b), usually peaking in the first year of therapy.

**Hyperprolactinemia.** Hyperprolactinemia is relatively common, especially with high-potency typical antipsychotics and risperidone, and can result in amenorrhea or irregular menses, galactorrhea, gynecomastia, sexual dysfunction, and osteoporosis.

**Weight gain.** All currently marketed antipsychotics (with the possible exception of molindone, ziprasidone, and aripiprazole) are associated with weight gain, which may increase health risks (hypertension, atherosclerosis, type 2 diabetes, cardiovascular disease, and stroke), stigmatization, noncompliance, impairment in quality of life, and social withdrawal. The relative propensity to cause weight gain among the atypical antipsychotics (from greatest to least) is clozapine > olanzapine > risperidone = quetiapine = aripiprazole (estimated) > ziprasidone (Tandon 2002).

**Syndrome of inappropriate antidiuretic hormone secretion.** SIADH can occur with typical as well as atypical antipsychotics (and some antidepressants and anticonvulsants). SIADH is characterized by a reduced ability to excrete water, resulting in extracellular dilution and hyponatremia. SIADH is distinguished from polydipsia (water intoxication) by urine osmolality, with relatively high urine osmolality in SIADH versus very low urine osmolality in polydipsia. Common symptoms include weakness, lethargy, headache, anorexia, and weight gain and may progress to confusion, convulsions, coma, and death.

**Hematological.** Hematological side effects of antipsychotics include agranulocytosis, aplastic anemia, neutropenia, eosinophilia, and thrombocytopenia (for a full review, see Oyesanmi et al. 1999). Transient leukopenia and leukocytosis are not uncommon in the first few weeks of therapy and are usually not clinically significant. Agranulocytosis is the most common serious hematological side effect with typical antipsychotics (<0.1%) and occurs more frequently with low-potency agents. Clozapine-associated agranulocytosis occurs in about 1%–2% of patients, with highest risk in the first 6 months. A white blood count less than 2,000/mm<sup>3</sup> or an absolute neutrophil count less than 1,000/mm<sup>3</sup> is an indication for immediate cessation of clozapine.

**Hepatic.** Liver function abnormalities during antipsychotic therapy have long been reported but seldom require drug discontinuation. Mild-to-moderate elevations in liver aminotransferases and alkaline phosphatase usually occur early in treatment and are unlikely to result in hepatic impairment. Cholestatic jaundice is an idiosyncratic reaction that occurs rarely with phenothiazines.

Allergic, dermatological, and ophthalmological. Dermatological adverse reactions include early allergic rashes, photosensitivity, and skin hyperpigmentation, especially with chlorpromazine. Pigmentary retinopathy occurred in patients taking more than 800 mg/day of thioridazine. Acute angle closure glaucoma may occur in patients with a physiologically narrow anterior chamber angle who take anticholinergic medications.

**Sexual.** Antipsychotics may cause sexual dysfunction (see Chapter 17, "Sexual Disorders," for detailed discussion).

**Toxicity/overdose.** Generally, antipsychotic overdose is associated with low morbidity and mortality. Most patients who have taken an antipsychotic overdose remain asymptomatic or develop mild sedation within 1–2 hours, but particular antipsychotics can cause serious cardiac effects (e.g., thioridazine-induced QTc prolongation) or neurotoxicity (e.g., clozapine-induced seizures), especially in medically vulnerable patients.

**Drug interactions.** Most antipsychotic drugs have sedating, hypotensive, anticholinergic, antiarrhythmic, and seizure threshold-lowering properties. Predictable drug interactions may occur when combining antipsychotics with other drugs also possessing these characteristics. For example, antipsychotics may strongly potentiate the sedative effects of other CNS depressants, and anticholinergic antipsychotics will have additive adverse effects with other anticholinergic drugs. Antipsychotics may greatly enhance the hypotensive effects of antihypertensive agents. Low-potency antipsychotics and ziprasidone should be avoided in patients receiving other drugs with quinidine-like properties.

Many antipsychotics, including aripiprazole, clozapine, olanzapine, and risperidone, are prone to pharmacokinetic drug interactions because of the limited number of cytochrome P450 isozymes involved in their metabolism (see Table 37–2).

## **Anxiolytics and Sedative-Hypnotics**

Benzodiazepines have long been considered the cornerstone of pharmacotherapy for anxiety and insomnia. Alternatives include buspirone for anxiety and the nonbenzodiazepine hypnotics zolpidem, zopiclone, and zaleplon. These newer agents appear to have much less tolerance and abuse potential and fewer adverse effects than benzodiazepines. Chloral hydrate has been used as a sedative-hypnotic since 1869, but dependence occurs rapidly and withdrawal can be fatal.

## **Side Effects and Toxicity**

### ***Benzodiazepines***

Benzodiazepines commonly cause dose-related CNS adverse effects but rarely affect organ systems other than the respiratory system.

**Central nervous system.** Acute adverse CNS effects, including sedation, fatigue and weakness, ataxia, slurred speech, confusion, and memory impairment, are common, especially in older individuals and the medically ill. When used for the treatment of insomnia, long-half-life benzodiazepines are more likely to cause daytime sedation and cognitive impairment than short-half-life drugs. The elderly and patients with brain injury are also susceptible to benzodiazepine-induced behavioral disinhibition resulting in excitement, aggression, and paradoxical rage (Kales et al. 1987).

Physical tolerance often develops with chronic use of benzodiazepines, and the therapeutic effects and adverse effects may diminish (Woods et al. 1992). A study of the cognitive effects of long-term benzodiazepine use in the elderly demonstrated that the impairment of memory, attention, and psychomotor speed evident with acute benzodiazepine use reverts to predrug levels over 6 months of therapy (McAndrews et al. 2003).

**Respiratory.** Benzodiazepines decrease the central respiratory response to hypoxia. Benzodiazepines differ in their ability to cause respiratory depression (Cohn 1983; Guilleminault 1990), with long-acting agents such as flurazepam (Dolly and Block 1982; Mendelson et al. 1981) and nitrazepam (Model 1973; Sanger and Zivkovic 1992) having the most pronounced effects. These drugs can cause apnea when used alone or in combination with other CNS depressants, most commonly alcohol (Guilleminault 1990; Mendelson et al. 1981). The respiratory depressant effects of benzodiazepines may become clinically significant in those with preexisting respiratory disorders, such as chronic obstructive pulmonary disease (COPD) (Clarke and Lyons 1977; Model 1973) or sleep apnea (Mendelson et al. 1981), or those with seizure disorders (which also can cause respiratory depression).

The incidence of respiratory depression associated with benzodiazepine treatment of seizure disorder ranges from 10.6% for lorazepam in adults (Allredge et al. 2001) to 14% in children treated mainly with lorazepam (Stewart et al. 2002) and 9%–20% for children treated with diazepam (Appleton et al. 1995; Norris et al. 1999). Benzodiazepines should be used with caution in patients with compromised respiratory function or seizure disorders. Use in patients with obstructive sleep apnea is pro-

tentially fatal (Dolly and Block 1982) (see Chapter 16, "Sleep Disorders").

**Drug interactions.** Additive CNS depressant effects, including respiratory depression, result from the combination of benzodiazepines and other CNS depressants, including alcohol.

Many benzodiazepines, including alprazolam, bromazepam, clonazepam, diazepam, midazolam, and triazolam, undergo hepatic and intestinal metabolism mediated by CYP3A4. Significant inhibitors of CYP3A4 may reduce the elimination of these benzodiazepines, whereas CYP3A4 inducers can increase their hepatic metabolism (see Table 37-2). Oxazepam, lorazepam, and temazepam are eliminated primarily by conjugation and renal excretion and so may be less problematic in patients with hepatic impairment.

**Toxicity/overdose.** Benzodiazepines have a wide margin of safety; death from overdose is rare unless part of a poly-drug overdose. Overdose may result in sedation, ataxia, slurred speech, confusion, seizures, respiratory depression, and coma. Treatment includes removal of any unabsorbed drug from the stomach (gastric lavage or emesis) followed by supportive therapy. The benzodiazepine antagonist flumazenil can also be used but may cause seizures.

Sudden discontinuation of benzodiazepines may result in severe withdrawal symptoms, including anxiety, agitation, dysphoria, anorexia, insomnia, sweating, vomiting, diarrhea, abdominal cramps, ataxia, psychosis, and seizures. The intensity of withdrawal symptoms is greater with higher doses, prolonged treatment, abrupt discontinuation, and short-half-life benzodiazepines. Patients should be gradually withdrawn from benzodiazepines; this is especially crucial for those with a history of seizure disorder. Withdrawal from short-half-life agents can be facilitated by switching to a long-half-life agent before tapering.

### ***Nonbenzodiazepine Sedatives (Zolpidem, Zopiclone, and Zaleplon)***

Zolpidem, zopiclone, and zaleplon are very well tolerated short-half-life hypnotics with very few dose-related adverse effects. Zolpidem's adverse effects include CNS (dizziness, drowsiness, and headache) and gastrointestinal effects (nausea and dyspepsia) (Hajak and Bandelow 1998). Zopiclone's adverse effects include bitter taste, dry mouth, difficulty arising in the morning, sleepiness, nausea, and nightmares (Allain et al. 1991). Clinical trials of zaleplon report adverse effects comparable to those seen with placebo. Tolerance to the hypnotic effects of these agents occurs less frequently than with benzodiazepines,

and they may be useful for treatment of rebound insomnia associated with benzodiazepine withdrawal (Pat-Horenczyk et al. 1998). Mild withdrawal symptoms have been reported in a small number of patients after discontinuation of zolpidem (Elie et al. 1999) and zopiclone (Bianchi and Musch 1990).

**Respiratory.** Zolpidem has been reported to cause respiratory depression at high doses (Cirignotta et al. 1988). Zopiclone dose not appear to have significant effects on respiratory function. The respiratory effects of zaleplon are unknown.

**Toxicity/overdose.** Although fatal overdose with zolpidem alone has been reported (Lichtenwalner and Tully 1997), it is rare. In a survey of 344 cases of intentional acute zolpidem overdose, death occurred in 6% of the cases but could not be directly linked to zolpidem because of multiple drug involvement (Garnier et al. 1994). Symptoms of intentional overdose of zolpidem include drowsiness, vomiting, coma, and respiratory failure. Treatment is generally limited to supportive measures and/or gastric lavage. Symptoms of toxicity rapidly subside in most cases (Garnier et al. 1994).

Fatal overdose with zopiclone has been reported but, as with zolpidem, appears rare (Boniface and Russell 1996; Bramness et al. 2001).

### ***Chloral Hydrate***

Chronic use and overdose of chloral hydrate have resulted in gastritis, gastric ulceration, hepatic and renal toxicity, and death (Graham et al. 1988). Chloral hydrate should be avoided in patients with severe renal, cardiac, or hepatic disease. Chloral hydrate is irritating to skin and mucous membranes and can cause dysgeusia, epigastric distress, nausea, and vomiting if taken on an empty stomach. Oral administration should be avoided in patients with esophagitis, gastritis, or peptic ulcer disease; rectal suppositories may be used instead. At high doses, chloral hydrate may cause hypotension and arrhythmias.

**Drug interactions.** Chloral hydrate is highly bound to plasma proteins and may displace other highly bound drugs, such as warfarin. Chloral hydrate does potentiate warfarin's anticoagulant effect, but only to an extent too small to be clinically significant (Udall 1975; Wells et al. 1994).

**Toxicity/overdose.** The average oral lethal dose of chloral hydrate in humans is 10 g; death has occurred with doses as low as 4 g. Symptoms of chloral hydrate overdose are similar to those of overdose with barbiturates and

include hypotension, hypothermia, respiratory depression, arrhythmias, coma, and death. Hepatic and renal injury following overdose may result in jaundice and albuminuria. Treatment includes removal of any unabsorbed drug from the stomach (gastric lavage with endotracheal tube, with cuff inflated to prevent aspiration of gastric contents) followed by supportive therapy (Frankland and Robinson 2001).

### ***Buspirone***

Buspirone is a well-tolerated anxiolytic with no apparent effects on cognitive function or seizure threshold. Buspirone has little or no potential for physiological or psychological tolerance and so has no abuse liability or withdrawal syndrome on discontinuation. Dizziness, drowsiness, nervousness, nausea, and headache are the most frequent adverse effects and occur in about 5%–10% of patients. Adverse effects appear to be dose- and age-related and diminish with continued therapy. Unlike benzodiazepines, buspirone does not potentiate the effects of alcohol (Sepala et al. 1982) or suppress respiration (Garner et al. 1989). Buspirone does not exhibit cross-tolerance with benzodiazepines and so cannot be used to manage benzodiazepine withdrawal. Buspirone stimulates prolactin secretion in a dose-related manner, but the clinical significance of this effect is uncertain. Menstrual irregularities and galactorrhea have occasionally been reported, but their relation to buspirone is unclear.

**Drug interactions.** Buspirone in combination with an MAOI has been associated with fatal serotonin syndrome as well as increased blood pressure (McEvoy 2003). Recent case reports also suggest that buspirone may very rarely precipitate serotonin syndrome when used in combination with St. John's wort (Dannawi 2002) or SSRIs (Manos 2000).

Buspirone undergoes hepatic and intestinal metabolism mediated by CYP3A4, so interactions are similar to those described earlier for benzodiazepines.

**Toxicity/overdose.** No fatalities have been reported from buspirone overdose. Overdose symptoms include nausea, vomiting, drowsiness, miosis, and gastric distention. Treatment includes removal of any unabsorbed drug from the stomach (gastric lavage or emesis), followed by supportive therapy.

## **Psychostimulants**

---

Psychostimulants are used in the treatment of attention-deficit/hyperactivity disorder (ADHD), narcolepsy, de-

pression, apathy, and analgesia augmentation in the medically ill. The well-established psychostimulant medications include methylphenidate, amphetamines (a mixture of amphetamine salts and dextroamphetamine), and pemoline.

Newer compounds include atomoxetine (a specific norepinephrine reuptake inhibitor) for ADHD (Kratovich et al. 2003) and modafinil for narcolepsy. Modafinil also has demonstrated efficacy for fatigue accompanying multiple sclerosis (Rammohan et al. 2002) and excessive daytime sleepiness accompanying obstructive sleep apnea (Black 2003).

### **Side Effects and Toxicity**

#### ***Methylphenidate, Amphetamines, and Pemoline***

Common adverse effects include CNS (insomnia, headache, nervousness, and social withdrawal) and gastrointestinal (stomachache and anorexia) symptoms. Adverse effects are generally mild and diminish with continued treatment, adjustment of dose, or dose timing.

Chronic use of pemoline is associated with hepatotoxicity in 3% of patients, usually reversible on drug withdrawal, but potentially fatal hepatotoxicity may occur; concerns over the risk of fatal hepatotoxicity resulted in a "black box" warning for pemoline (Berkovitch et al. 1995). Pemoline may also decrease seizure threshold.

Although psychostimulants may suppress appetite, this does not tend to occur with the low doses used in medically ill patients (Masand et al. 1991). In healthy adults, methylphenidate ( $\leq 30$  mg) and dextroamphetamine ( $\leq 15$  mg) did not significantly alter heart rate or blood pressure (Martin et al. 1971). However, psychostimulants can cause elevated heart rate and blood pressure, palpitations, hypertension, hypotension, and cardiac arrhythmias when taken at doses higher than those routinely used in the medically ill. In a review of side effects associated with methylphenidate therapy in children with ADHD, methylphenidate increased heart rate by 3–10 beats/minute and blood pressure by 3.3–8 mm Hg systolic and 1.5–14 mm Hg diastolic (Rappoport and Moffitt 2002).

**Drug interactions.** Psychostimulants may interact with sympathomimetics and MAOIs (including selegiline), resulting in headache, arrhythmias, hypertensive crisis, and hyperpyrexia. Psychostimulants should not be administered with MAOIs or within 14 days of their discontinuation. Despite the paucity of empirical evidence regarding TCA-stimulant metabolic interactions, warning statements are included in many drug manuals. One review of the effects of stimulants on the pharmacokinetics of desip-

ramine in children found no statistically or clinically significant interaction regardless of age, gender, or type of stimulant (Cohen et al. 1999). Several reports suggest that methylphenidate may interact pharmacodynamically with TCAs to cause increased anxiety, irritability, agitation, and aggression. Symptoms subsided on drug discontinuation (Grob and Coyle 1986; Gwirtsman et al. 1994; Markowitz and Patrick 2001).

Higher doses of psychostimulants may also reduce the therapeutic effectiveness of antihypertensive medications. When psychostimulants are used concurrently with beta-blockers, the excessive alpha-adrenergic activity may cause hypertension, reflex bradycardia, and possible heart block.

**Toxicity/overdose.** Symptoms of overdose include cardiovascular (flushing, palpitations, hypertension, arrhythmias, and tachycardia), CNS (delirium, euphoria, hyperreflexia, and psychosis), and autonomic (hyperpyrexia and sweating) effects. Treatment is primarily supportive. Any unabsorbed drug should be removed from the stomach (gastric lavage or emesis). A short-acting sedative may be needed in patients with severe intoxication.

### *Modafinil and Atomoxetine*

Modafinil and atomoxetine have different adverse effect profiles than psychostimulants and do not have their same abuse potential. Modafinil's adverse effects include delayed sleep onset, nausea, and rhinitis (U.S. Modafinil in Narcolepsy Multicenter Study Group 2000). Palpitations, tachycardia, hypertension, excitation, and aggression have also been infrequently observed. Modafinil has been associated in rare cases with chest pain, palpitations, dyspnea, and transient ischemic T-wave changes in association with mitral valve prolapse or left ventricular hypertrophy. Modafinil does not cause appetite reduction (Rugino and Copley 2001).

Because of atomoxetine's recent introduction to the market (it received FDA approval in November 2002), experience with it is limited. Side effects in the clinical trials included insomnia, nausea, dry mouth, constipation, dizziness, decreased appetite, urinary hesitancy, sexual dysfunction, and palpitations (Alaka 2003).

Elimination of atomoxetine and modafinil is reduced in patients with hepatic impairment. Atomoxetine dose should be reduced by 50% in patients with moderate hepatic impairment and 75% in those with severe hepatic impairment (Alaka 2003). In patients with severe hepatic impairment, modafinil dose should be reduced by 50% (McEvoy 2003). Blood levels of modafinil acid, a modafinil metabolite, increase ninefold in patients with severe renal insufficiency, but its effects are unknown.

**Drug interactions.** Atomoxetine is a potent inhibitor of CYP2D6 and is primarily eliminated through metabolism by CYP2D6 (see Table 37-2). Atomoxetine may increase the toxicity of other coadministered narrow therapeutic index medications primarily metabolized by CYP2D6.

Drug interaction data for modafinil are limited. Clinical studies suggest that significant metabolic drug interactions are most likely with compounds, such as ethinylestradiol and triazolam, that undergo significant gastrointestinal CYP3A4-mediated first-pass metabolism (Robertson and Hellriegel 2003; Robertson et al. 2002). Modafinil-clozapine interactions have been the subject of two case reports, one showing an increase in clozapine level (Dequardo 2002) and the other showing a decrease in clozapine's therapeutic effect (Narendran et al. 2002).

Like other psychostimulants, atomoxetine and modafinil should not be administered to patients receiving MAOIs or within 14 days of MAOI withdrawal.

## **Cognitive Enhancers**

---

The currently approved treatments for dementia of the Alzheimer's type are cholinesterase inhibitors, including tacrine, donepezil, rivastigmine, and galantamine. The NMDA receptor antagonist memantine has been approved in Germany for the treatment of dementia for more than 10 years (Reichman 2003) and in October 2003 was approved for use in the United States.

### Side Effects and Toxicity

#### *Cholinesterase Inhibitors*

Tacrine is now rarely prescribed because of frequent reversible hepatotoxicity (Watkins et al. 1994). Other mainstream cholinesterase inhibitors are well tolerated; most of their adverse effects are mild, dose-related, and gastrointestinal in nature (nausea, vomiting, and diarrhea), as expected from procholinergic agents. Gastrointestinal side effects can be minimized by slow dose titration and administration with food. Adequate hydration reduces nausea.

Agent-specific side effects include muscle cramps and insomnia with donepezil and anorexia with rivastigmine and galantamine.

**Overdose.** Overdose of cholinesterase inhibitors can cause a potentially fatal cholinergic crisis, with bradycardia, hypotension, muscle weakness, nausea, vomiting, respiratory depression, sialorrhea, diaphoresis, and seizures. Treatment is with atropine (1-2 mg intravenously, repeat as required) and supportive care.

**Drug interactions.** Donepezil and galantamine are metabolized by CYP2D6 and CYP3A4 isozymes but are not associated with any clinically important cytochrome P450-mediated pharmacokinetic interactions (Tiseo et al. 1998a, 1998b, 1998c, 1998d, 1998e). Rivastigmine is metabolized primarily by esterase-mediated hydrolysis and has been shown not to interact with cytochrome P450 isozymes *in vitro* (Grossberg et al. 2000).

Cholinesterase inhibitors do, however, have the potential to exacerbate the effects of other cholinesterase inhibitors (e.g., physostigmine) or cholinomimetic agents (e.g., bethanechol). The neuromuscular blocking agents succinylcholine and mivacurium are metabolized by plasma cholinesterases, so cholinesterase inhibitors can prolong their effects and increase their toxicity.

Many prescription and nonprescription drugs possess anticholinergic activity that may impair cognitive function. In addition to those drug classes commonly recognized as having anticholinergic effects, such as antiparkinsonian agents, antispasmodics, tricyclic antidepressants, low-potency antipsychotics, and antihistamines, many individual drugs from unrelated drug classes also have these effects. Drugs with anticholinergic properties may decrease the effect of cognitive enhancers. The use of anticholinergic agents in a patient with compromised cognitive function should be minimized. A partial listing of drugs with significant CNS anticholinergic effects is presented in Table 37–8. Conversely, cholinesterase inhibitors may have a countertherapeutic effect in those patients receiving anticholinergic medication for medical conditions.

### ***NMDA Receptor Antagonists***

On the basis of limited data in small clinical trials (Forest Laboratories 2003), memantine appears well tolerated, with dizziness and constipation the most prominent side effects.

**Drug interactions.** The systematic evaluation of potential drug–drug interactions with memantine awaits more widespread use of the drug.

## **Alternative Routes of Administration**

Some medically ill or surgical patients may not be able to take medication by mouth and therefore will require a parenteral route of administration. Parenteral routes of administration include sublingual, intravenous, intramuscular, intranasal, rectal, and topical or transdermal. The most common parenteral route of administration is intravenous. Some psychotropics are commonly available in

parenteral forms, and customized formulations have been reported for a few of the others. Caution is indicated when using a medication for which adequate studies of safety and efficacy regarding parenteral administration are lacking.

The potential advantages of parenteral administration of psychotropics include guaranteeing compliance, providing options for those patients who cannot take oral medications, and potential pharmacokinetic advantages such as greater bioavailability, bypassing first-pass hepatic metabolism, potential reduction in toxic metabolites or adverse effects, and acceleration of achieving steady state plasma drug levels.

## **Antidepressants**

Few antidepressants are available for parenteral administration. Intravenous clomipramine, imipramine, maprotiline, doxepin, dibenzepine, viloxazine, trazodone, and citalopram have been studied or widely used abroad, mainly in Europe. None are currently available in the United States. Recently, intravenous mirtazapine was found to be safe, efficacious, and well tolerated in 27 moderately to severely depressed inpatients (Konstantinidis et al. 2002). Citalopram is the only SSRI available for parenteral administration. To date, open and double-blind randomized, controlled clinical trials have shown that citalopram infusion followed by oral administration is an effective and well-tolerated treatment for severely depressed patients (Kasper and Muller-Spahn 2002). All the studies of intravenous antidepressants have been performed in medically healthy patients, leaving uncertain their safety and efficacy in the medically ill.

The rectal mucosa provides an alternative surface for drug absorption. The pharmacokinetics of rectal administration have been extensively reviewed by van Hoogdalem et al. (1991a, 1991b). No antidepressants are currently marketed in a rectal preparation. Rectal administration may be in the form of an enema, foam, semisolid suppository, and (to some extent) gelatin capsules. Independent or compounding pharmacies reportedly have made suppositories for amitriptyline, trazodone, imipramine, and clomipramine (Adams 1982; Chaumeil et al. 1988; Mirasou 1998). However, creating custom suppositories is a very labor-intensive process, and the bioavailability of rectal administration remains unpredictable.

Transdermal drug delivery offers several potential advantages, such as consistent drug levels, lack of peaks in plasma concentration, avoidance of first-pass metabolism, and convenience, with improvements in patient adherence. There has been one case report of transdermal amitriptyline gel in a depressed patient with chronic pain who

**TABLE 37–8. Common drugs with significant anticholinergic effects**

<b>Antianginals</b>	<b>Antispasmodics</b>
Isosorbide dinitrate	Atropine
<b>Antiarrhythmics</b>	Belladonna
Disopyramide	Clidinium
Procainamide	Dicyclomine
Quinidine	Glycopyrrolate
<b>Antiasthmatics</b>	Homatropine
Theophylline	Hyoscine
<b>Anticoagulants</b>	Hyoscyamine
Warfarin	Mepenzolate
<b>Antidepressants</b>	Methscopolamine
Tricyclics	Oxybutynin
Amoxapine	Propantheline
Imipramine	Scopolamine
Maprotiline	Tolterodine
<b>Antidiarrheals</b>	<b>Calcium channel blockers</b>
Diphenoxylate	Nifedipine
<b>Antihistamines</b>	<b>Cardiac glycosides</b>
H <sub>1</sub> antagonists (e.g., diphenhydramine)	Digoxin
H <sub>2</sub> antagonists (e.g., cimetidine)	<b>Diuretics</b>
<b>Antiparkinsonian agents</b>	Furosemide
Amantadine	<b>Narcotic analgesics</b>
Benztropine	Codeine
Biperiden	<b>Antiemetics</b>
Ethopropazine	Prochlorperazine
Orphenadrine	Promethazine

also had severe inflammatory bowel disease (Scott et al. 1999). The only potential transdermal antidepressant under development is selegiline (EmSam) (FDA approval letter February 2004) (Amsterdam 2003; Bodkin and Amsterdam 2002). The dose of oral selegiline needed for effective antidepressant treatment requires dietary tyramine restriction because of the clinically significant inhi-

bition of intestinal MAO-A. Transdermal administration of selegiline was developed to circumvent this problem. Transdermal selegiline has the following pharmacological advantages: 1) it limits intestinal MAO-A inhibition, leaving adequate intestinal MAO-A activity to digest tyramine; and 2) it circumvents first-pass metabolism, resulting in higher plasma concentrations and decreased

metabolite formation. Double-blind, placebo-controlled studies found that transdermal selegiline was an effective and well-tolerated treatment for major depression (Amsterdam 2003; Bodkin and Amsterdam 2002). This agent may also be an option for the treatment of depression in medically ill patients and warrants further study.

## Anxiolytics and Sedative-Hypnotics

Routes of administration available for some benzodiazepines include oral, sublingual, liquid, nasal, intramuscular, and intravenous. Intravenous formulations are available for midazolam, lorazepam, and diazepam. Intravenous benzodiazepines are commonly used to treat status epilepticus or to calm severely agitated patients. Intravenous lorazepam has the longest distribution half-life and therefore has the longest duration of effect after a single intravenous dose. Compared with diazepam, lorazepam pharmacokinetics after intravenous administration are more predictable. Because of its high lipid solubility, intravenous diazepam leads to rapid redistribution of the drug and a relatively rapid loss of clinical effect compared with lorazepam. Midazolam is a short-acting, water-soluble benzodiazepine frequently used in preoperative sedation, induction and maintenance of anesthesia, anxiolysis, and the treatment of status epilepticus. Midazolam's onset of action following intravenous administration is usually within 1–5 minutes, and the action lasts usually less than 2 hours. Intravenous flunitrazepam (Rohypnol), available in Europe, has been used in both the treatment and the prevention of alcohol withdrawal (Pycha et al. 1993; Spies et al. 1995). Intravenous benzodiazepine administration should always occur in a setting where there is ready access to personnel and equipment necessary for respiratory resuscitation.

Benzodiazepines that may be administered intramuscularly include lorazepam and midazolam. Lorazepam is usually chosen as the benzodiazepine for intramuscular administration because it is readily absorbed and has no active metabolites. Other benzodiazepines, such as diazepam, are not recommended for intramuscular use because they are erratically absorbed. Midazolam is also rapidly absorbed after intramuscular administration, with an onset of action between 5 and 15 minutes. When intravenous and intramuscular routes are not preferred or are unavailable, subcutaneous administration of some benzodiazepines, such as clonazepam, may be an option.

The pharmacokinetics of sublingual benzodiazepine administration has been studied by several groups. Several benzodiazepines, including lorazepam, alprazolam, triazolam, temazepam, prazepam, midazolam, clonazepam, and diazepam, have been administered sublingually,

using commercial nonsublingual formulations or custom preparations. The only benzodiazepines specifically marketed in a sublingual form are lorazepam in North America and temazepam in Europe (Russell et al. 1988). Although the sublingual form of lorazepam is more rapidly absorbed than the oral form, the pharmacokinetic profiles of sublingual and orally administered lorazepam are similar.

Rectal administration of benzodiazepines is routinely performed in the management of acute seizures in children. Diazepam can be administered rectally when venous access is not readily available. However, bioavailability seems to vary (Magnussen et al. 1979; Remy et al. 1992). Other benzodiazepines, such as triazolam, have been administered rectally but are not recommended for clinical use. In addition, since lorazepam may be given intravenously, intramuscularly, or sublingually, there is essentially no practical reason for rectal administration of benzodiazepines in adults.

Still other routes of administration for benzodiazepines include intrathecal and nasal midazolam. Intrathecal midazolam has been used principally for adjunctive pain management and has been found to be safe and effective in a variety of settings (Kim and Lee 2001; Sen et al. 2001; Serrao et al. 1992; Valentine et al. 1996). Intranasal administration via spray has been used effectively in a variety of settings, including acute seizure management in children, conscious sedation in children undergoing dental procedures, and management of claustrophobia in patients undergoing magnetic resonance imaging procedures (al Rakaf et al. 2001; Fisgin et al. 2002; Hollenhorst et al. 2001).

## Antipsychotics

Haloperidol, droperidol, perphenazine, trifluoperazine, thiothixene, and triflupromazine are available in a form that may be administered by intravenous, intramuscular, or subcutaneous routes. Intravenous agents are usually reserved for acute agitation in which a rapid onset of effect is desirable. Droperidol is FDA approved for use as an intravenous anesthetic adjunct (but not for psychiatric conditions) but has been used for rapid tranquilization in the medical/surgical setting. Droperidol causes dose-dependent prolongation of the QTc interval and has been withdrawn from the United Kingdom and received a black-box warning in North America. Although haloperidol is not approved by the FDA for intravenous use, it is the antipsychotic most commonly administered intravenously in medical settings—usually in critical care units, in emergencies, or whenever there is a lack of oral access. High doses of haloperidol, up to 1,000 mg daily, in pa-

tients with severe delirium have been reported to have minimal effects on heart rate, respiratory rate, blood pressure, and pulmonary artery pressure, with minimal EPS (Levenson 1995; Stern 1985).

Many antipsychotics, including three atypical antipsychotics, ziprasidone, olanzapine, and risperidone, are available for intramuscular use. Intramuscular formulations can be subdivided into two categories on the basis of their pharmacokinetic features: short-acting preparations and long-acting depot preparations. Long-acting antipsychotics are typically used as antipsychotic maintenance treatment to ensure adherence and to eliminate bioavailability problems. Short-acting antipsychotics are usually used in acute management of delirium, psychosis, mania, or aggression (see Chapter 6, "Delirium"; Chapter 8, "Aggression and Violence"; and Chapter 11, "Mania, Catatonia, and Psychosis" for further discussion). Haloperidol is the most common (and least costly) intramuscularly administered antipsychotic in medical settings. However, acute parenteral administration of high-potency antipsychotics such as haloperidol is associated with more dystonia and other EPS. In patients who already have extrapyramidal disorders, an intramuscular antipsychotic other than haloperidol would be preferred. Parenteral administration of low-potency agents may cause more hypotension and lowered seizure threshold.

Intramuscular ziprasidone was launched in August 2002 and was recommended for the control of agitated behavior associated with schizophrenia. Peak plasma concentrations after an intramuscular dose of ziprasidone are achieved in 30–45 minutes. Unlike haloperidol, intramuscular ziprasidone cannot be mixed in the same syringe with a benzodiazepine. The magnitude of the QTc interval increase with intramuscular ziprasidone is comparable to that of the oral formulation. Ziprasidone is contraindicated in patients receiving other agents known to prolong the QTc interval and for patients with a known history of QTc prolongation, recent myocardial infarction, recent uncompensated heart failure, or a history of cardiac arrhythmias. Intramuscular ziprasidone has not been systematically studied in patients 65 years or older or in patients with significant hepatic or renal impairment. Intramuscular olanzapine is recommended for the management of agitation in patients with schizophrenia, bipolar mania, or dementia. At the time of this writing, there are no data on intramuscular ziprasidone or olanzapine in the management of agitation in medically ill patients without an underlying psychiatric condition, so caution is advised.

Subcutaneous administration is another route available for some antipsychotics. This route is more commonly used with haloperidol and methotrimeprazine (available

in Canada and Europe) in the management of terminal restlessness and for nausea/vomiting in palliative care patients. Loxapine has also been used subcutaneously in the palliative care setting.

## Psychostimulants

There are no formulations of methylphenidate available for intravenous administration, and preparation of a solution from tablets is inadvisable. However, intravenous methylphenidate has been studied (Cantello et al. 1989; Janowsky et al. 1978; Lucas et al. 1987; Robinson et al. 1991), mostly in drug-induced provocation of psychotic symptoms. Dextroamphetamine has been administered intravenously to human subjects in research, but to date there are no reports of use of intravenous dextroamphetamine in clinical settings (Ernst and Goldberg 2002). There is one published case report of 5-mg dextroamphetamine suppositories compounded by a pharmacy for treating depressed mood in a woman with gastrointestinal obstruction (Holmes et al. 1994). Pemoline comes in a chewable tablet that was administered sublingually in four medically ill patients for the treatment of depression (Breitbart and Mermelstein 1992).

In summary, there are no systematic studies of safety and efficacy of psychostimulants given via non-enteral routes.

## Mood Stabilizers

Mood stabilizers that have been administered intravenously include lithium carbonate and valproate. Published literature regarding parenteral administration of lithium salts is scarce. Because lithium is not subject to hepatic metabolism, the potential pharmacokinetic advantages of parenteral administration are much fewer than for other psychotropics. Parenteral lithium has rarely been used in the treatment of psychiatric disorders but has been used as a possible treatment in thyroid storm. Lithium was administered intraperitoneally in patients on continuous ambulatory peritoneal dialysis (Flynn et al. 1987). Lithium carbonate is not approved by the FDA for parenteral use, and there is not enough clinical experience or data to recommend its use by nonenteral routes.

Valproic acid has been available in parenteral form (Depacon) in Europe for over 18 years and was approved by the FDA in the United States in 1997. To date, there are no randomized, controlled trials documenting its safety and efficacy in psychiatric conditions, although case reports have been encouraging (Norton 2001; Norton and Quarles 2000; Regenold and Prasad 2001). The intravenous formulation of valproic acid can be given in

dextrose, saline, or lactated Ringer's solution, prepared by adding 1 g to 500 mL of solution. The solution should not be infused at more than 20 mg/minute, with the dosage reduced in the elderly and in those with organic brain syndromes. The dosage varies between 1 and 3 g for most adults and one-half of this in the elderly. The infusion does not require cardiac monitoring and causes no significant risk of orthostatic hypotension (Norton 2001). Valproic acid is the only mood stabilizer available in an approved parenteral formulation supported by case reports of use in psychiatric conditions.

## Cholinesterase Inhibitors

Currently, there have been no reports of non-enteral routes of administration for donepezil, galantamine, rivastigmine, or tacrine.

## Complementary Medicines

An increasing number of patients are taking herbal medicines and nonherbal dietary supplements, often without disclosing their use. Many people assume that complementary medicines are "naturally" safe, and they combine complementary and conventional therapies, believing that the combination will be more effective (Eisenberg et al. 2001). This raises concerns about the appropriate therapeutic use, contraindications, adverse effects, and drug interactions of herbal and nonherbal drugs. Patients with chronic disease may be especially vulnerable to adverse effects from herbal medicines because of compromised organ function and polypharmacy with conventional agents.

The lack of government oversight and regulation further complicates attempts to assess the safety of herbal medicines. Manufacturers are not required to standardize the concentration of active ingredients or even to identify them (Chandler 2000; De Smet 2002). Herbal preparations may contain several plant species used under a single name (Chandler 2000) and may be adulterated with unlisted pharmacological agents, pesticides, and heavy metals, including cadmium, lead, mercury, or arsenic (Crone and Wise 1998). Drugs such as anti-inflammatory agents, steroids, diuretics, antihistamines, sildenafil-like compounds (Wooltorton 2003), and benzodiazepines may be intentionally added to the herbal product for therapeutic effect.

Contraindications, major adverse effects, and significant drug interactions for those herbal medicines and nonherbal dietary supplements commonly used for neuropsychiatric symptoms are summarized in the following

subsections, derived from available reviews (Ang-Lee et al. 2001; Chandler 2000; Corns 2003; Crone and Wise 1998; Crone et al. 2001; De Smet 2002; Ernst 2002, 2003; Fugh-Berman 2000; Henney 2003; Izzo and Ernst 2001).

## Selected Herbal Medicines

### *Black Cohosh*

Purported use. Menopausal symptoms

Pharmacological effects and drug interactions. Black cohosh binds to estrogen receptors and lowers levels of luteinizing hormone. It is contraindicated in pregnancy and lactation and should be avoided by women with estrogen-dependent tumors.

### *Feverfew*

Purported use. Migraine prophylaxis, anti-inflammatory

Pharmacological effects and drug interactions. Used as an abortifacient in animals, feverfew is contraindicated in pregnancy in humans. It inhibits platelet activation factor and may prolong bleeding time. Use caution with drugs known to increase bleeding times, such as anticoagulants, NSAIDs, and platelet inhibitors. Allergic reactions are common. Withdrawal syndrome (anxiety, fatigue, joint ache) may occur on sudden discontinuation.

### *Ginger*

Purported use. Antispasmodic, antiemetic

Pharmacological effects and drug interactions. Ginger is a possible mutagen and abortifacient; avoid use in pregnancy. It inhibits thromboxane synthesis and thus may prolong bleeding time. Use caution with drugs known to increase bleeding times, such as anticoagulants, NSAIDs, and platelet inhibitors. These cautions do not apply to typical culinary doses.

### *Ginkgo Biloba*

Purported use. Ginkgo biloba improves peripheral and CNS blood flow and is used as a treatment for ischemia associated with peripheral artery disease and vascular dementia.

Pharmacological effects and drug interactions. Ginkgo biloba inhibits platelet activation factor and prolongs bleeding time. It carries an increased risk for bleeding disorders when used with drugs known to increase bleeding times (anticoagulants, NSAIDs, platelet inhibitors). In-

tracerebral and intraocular hemorrhages have been reported, and it may cause palpitations. Seizures have been reported in children, and efficacy of anticonvulsants may be reduced. The ginkgo biloba fruit, including the seeds, is poisonous and very allergenic. Ingestion of the fruit has resulted in loss of consciousness, seizures, and death, with a mortality rate of 27%. Ingestion of fruit also causes contact dermatitis of mucous membranes. Discontinue use at least 2 days before surgery.

### *Ginseng*

**Purported use.** Ginseng is promoted as a physical, mental, and sexual tonic, immunostimulant, and mood enhancer.

**Pharmacological effects and drug interactions.** Ginseng possesses estrogenic activity; it is contraindicated in patients with estrogen receptor–positive breast cancer. It may cause estrogen-related bleeding disorders (vaginal bleeding) and breast nodules. Sympathomimetic activity may cause tachycardia, hypertension, nervousness, agitation, mania, and headache. It also has hypoglycemic and anti–platelet aggregation properties. Ginseng may reduce the effects of loop diuretics (furosemide), antihypertensives, anxiolytics, antidepressants, mood stabilizers, and antiestrogens. It inhibits platelet activation factor and prolongs bleeding time. Ginseng increases the risk of bleeding disorders with drugs known to increase bleeding times (anticoagulants, NSAIDs, platelet inhibitors). Avoid use in patients with diabetes, hypertension, anxiety disorders, and bipolar disorder or those using estrogen therapy, antiestrogen therapy, or anticoagulants. Avoid long-term use, which may be associated with “ginseng abuse syndrome”; symptoms include hypertension, nervousness, insomnia, skin eruptions, diarrhea, and tremor. A withdrawal syndrome (hypotension, weakness, tremor) may occur on discontinuation. Discontinue at least 7 days before surgery.

### *Kava Kava*

**Purported use.** Anxiolytic, sedative

**Pharmacological effects and drug interactions.** Kava kava is a possible dopamine antagonist; avoid use with antipsychotics and drugs used to treat Parkinson’s disease. It potentiates the effects of CNS depressants, such as barbiturates, benzodiazepines, and alcohol. Dermopathy is common with heavy use. Antithrombotic action may prolong bleeding time. Use caution with drugs known to increase bleeding times. Kava kava is also hallucinogenic. Sale of kava has been banned in many jurisdictions because of

several incidents of fatal hepatotoxicity. Discontinue at least 24 hours before surgery.

### *Ma Huang (Ephedra)*

**Purported use.** Weight loss, stimulant

**Pharmacological effects and drug interactions.** Ma huang is an indirect sympathomimetic; it contains ephedrine and pseudoephedrine, which cause release of epinephrine and norepinephrine. Excessive sympathetic stimulation can lead to dizziness, headache, decreased appetite, gastrointestinal distress, irregular heartbeat, tachycardia, hypertension, insomnia, flushing, seizures, stroke, and death. Drug interactions include increased risk of cardiac arrhythmia with cardiac glycosides and antiarrhythmics; reduced effects of antihypertensives, beta-blockers, sedative-hypnotics, and anesthetics; hypertensive crisis with MAOIs; and increased stimulant effects with theophylline and caffeine. Discontinue at least 24 hours before surgery.

### *St. John’s Wort*

**Purported use.** Antidepressant for mild to moderate depression, sedative

**Pharmacological effects and drug interactions.** St. John’s wort increases serotonin and norepinephrine activity, which may cause sinus tachycardia and gastrointestinal distress and may exacerbate bipolar disorder, causing mania. It is a photosensitizer and may cause sun-induced skin rash, neuropathy, and possibly increased incidence of cataracts. It may exacerbate photosensitivity due to tetracycline, piroxicam, and phenothiazines. St. John’s wort induces CYP3A4 and has the potential to interact with medications metabolized by this enzyme to lower drug levels and decrease therapeutic effect (see Table 37–2.) It induces renal P-gp drug transport systems, increasing renal elimination of several drugs, including digoxin and cyclosporine. St. John’s wort may induce serotonin syndrome in combination with other serotonergic drugs. Discontinue at least 5 days before surgery.

### *Valerian*

**Purported use.** Sedative, short-term treatment of insomnia, anxiolytic

**Pharmacological effects and drug interactions.** Tolerance to valerian may develop and lead to withdrawal effects if it is discontinued abruptly after prolonged usage. Withdrawal effects are similar to benzodiazepine withdrawal and can be managed with benzodiazepines. Valerian potentiates the sedative effects of CNS depressants.

***Yohimbe, Yohimbine***

**Purported use.** Aphrodisiac, stimulant

**Pharmacological effects and drug interactions.** Yohimbine, an  $\alpha_2$  antagonist, has indirect sympathomimetic activity. Adverse effects include insomnia, anxiety, panic attacks, hallucinations, hypertension, tachycardia, nausea, and vomiting. It should be avoided in patients with hypertension, sleep disorders, anxiety disorders, and psychosis. Yohimbine exacerbates the CNS and autonomic effects of stimulants and TCAs. Discontinue at least 2 days before surgery.

## Selected Nonherbal Nutritional Supplements

***DHEA (Dehydroepiandrosterone)***

**Purported use.** Depression, postmenopausal osteoporosis, systemic lupus erythematosus, erectile dysfunction, multiple sclerosis, dementia

**Pharmacological effects and drug interactions.** DHEA is an endogenous anabolic steroid that may undergo conversion in vivo to testosterone or androstenedione followed by conversion to estriol, estrone, and estradiol. DHEA may cause weight gain, voice change, hirsutism, and menstrual irregularities in females and gynecomastia and prostatic hypertrophy in males. DHEA is contraindicated in patients who have liver dysfunction, prostate cancer, or hormone-dependent diseases such as estrogen-dependent breast cancer. DHEA may inhibit CYP3A4.

***Gamma-Hydroxybutyrate (GHB), Gamma-Butyrolactone, and 1,4-Butanediol***

**Purported use.** Narcolepsy, recreational fast-acting hypnotic

**Pharmacological effects and drug interactions.** GHB is a partial agonist at GABA<sub>B</sub> receptors with fast-onset hypnotic action. Gamma-butyrolactone and 1,4-butanediol are metabolized to GHB in vivo. Adverse effects include nystagmus, ataxia, apnea, sedation, dizziness, and respiratory depression. Coma, bradycardia, and death can result. Psychiatric side effects of GHB include hallucinations, delusions, agitation, confusion, and euphoria. A withdrawal syndrome (anxiety, insomnia, tremor, muscle cramps) has been observed. GHB is a banned drug in many jurisdictions, but its precursors, gamma-butyrolactone and 1,4-butanediol, are industrial solvents and are available as street drugs.

***S-Adenosyl-L-Methionine (SAME)***

**Purported use.** Depression, osteoarthritis, chronic liver disease

**Pharmacological effects and drug interactions.** SAME is the principal endogenous methyl donor for methylation reactions. Adverse effects include nausea, vomiting, and diarrhea. SAME may increase anxiety and restlessness in patients with depression and mania and hypomania in patients with bipolar disorder. Serotonin syndrome has been reported. Use caution with SAME in patients with bipolar disorder, patients with movement disorders, or patients taking serotonergic drugs.

## Psychotropic Drug Use in the Medically Ill

---

Psychosomatic medicine specialists routinely prescribe and advise other physicians regarding the use of psychotropic medications in patients with multiple complex medical problems. This gives rise to many issues regarding changes in pharmacokinetics and pharmacodynamics as previously outlined in this chapter. This section outlines clinical recommendations for the use of psychotropic medications in specific medical/surgical populations.

### Gastrointestinal Disease

***Hepatic Disease***

Alterations in psychopharmacology in patients with liver disease largely center on the changes in pharmacokinetics brought about by the disease (discussed earlier in this chapter). Acute hepatitis usually does not require dose alteration. The dosage of psychotropics in patients with chronic hepatitis may need to be modified depending on the severity of liver dysfunction. In patients with cirrhosis, drug dose will require significant modification. The severity of liver disease can be approximated using the Child-Pugh scoring system (see Chapter 21, "Gastrointestinal Disorders"). All plasma proteins are synthesized in the liver, so protein binding is altered in liver disease. The main clinical effect of chronically decreased protein binding is on the interpretation of blood levels (see discussion under "Distribution" subsection earlier in this chapter). When psychotropic medication is being prescribed for patients with impaired hepatic function, it is prudent to reduce the initial dose and titrate more slowly for any drug primarily metabolized by the liver, to carefully monitor for clinical response and side effects, and to

choose drugs with a wide therapeutic index. Table 37-9 lists recommendations regarding dosing of psychotropics in patients with hepatic disease.

**Antidepressants.** Most antidepressants undergo extensive phase I hepatic oxidative metabolism and should be dosed according to the recommendations just described. Anticholinergic TCAs may exacerbate hepatic encephalopathy in susceptible individuals via intestinal stasis and central anticholinergic effects. The use of newer antidepressants in patients with hepatic disease has received very little study. Citalopram, paroxetine, sertraline, and fluoxetine have all been used safely in patients with hepatitis C, usually in the context of interferon- $\alpha$  treatment (Farah 2002; Gleason et al. 2002; Hauser et al. 2002; Kraus et al. 2002; Levenson and Fallon 1993; Sammut et al. 2002; Schramm et al. 2000).

Hepatotoxicity is a known rare side effect of many antidepressants, but nefazodone has a higher reported incidence than other current antidepressants and thus should be avoided in patients with preexisting hepatic disease (Carvajal et al. 2002; Stewart 2002). As a general guideline, minor elevations in transaminases are common and usually benign. Elevation of aspartate transaminase (AST) or alanine transaminase (ALT) levels of two to three times baseline or two times normal is significant, and any elevation of alkaline phosphatase (ALP) or bilirubin may be significant.

**Antipsychotics.** Although very little has been written about the use of antipsychotics in patients with liver failure, haloperidol remains the most commonly chosen antipsychotic for patients with hepatic disease. Chlorpromazine should be avoided because of its greater risk for hepatotoxicity. Low-potency typical antipsychotics, which are more anticholinergic than high-potency typicals, may precipitate hepatic encephalopathy in patients with cirrhosis (as described for TCAs). The atypical antipsychotics remain viable alternatives. Because they are extensively metabolized, their dosage should be reduced in patients with hepatic insufficiency.

**Anxiolytics and sedative-hypnotics.** Most benzodiazepines are metabolized by phase I processes, and liver disease affects phase I processes significantly more than phase II processes. For this reason, the preferred benzodiazepines for any patient with liver disease are lorazepam, oxazepam, and temazepam because they are principally metabolized by phase II processes. All benzodiazepines should be avoided in patients at risk for developing hepatic encephalopathy because they may precipitate its onset. When their use cannot be avoided (e.g., alcohol with-

drawal in a patient with cirrhosis), the benzodiazepines just mentioned are preferred, with vigilant monitoring of changes in mental status.

**Mood stabilizers.** Because of the risk of hepatotoxicity, carbamazepine and valproic acid are relatively contraindicated in patients with preexisting liver disease. If either of these agents is used, reduce dose and monitor liver function regularly, especially during the first 6 months of therapy. Gabapentin is renally excreted and does not require dosage adjustment in patients with hepatic disease. Lithium, although renally excreted, may require dose adjustment and close monitoring secondary to fluctuating fluid balance in patients with liver disease accompanied by ascites (secondary hyperaldosteronism). Oxcarbazepine's manufacturer states that no disease adjustment is needed for patients with mild to moderate hepatic insufficiency. Lamotrigine dose should be reduced according to the severity of hepatic impairment. There are no current dosing recommendations for topiramate.

**Cholinesterase inhibitors.** Donepezil clearance may be reduced in cirrhosis, but there are no specific dosing recommendations for hepatic insufficiency. Galantamine should be used with caution in patients with mild to moderate hepatic insufficiency, and its dose should not exceed 16 mg daily in patients with a Child-Pugh Score of 7-9 (see Chapter 21, "Gastrointestinal Disorders"). Rivastigmine clearance may be reduced by 60%-65% in patients with mild to moderate hepatic insufficiency, and dosing should be guided by monitoring efficacy and tolerability.

**Psychostimulants.** There are no specific dosing recommendations for methylphenidate. Modafinil clearance is reduced in hepatic insufficiency, and its dosage should be reduced by 50% in patients with severe hepatic insufficiency. For atomoxetine, initial doses should be reduced to 25% and 50% of the normal dose for patients with severe and moderate hepatic impairment, respectively (Chalon et al. 2003).

### ***Gastrointestinal Bleeding***

**Antidepressants.** Recent reports have raised concern regarding SSRIs and the risk of gastrointestinal bleeding (Dalton et al. 2003; de Abajo et al. 1999). Serotonin plays a role in hemostasis, and there have been cases of prolonged bleeding time, ecchymosis, purpura, and epistaxis, as well as gastrointestinal, genitourinary, and intracranial bleeding, in patients receiving SSRIs. Although the reports indicate an increase in the relative risk of gastrointestinal bleeding in patients taking SSRIs, the absolute effects are modest and about equivalent to low-dose

**TABLE 37-9. Selected psychotropic drugs in hepatic insufficiency (HI)****Antidepressants**

MAOIs	Potentially hepatotoxic. No dosing guidelines.
SSRIs	Extensively metabolized. Decreased clearance and prolonged half-life. Initial dose should be reduced 50% and subsequent increments at longer intervals than usual. Target doses are typically substantially lower than usual.
TCAs	Extensively metabolized. Potentially serious hepatic effects. No dosing guidelines.
Bupropion	Extensively metabolized; decreased clearance. In even mild cirrhosis, use at reduced dose and/or frequency. In severe cirrhosis, dose should not exceed 75 mg daily for conventional tablets, or 100 mg daily for sustained-release formulations.
Duloxetine	Extensively metabolized; decreased metabolism and elimination. Do not use in patients with any hepatic insufficiency.
Mirtazapine	Extensively metabolized; decreased clearance. No dosing guidelines.
Nefazodone	May cause hepatic failure. Avoid use in patients with active liver disease.
Trazodone	Extensively metabolized. No dosing guidelines.
Venlafaxine	Decreased clearance and increased elimination half-life of venlafaxine and its active metabolite <i>O</i> -desmethylvenlafaxine. Dosage should be reduced by 50% in moderate HI.

**Atypical antipsychotics**

Clozapine	Extensively metabolized. Clozapine should be discontinued in patients with marked transaminase elevations or jaundice. No dosing guidelines.
Olanzapine	Extensively metabolized. Periodic assessment of transaminases is recommended. No dosage adjustment needed per manufacturer.
Quetiapine	Extensively metabolized; clearance decreased 30%. Start at 25 mg/day; increase by 25–50 mg daily.
Risperidone	Extensively metabolized; 35% increase in free fraction. Starting dosage and dose increments not to exceed 0.5 mg bid. Increases over 1.5 mg bid should be made at intervals of at least 1 week.
Ziprasidone	Extensively metabolized; increased half-life and serum level in mild to moderate HI. In spite of this, manufacturer recommends no dosage adjustment.

**Conventional antipsychotics**

Haloperidol et al.	All metabolized in the liver. No specific dosing recommendations. Phenothiazines (e.g., thioridazine and trifluoperazine) should be avoided. If nonphenothiazines are used, dosage should be reduced and titration should proceed more slowly than usual
--------------------	---

**Anxiolytic and sedative-hypnotic drugs**

Alprazolam	Decreased metabolism and increased half-life. Dosage should be reduced by 50%–60%. Avoid use in patients with cirrhosis.
Buspirone	Extensively metabolized, half-life may be prolonged. Use at reduced dose. Do not use in patients with severe impairment.
Chlordiazepoxide	Extensively metabolized; reduced clearance and prolonged half-life in. Avoid use if possible.
Clonazepam	
Diazepam	
Flurazepam	
Triazolam	
Lorazepam	Metabolized by conjugation; clearance not affected. No dosage adjustment needed. Lorazepam preferred choice.
Oxazepam	
Temazepam	
Zaleplon	Metabolized in the liver. Reduced clearance. Usual ceiling dose is 5 mg.
Zolpidem	Not recommended in severe HI.

**Mood stabilizers**

Carbamazepine	Extensively metabolized. Perform baseline liver function tests and periodic evaluations during therapy. Discontinue for active liver disease or aggravation of liver dysfunction. No dosing guidelines.
Oxcarbazepine	Manufacturer states that no dosage adjustment is needed in mild to moderate HI.
Gabapentin	Renally excreted; not appreciably metabolized. No dosage adjustment needed.

**TABLE 37-9. Selected psychotropic drugs in hepatic insufficiency (HI) (continued)****Mood stabilizers (continued)**

Lamotrigine	Initial, escalation, and maintenance dosages should be reduced by 50% in moderate HI (Child-Pugh B) and by 75% in severe HI (Child-Pugh C).
Lithium	Renally excreted; not metabolized. Dosage adjustment depends on fluid status.
Topiramate	Reduced clearance. No dosing guidelines.
Valproate	Extensively metabolized; reduced clearance and increased half-life. Reduce dosage, monitor liver function tests frequently, especially in first 6 months of therapy. Avoid in patients with substantial hepatic dysfunction. Use with caution in patients with prior history of hepatic disease.

**Cholinesterase inhibitors**

Donepezil	Mildly reduced clearance in cirrhosis. No specific recommendations for dose adjustment.
Galantamine	Use with caution in mild to moderate HI. Dose should not exceed 16 mg daily in moderate HI (Child-Pugh 7-9). Use not recommended in severe HI (Child-Pugh 10-15).
Rivastigmine	Clearance reduced 60%-65% in mild to moderate HI, but dose adjustment may not be necessary.

**Central nervous system stimulants**

Methylphenidate	Unclear association with hepatotoxicity, particularly when co-administered with other adrenergic drugs. No dosing guidelines.
Modafinil	Decreased clearance. Reduce dose by 50% in severe HI.

*Note.* MAOI=monoamine oxidase inhibitor; SSRI=selective serotonin reuptake inhibitor; TCA=tricyclic antidepressant.

*Source.* Adapted from Jacobson S: "Psychopharmacology: Prescribing for Patients With Hepatic or Renal Dysfunction." *Psychiatric Times* 19, 2002. Used with permission.

ibuprofen. This relative risk is further increased by concurrent administration of NSAIDs and low-dose aspirin (Weinrieb et al. 2003).

**Cholinesterase inhibitors.** Increased cholinergic activity is expected to increase gastric acid secretion, thereby increasing risk of peptic ulcers. Therefore, caution is warranted when using cholinesterase inhibitors in patients who are at increased risk of developing ulcers or who are receiving NSAIDs.

**Other Gastrointestinal Disorders**

Many diseases can cause malabsorption. Depending on the type of malabsorption syndrome and the mechanism involved, varied effects on pharmacokinetics may be observed. In general, however, orally administered drugs may be poorly absorbed in the presence of malabsorption syndromes. In patients with delayed gastric emptying (due to diabetes mellitus, atrophic gastritis, gastric cancer, pyloric stenosis, pancreatitis, or gastric ulcer or drug induced), the pharmacokinetic effect may be to slow absorption rate and delay time to onset of the medication. The effects of gastric dysfunction, including reduced gastric acidity and reduced gastric emptying on drug absorption, are complex (see Gubbins and Bertch 1991; Parsons 1977). For non-enteric-coated preparations, increased gastric emptying is likely to increase the rate of drug absorption, and conversely, delayed gastric emptying will slow the rate of drug absorption. However, because of the large

intestinal surface area, overall absorption is not likely to change significantly. Similarly, for most drugs, reduced gastric acidity is unlikely to significantly affect the extent of absorption. For enteric-coated preparations, however, reduced gastric acidity increases the rate of drug absorption because dissolution of the preparation will occur in the stomach. The rate and extent of absorption of drugs, such as clorazepate, that require gastric acid-induced hydrolysis for conversion to the active form (desmethyldiazepam in the case of clorazepate) are impaired by agents, and presumably disease states, that reduce gastric acidity (Greenblatt et al. 1978; Parsons 1977). Anticholinergic drugs should be avoided in patients with gastroparesis, constipation, or ulcerative colitis. SSRIs may be undesirable in patients with increased gastric motility or diarrhea.

**Renal Disease**

Although most psychotropic drugs do not depend on the kidney for excretion, a variety of factors may affect pharmacokinetics during renal failure, including changes in absorption, distribution, and protein binding (discussed earlier in this chapter). Despite the complexity of pharmacokinetic changes in renal failure, most psychotropics, other than lithium and gabapentin, do not require drastic dosage adjustment. However, many problems associated with use of psychotropics in patients with end-stage renal disease (ESRD) are related to comorbid illnesses rather

than to the renal failure per se. Specific dosing guidelines based on creatinine clearance are not available for most psychotropics, but many clinicians use the rule of “two-thirds”—that is, for patients with renal insufficiency, use two-thirds of the dose (except for lithium and gabapentin) used for patients with normal renal function.

Because most psychotropics are lipophilic compounds with large volumes of distribution, they are not dialyzable. Only lithium, gabapentin, valproate, topiramate, and levetiracetam are removed by dialysis. Significant fluid shifts occur during and several hours after each hemodialysis treatment, making dialysis patients more prone to orthostasis. Hence, drugs that frequently cause orthostatic hypotension should ideally be avoided.

Table 37–10 provides recommendations for dosing psychotropics in patients with renal disease.

### *Antidepressants*

Virtually all antidepressants may be used in patients with renal failure, although the greatest experience is with the TCAs. However, patients with ESRD tend to be more sensitive to the side effects of TCAs, including sedation, anticholinergic toxicity, and orthostatic hypotension. Hydroxylated metabolites have been shown to be markedly elevated in patients with ESRD and are hypothesized to be responsible for some TCA side effects. Nortriptyline is considered the preferred TCA because its blood levels correlate well with clinical effect, and the “therapeutic window” is the same in renal failure patients as in physically healthy patients. Limited data are available on the use of newer antidepressants in patients with renal failure. Some evidence suggests that dosage adjustments may not be needed for citalopram and fluoxetine in those with ESRD. However, the half-life of venlafaxine is prolonged in renal insufficiency; its clearance is reduced by over 50% in patients undergoing dialysis. Paroxetine clearance is also reduced in renal insufficiency. Because most antidepressants are metabolized by the liver and excreted by the kidney, initial dosage reduction of all antidepressants is reasonable as a way to reduce the possibility that potentially active metabolites will accumulate.

### *Antipsychotics*

All antipsychotics may be used in patients with renal failure. Difficulties arise from the complications of renal failure and dialysis or from the chronic disease causing renal failure (e.g., diabetes). For example, patients with ESRD who also have diabetic autonomic neuropathy will be at higher risk for drug side effects, including postural hypotension and bladder, gastrointestinal, and sexual dysfunction.

### *Anxiolytics and Sedative-Hypnotics*

Virtually all sedative-hypnotics can be used in patients with renal failure with the exception of barbiturates. Barbiturates should be avoided because they may increase osteomalacia and because of excessive sedation. Preferred benzodiazepines include those with inactive metabolites such as lorazepam and oxazepam. Even so, the half-lives of lorazepam and oxazepam may almost quadruple in patients with ESRD, and dosage reduction is required. Other benzodiazepines with inactive metabolites include clonazepam and temazepam, but less is known about changes in their half-lives in ESRD.

### *Mood Stabilizers*

Lithium is almost entirely excreted by the kidneys. It is contraindicated in patients with acute renal failure, but not in those with chronic renal failure. For patients with stable partial renal insufficiency, dose conservatively and monitor renal function frequently. For patients on dialysis, lithium is completely dialyzed and may be given as a single oral dose (300–600 mg) following hemodialysis treatment. Lithium levels should not be checked until at least 2–3 hours after dialysis, because re-equilibration from tissue stores occurs in the immediate postdialytic period. For patients on peritoneal dialysis, lithium can be given in the dialysate. Dosage adjustment recommendations based on creatinine clearance are available for gabapentin, lithium, topiramate, and carbamazepine (Jacobson 2002).

### *Cholinesterase Inhibitors*

It appears, from the limited data available, that dosage adjustment of donepezil is not required. As in patients without renal disease, rivastigmine dose should be titrated according to efficacy and individual tolerability. Galantamine should be used cautiously in patients with moderate renal insufficiency; according to the manufacturer, its use in patients with severe renal insufficiency is not recommended.

### *Psychostimulants*

No specific dosing recommendations are currently available for psychostimulants.

## Cardiovascular Disease

Potential adverse cardiovascular effects of psychotropics include orthostatic hypotension, conduction disturbances, and arrhythmias (see also Chapter 19, “Heart Disease”). Orthostatic hypotension can be a serious problem for many debilitated patients, aggravated by dehydration,

**TABLE 37–10. Psychotropic drugs in renal insufficiency (RI)<sup>a</sup>****Antidepressants**

MAOIs	May accumulate in RI.
Most SSRIs	Mild to moderate RI: no dosage adjustment needed. Severe RI: may need to reduce dosage or lengthen dosing interval.
Paroxetine	Mild RI: no dosage adjustment needed. Moderate RI: 50%–75% of usual dose. Severe RI: initial dosage of 10 mg/day; increase as needed by 10 mg at weekly intervals to a maximum dosage of 40 mg/day. Controlled-release formulation: initial dose of 12.5 mg/day; increase if needed by 12.5 mg at weekly intervals to a maximum dose of 50 mg/day.
TCAs	Water-soluble active metabolites may accumulate. No recommended dosage adjustments.
Bupropion	Water-soluble active metabolites may accumulate. Reduce initial dosage.
Duloxetine	Mild RI: population CPK analyses suggest no significant effect on apparent clearance. No data regarding use in moderate to severe RI. Not recommended for patients with end-stage renal disease.
Mirtazapine	Moderate RI: clearance decreased by 30%. Severe RI: clearance decreased by 50%.
Nefazodone	No dosage adjustment needed.
Trazodone	Mild RI: use with caution. No data regarding use in moderate to severe RI.
Venlafaxine	Moderate RI: 75% of usual dose. Severe RI: 50% of usual dose. Hemodialysis patients should be dosed after dialysis session.

**Atypical antipsychotics**

Clozapine, olanzapine, quetiapine	No dosage adjustment needed.
Risperidone	Clearance decreased in RI. Initiate therapy at 0.25–0.5 mg bid. Increase beyond 1.5 mg should be made at intervals of at least 7 days.
Ziprasidone	No recommendations made regarding dosage adjustment.

**Conventional antipsychotics**

Haloperidol et al.	No dosage adjustment needed.
--------------------	------------------------------

**Anxiolytics and sedative-hypnotics**

Most benzodiazepines	No dosage adjustment needed.
Chlordiazepoxide	Severe RI: 50% of usual dose.
Buspirone	Use in severe RI not recommended.
Zaleplon	Mild to moderate RI: no dosage adjustment needed. Severe RI not adequately studied.
Zolpidem	Dosage adjustment may not be needed in RI.

**Anticonvulsant/antimanic agents**

Carbamazepine	Severe RI: 75% of usual dose.
Oxcarbazepine	Initiate therapy at 300 mg/day (50% of usual starting dose).
Gabapentin	$Cl_{cr} < 60$ mL/min: 1,200 mg/day (400 mg tid). $Cl_{cr}$ 30–60 mL/min: 600 mg/day (300 mg bid). $Cl_{cr}$ 15–30 mL/min: 300 mg/day. $Cl_{cr} < 15$ mL/min: 150 mg/day (300 mg every other day). Hemodialysis: 300–400 mg loading dose to patients who have never received gabapentin, then 200–300 mg after each dialysis session.
Lamotrigine	Reduced dose may be effective in significant RI.
Lithium	Moderate RI: 50%–75% of usual dose. Hemodialysis: usual dose 300 mg once after each dialysis session.

**TABLE 37–10. Psychotropic drugs in renal insufficiency (RI)<sup>a</sup> (continued)****Anticonvulsant/antimanic agents (continued)**

Topiramate	Mild RI: 100% of usual dosage. Moderate RI: 50% of usual dosage. Severe RI: 25% of usual dosage. Supplemental dose may be needed after hemodialysis.
Valproate	No dosage adjustment needed in RI, but valproate level measurements are misleading.

**Cholinesterase inhibitors**

Donepezil	Limited data suggest no dosage adjustment needed.
Galantamine	Moderate RI: maximum dose 16 mg/day. Severe RI: use not recommended.
Rivastigmine	Dosage adjustment not recommended.

**Central nervous system stimulants**

Methylphenidate	No dosage adjustment needed.
Modafinil	No dosage adjustment needed.

**Antiparkinsonian agents**

Amantadine	Cl <sub>cr</sub> 80 mL/min: 100 mg bid. Cl <sub>cr</sub> 60 mL/min: 100 mg qd/bid on alternate days. Cl <sub>cr</sub> 40 mL/min: 100 mg/day. Cl <sub>cr</sub> 30 mL/min: 200 mg twice weekly. Cl <sub>cr</sub> 20 mL/min: 100 mg three times weekly. Cl <sub>cr</sub> 10 mL/min: 200 mg alternated with 100 mg every 7 days.
------------	---

*Note.* MAOIs=monoamine oxidase inhibitors; SSRI=selective serotonin reuptake inhibitors; TCAs=tricyclic antidepressants.

<sup>a</sup>Mild RI is >50 mL/min; moderate RI is 10–50 mL/min; severe RI is <10 mL/min.

*Source.* Adapted from Jacobson S: "Psychopharmacology: Prescribing for Patients With Hepatic or Renal Dysfunction." *Psychiatric Times* 19, 2002. Used with permission.

with increased morbidity resulting in patients with poor tissue perfusion and leading to injuries due to falls (fractures, subdural hematomas).

**Antidepressants**

For an extensive review of the safety of antidepressant drugs in patients with cardiac disease, please refer to the article by Alvarez and Pickworth (2003). In summary, patients most at risk for developing cardiac side effects include those with unstable coronary artery disease (especially recent myocardial infarction), conduction abnormalities, orthostatic hypotension, and congestive heart failure (Alvarez and Pickworth 2003). Although there are more studies of TCAs than other antidepressants in cardiac patients, the SSRIs have been studied in the largest number of patients.

**Tricyclic antidepressants.** The TCAs have been shown to be relatively safe for short-term treatment of patients with stable ischemic heart disease, previous myocardial infarction, and congestive heart failure. Long-term safety has not been studied. In healthy individuals, the cardiovascular complications from TCAs administered at therapeutic levels are largely limited to orthostatic hypoten-

sion (Glassman 1984). In patients with heart disease, the cardiovascular risks become clinically significant. TCAs are more likely to cause orthostatic hypotension in patients with impairment in left ventricular function but are relatively safe to use in most patients with congestive heart failure. Caution is required if the patient has symptomatic orthostatic hypotension or markedly reduced cardiac ejection fraction. Nortriptyline is considered the safest TCA in patients with congestive heart failure because it is least likely to cause orthostasis (Roose et al. 1981) and has little to no effect on cardiac ejection fraction (Giardina et al. 1985; Roose et al. 1986).

All TCAs have quinidine-like antiarrhythmic properties that delay cardiac conduction and increase heart rate. In healthy individuals, this is usually not clinically significant. Patients with existing conduction delays (e.g., bundle branch block) may have clinically relevant deleterious effects on conduction time. In patients with bundle branch block (especially those with second-degree heart block), dissociative (third-degree) atrioventricular heart block may develop. Some calcium channel blockers (diltiazem and verapamil, but not nifedipine) may also slow atrioventricular conduction, making their combination with TCAs more dangerous.

Another potential quinidine-like effect of the TCAs is prolongation of the QTc interval, which may lead to the potentially fatal arrhythmia torsades de pointes. Those at particular risk include patients with a preexisting familial long QTc syndrome and those who develop undue QTc prolongation during treatment with TCAs (or other QTc-prolonging drugs). An electrocardiogram is indicated for patients treated with TCAs who have a personal or family history of sudden death or syncope or a personal history of angina, myocardial infarction, congestive heart failure, arrhythmias, hypokalemia, hypomagnesemia, or other significant cardiac risk factors (Vieweg 2002). If TCAs are absolutely necessary in patients with existing conduction disturbances, cardiology consultation should be sought prior to their use.

Wolff-Parkinson-White syndrome, or atrioventricular nodal reentrant tachycardia, affects approximately 0.15%–0.2% of the general population. Of these individuals, 60%–70% have no other evidence of heart disease. In some, more serious and potentially life-threatening abnormal rhythms may develop. The most common is atrial fibrillation. Quinidine-like drugs given to patients with atrial flutter-fibrillation may lead to ventricular tachycardia or fibrillation. All patients with Wolff-Parkinson-White syndrome should be evaluated by a cardiologist prior to considering TCA treatment.

**Newer antidepressants.** SSRIs are currently considered the safest antidepressants in patients with cardiac disease. Paroxetine, sertraline, and fluoxetine have been studied, and citalopram is currently under study. In these studies, SSRIs have shown no orthostatic hypotension, minimal effects on conduction, and virtually no effects on ventricular function (Alvarez and Pickworth 2003). Trazodone and bupropion have been studied in small clinical trials. Trazodone is reportedly safe despite causing orthostatic hypotension. Bupropion has been used safely in patients with conduction disease and left ventricular dysfunction (Roose et al. 1991). Mirtazapine is currently being studied in patients following myocardial infarction (van den Brink et al. 2002).

### *Antipsychotics*

Antipsychotics that cause orthostatic hypotension, including low-potency antipsychotics, clozapine, and perhaps quetiapine, should be avoided in patients with congestive heart failure. Orthostasis occurs far less frequently with high-potency typical antipsychotics such as haloperidol, which can usually be used safely even during acute unstable cardiac disease.

Patients with preexisting intraventricular conduction delays are at increased risk of heart block when given an-

tipsychotics with quinidine-like properties such as thioridazine. Although the cardiovascular risks with antipsychotics may vary, pimozone, thioridazine, mesoridazine, droperidol, sertindole, and ziprasidone carry the highest risk for prolonging the QTc interval and causing torsades de pointes. Other atypical antipsychotics and haloperidol appear to demonstrate the least risk for prolonging the QTc interval. Although haloperidol has caused QTc prolongation and torsades, especially when parenterally administered at a high dosage (>100 mg/day), it is generally accepted to be minimally cardiotoxic. An electrocardiogram is indicated in patients taking antipsychotic drugs with increased risk of QTc prolongation (droperidol, mesoridazine, thioridazine, pimozone, high intravenous dose haloperidol).

### *Anxiolytics and Sedative-Hypnotics*

Generally, benzodiazepines are free of cardiovascular effects. Their safety has been documented even in the immediate post-myocardial infarction period (Risch et al. 1982). However, rapid intravenous administration may cause hypotension. Buspirone is essentially free of cardiovascular effects.

### *Mood Stabilizers*

The cardiac effects of lithium at nontoxic levels are generally insignificant; there may be nonspecific electrocardiographic changes, which are usually benign. Lithium uncommonly causes sinus node dysfunction or first-degree atrioventricular block and should be used cautiously in patients at risk (Dasgupta and Jefferson 1990). For patients with congestive heart failure, reduced doses are required secondary to decreased lithium clearance. However, lithium is difficult to use in these patients because of salt restriction and diuretic therapy. Valproic acid is safe to use in patients with cardiovascular disease. Carbamazepine is more cardiotoxic and has been associated with the development of atrioventricular conduction disturbances. Before carbamazepine is prescribed, a baseline electrocardiogram should be obtained in patients at risk, and alternative therapy should be considered if there is evidence of heart block or atrioventricular conduction delay. Lamotrigine has been associated with clinically insignificant prolongation of the PR interval. Caution is warranted with other mood stabilizers because they have not been systematically studied in patients with cardiac disease.

### *Cholinesterase Inhibitors*

Cholinesterase inhibitors may have vagotonic effects on the heart (e.g., bradycardia). This effect may be of partic-

ular concern in patients with “sick sinus syndrome” or other supraventricular conduction abnormalities. Cholinesterase inhibitors should be avoided in patients with most cardiac conduction abnormalities and those with unexplained syncopal episodes.

### ***Psychostimulants***

Methylphenidate and dextroamphetamine in low doses have no significant cardiovascular effects, including no effect on blood pressure or heart rate. Safe use has been described in many cardiac patients, including those with congestive heart failure, coronary artery disease, arrhythmias, and hypertension (Masand and Tesar 1996).

## Central Nervous System Disease

### ***Cerebrovascular Disease***

The most common problems encountered when prescribing psychotropics to patients with cerebrovascular disease include lowered threshold for CNS side effects, orthostatic hypotension, and comorbid disorders (e.g., cardiac disease, diabetes).

**Antidepressants.** Depression follows stroke in up to one-third of patients (see also Chapter 9, “Depression,” and Chapter 32, “Neurology and Neurosurgery”). Treatment of poststroke depression has been most studied with nortriptyline, trazodone, fluoxetine, and citalopram, with favorable therapeutic effects in those patients able to tolerate these medications. Although more evidence is needed regarding the safety and efficacy of newer antidepressants in poststroke patients, they may be the drugs of choice given their favorable side-effect profile.

**Antipsychotics.** In April 2003, Janssen Pharmaceutica, in conjunction with Health Canada, first reported a labeling change indicating that cerebrovascular events (stroke, transient ischemic attack), including fatalities, were reported in four placebo-controlled trials of risperidone in elderly patients ( $N=1,230$ ; mean age, 85 years; range, 73–97) with dementia-related psychosis (Health Canada 2003). There was a significantly higher incidence of cerebrovascular adverse events in patients treated with risperidone than in those receiving placebo. Since then, Eli Lilly & Company has reported some data on cerebrovascular event rates in 5 placebo-controlled trials of olanzapine in elderly patients with dementia (including Alzheimer’s, vascular, and mixed dementia). According to information supplied, the absolute increased risk for cerebrovascular accidents was 0.9% for patients taking olanzapine (Wooltorton 2004). These rates are similar to those reported for risperidone (Wooltorton 2002). Addi-

tionally, in placebo-controlled clinical trials of elderly patients with dementia-related psychosis, the incidence of death in olanzapine patients was significantly greater than that in placebo-treated patients (3.5% vs. 1.5%, respectively). Risk factors that may predispose this patient population to increased mortality when treated with olanzapine include age greater than 80 years, sedation, concomitant use of benzodiazepines or the presence of pulmonary conditions (e.g., pneumonia with or without aspiration) (Eli Lilly & Company 2004). In a retrospective analysis comparing mortality effects of haloperidol with those of atypical antipsychotics risperidone or olanzapine over a 2-year period in patients 65 years or older, the authors reported a statistically significant difference in mortality, with 21.4% (64 of 299) in the haloperidol group and 4.75% (61 of 1,254) in the atypical group (Nasrallah et al. 2004). It is difficult to know how to interpret this information, given the increased risk of stroke in the elderly and no reliable means to quantify the degree of vascular dementia (a marker for underlying cerebrovascular disease) in individual patients. It is unknown whether other antipsychotics pose elevated risk.

**Psychostimulants.** Psychostimulants offer an alternative in treating poststroke depression, but poststroke patients may be more sensitive to their side effects. Hence, psychostimulants should be initiated at a very low dose and gradually increased as necessary (Masand and Tesar 1996).

### ***Seizures***

Psychotropics that may lower seizure threshold at normal doses primarily pose a risk in patients with untreated (or undertreated) seizure disorder.

**Antidepressants.** Seizure disorder patients are frequently prescribed psychotropic medications, including antidepressants, because of high psychiatric comorbidity. How much risk for increased seizures do antidepressants cause in such patients? Studies to date are difficult to interpret because of methodological limitations and confounding factors. Clinical recommendations are based largely on observational studies and case reports. These include reports that assess risk for seizures after psychotropic drug overdose and during therapeutic use in patients with and without epilepsy (Alldredge 1999). Most antidepressants at therapeutic doses in nonepileptic patients exhibit a seizure risk close to that reported for the first spontaneous seizure in the general population (0.1%). Risk of seizures with bupropion SR (dosage of 450 mg/day) is comparable with that of SSRIs but elevated at dosages greater than 450 mg/day. The use of

bupropion in patients with preexisting seizure disorder, or in patients who may be at higher risk for developing seizures, warrants caution. Although newer antidepressants are thought to have a decreased relative risk for seizures, identification of relative seizure risk is thwarted by lack of systematic prospective comparisons.

**Antipsychotics.** Low-potency typical antipsychotics, especially at high dosages (1,000 mg/day chlorpromazine), and clozapine have higher reported risk of seizures and ideally should be avoided in patients with existing seizure disorders. Seizures have been reported with most antipsychotics; however, haloperidol and atypical antipsychotics (other than clozapine) appear to have a much lower seizure risk (Allredge 1999).

**Cholinesterase inhibitors.** Cholinomimetics may reduce the seizure threshold, and seizures have been reported during clinical trials with all cholinesterase inhibitors. However, seizure activity may also be a manifestation of Alzheimer's disease. Donepezil has been reported to increase seizure frequency in patients with epilepsy (Fisher et al. 2001). The risk–benefit ratio of cholinesterase treatment for patients with seizures must be carefully evaluated.

**Psychostimulants.** Many physicians believe that psychostimulants can lower seizure threshold, but evidence is lacking. One study of traumatic brain injury patients with posttraumatic seizures concluded that methylphenidate can be safely used even in those at high risk for seizures (Wroblewski et al. 1992). A small number of patients may experience an increase in seizure frequency when they are treated with psychostimulants. If seizure frequency rises, the drug should be discontinued. To our knowledge, seizures have not been reported during therapeutic use of atomoxetine.

### ***Migraine Headache***

**Antidepressants.** Many patients with migraine headaches take triptans, which are potent 5-HT<sub>1B/1D</sub> receptor agonists. Antidepressants are also frequently prescribed for migraine prophylaxis or comorbid depression. The two main concerns regarding the use of antidepressants in patients who use triptans are the risk for serotonin syndrome and the risk for pharmacokinetic interactions with the triptans. Serotonin syndrome as a complication of triptan use is quite rare, with only a few cases reported (Mathew et al. 1996; Putnam et al. 1999). Use of triptans does not contraindicate the use of serotonergic antidepressants. The pharmacokinetics of the triptans vary widely (Jhee et al. 2001). Some triptans, including rizatriptan and

sumatriptan, are metabolized by MAO and should not be used during MAOI therapy or within 2 weeks of MAOI discontinuation (McEvoy 2003). Almotriptan and naratriptan are eliminated primarily through metabolism by cytochrome P450 enzymes and/or renal elimination and thus can be more safely used in conjunction with MAOIs.

### ***Parkinsonism***

For additional discussion of use of medications in patients with Parkinson's disease, see Chapter 32, "Neurology and Neurosurgery."

**Antidepressants.** Double-blind studies of imipramine, nortriptyline, desipramine, and bupropion demonstrate antidepressant efficacy with no change in Parkinson's disease symptoms. The anticholinergic effects of TCAs may even be therapeutic for parkinsonism.

There is a theoretical concern that serotonergic antidepressants could worsen parkinsonism through inhibition of nigrostriatal dopamine release by serotonin—an effect that has been reported in a few cases (Hauser and Zesiewicz 1997). However, in open-label studies and case reports, sertraline, citalopram, reboxetine, paroxetine, and moclobemide have all been reported to be efficacious and well tolerated by patients with Parkinson's disease (Hauser and Zesiewicz 1997; Lemke 2002; Rampello et al. 2002; Steur and Ballering 1997; Tessei et al. 2000).

Early reports suggest that mirtazapine may reduce tremor (Gordon et al. 2002; Pact and Giduz 1999). Selegiline, a highly selective MAO-B inhibitor at doses used in the treatment of Parkinson's disease, is another antidepressant option, but it loses selectivity at the doses required for antidepressant efficacy and so requires standard MAOI precautions.

**Antipsychotics.** The major concern about using antipsychotics in treating patients with Parkinson's disease is that they all produce some degree of dopamine D<sub>2</sub> receptor blockade—especially high-potency typical antipsychotics—potentially aggravating the disease. Clozapine is the only atypical antipsychotic demonstrated in a controlled trial in patients with Parkinson's disease to be effective against psychosis without aggravating the disease, and it may even be beneficial in reducing tremor (Parkinson Study Group 1999). Initial case reports suggesting that olanzapine and risperidone were well tolerated were followed by other reports of deterioration in motor functioning. Case reports regarding quetiapine have been more positive.

To date, the limited case reports of the use of aripiprazole or ziprasidone in patients with Parkinson's disease have described mixed efficacy of these agents in reducing

psychosis while not worsening parkinsonian symptoms (Connemann and Schonfeldt-Lecuona 2004; Fernandez et al. 2004; Schonfeldt-Lecuona and Connemann 2004).

### ***Dementia With Lewy Bodies***

**Antipsychotics.** Patients with dementia with Lewy bodies (see Chapter 7, “Dementia”) typically present with extreme sensitivity to EPS of antipsychotics, a consideration that is especially important to remember when prescribing antipsychotics for the treatment of hallucinations, delusions, and/or agitation in patients with dementia. No randomized, controlled trials of antipsychotics in patients with dementia with Lewy bodies exist. Overall, atypical antipsychotics are probably safer than typical antipsychotics and should be used at very low dosages.

## **Endocrine Disease**

### ***Diabetes Mellitus***

**Antidepressants.** An increase in catecholamine increases serum glucose levels while reducing both insulin release and insulin sensitivity. In contrast, increases in serotonergic function seem to increase sensitivity to insulin and reduce serum glucose. Thus, in theory, SSRIs may be preferred agents in patients with diabetes because of their minimal effects on glucose metabolism. However, in diabetic neuropathic pain, dual-action antidepressants appear more effective at lower doses than do specific serotonergic agents, perhaps because catecholamines and serotonin have both been implicated in pain pathways (Goodnick 2001).

**Antipsychotics.** An assessment of relative risks of particular antipsychotics in diabetes should include the risks of weight gain, glucose intolerance, and hyperlipidemia. Although there are insufficient data to define a first choice, it is generally agreed that clozapine and olanzapine should be avoided. There is no current consensus on when to monitor glucose and lipids when atypical antipsychotics are being prescribed.

### ***Obesity***

**Antipsychotics.** Almost all antipsychotics can cause weight gain, but they vary in their propensity to cause this effect. There is some controversy as to who is more likely to gain weight on antipsychotics—those at normal weight to begin with or those who are already obese. Nevertheless, in patients who are already obese, weight-neutral antipsychotics such as molindone, ziprasidone, and aripiprazole are sensible as preferred agents.

### ***Lipids***

**Antipsychotics.** Phenothiazines, clozapine, olanzapine, and quetiapine are known to elevate serum triglyceride levels and thus should be avoided in patients who already have hypertriglyceridemia or hypercholesterolemia.

## **Respiratory Disease**

For additional discussion of use of medications in patients with respiratory disease, see Chapter 20, “Lung Disease.”

### ***Antidepressants***

Antidepressants generally do not cause problems in patients with respiratory disease. However, MAOIs are problematic in asthmatic patients because of their potential to interact with epinephrine and other sympathomimetic medications. Use of antidepressants with anticholinergic properties is of theoretical benefit because of their mild bronchodilator effect. Cyclic antidepressants, SSRIs, and other newer antidepressants have little to no effect on respiratory function.

### ***Anxiolytics and Sedative-Hypnotics***

The respiratory depressant effects of all benzodiazepines are well established; most of these agents can significantly reduce the ventilatory response to hypoxia. This may precipitate respiratory failure in a patient with marginal respiratory reserve. Patients with moderate-to-severe COPD are at risk for carbon dioxide retention with long-acting benzodiazepines, even at relatively low doses. However, benzodiazepines should not automatically be rejected for use in patients with COPD. Anxiety can often reduce respiratory efficiency, and benzodiazepines may actually improve respiratory status in some patients, especially those with asthma or emphysema (“pink puffers”) (Mitchell-Heggs et al. 1980). Patients with severe bronchitis (“blue bloaters”) or severe restrictive lung disease are the most vulnerable to the adverse effects of benzodiazepines. Intermediate-acting agents (oxazepam, temazepam, lorazepam) have fewer respiratory depressant effects and are the benzodiazepines of first choice for anxiolysis in patients with COPD. For patients with severe COPD, baseline assessment of blood gases and pulmonary consultation may be necessary in deciding whether benzodiazepines are appropriate for use. Oximetry is likely adequate for ongoing monitoring of the patient’s clinical status during benzodiazepine use unless the patient is a known CO<sub>2</sub> retainer, in which case blood gases are more appropriate.

Controlled trials with short-acting hypnotics, including triazolam, zolpidem, and zaleplon, suggest that they may be safely used in selected patients who have mild to

moderate COPD without daytime hypercapnia (George 2000). Zopiclone has been studied in patients with upper airway resistance syndrome and has no adverse effects on sleep architecture, respiratory parameters during sleep, and daytime sleepiness (Lofaso et al. 1997). Further study is needed to better define the risk–benefit ratio of hypnotics in patients with COPD. Benzodiazepines are currently contraindicated in individuals with sleep apnea.

Buspirone is potentially a safer anxiolytic in pulmonary patients because it does not depress respiration, at least in healthy volunteers (“Buspirone: Seven-Year Update” 1994). It also does not adversely affect sleep apnea (Mendelson et al. 1991). In the one open-label study of buspirone in subjects with severe lung disease, none of the subjects showed deterioration in respiratory function or increased carbon dioxide retention (Craven and Sutherland 1991). In patients with COPD, a double-blind study demonstrated no adverse effects on respiratory measures but also failed to show clinical benefit (Singh et al. 1993). Although buspirone does not adversely affect pulmonary function, its limitations are its potency and delayed therapeutic effect (Robinson and Levenson 2000).

### *Antipsychotics*

Antipsychotics may be helpful in pulmonary patients who are incapacitated by extreme panic and dyspnea that mutually exacerbate each other. Most typical and atypical antipsychotics can be used in patients with chronic respiratory disease. Uncommon but serious concerns include the provocation of laryngeal dystonia and development of tardive dyskinesia affecting respiratory musculature. Low-potency typical antipsychotics may have some additional bronchodilatory effects. Clozapine has been associated with respiratory arrest and depression as well as allergic asthma (Lieberman and Safferman 1992; Stoppe et al. 1992).

### *Cholinesterase Inhibitors*

Because acetylcholine is a potent mediator of bronchoconstriction, care must be taken in prescribing cholinesterase inhibitors to patients with asthma or COPD.

## Cancer

For additional discussion of use of medications in patients with cancer, see Chapter 24, “Oncology.”

### *Breast Cancer*

**Antidepressants.** Recent case–control studies have reported an increased risk of developing breast cancer for patients taking some TCAs for longer than 10 years (Sharpe et al. 2002). Another case–control study concluded

that “paroxetine may be associated with a substantial increase in breast cancer risk” (Cotterchio et al. 2000, p. 779). These studies, and the resulting media attention, have caused considerable anxiety in women currently or previously taking antidepressants. A critical evaluation of these studies noted many methodological limitations and concluded that the current evidence does not merit changing depression treatment practice (Kurdyak et al. 2002; Sternbach 2003).

## HIV/AIDS

See Chapter 28, “HIV/AIDS,” and a review by Robinson and Qaqish (2002) for discussion of the use of psychotropics in patients with HIV/AIDS.

## **Psychotropic Drug Use During Pregnancy and Breast-Feeding**

---

For additional discussion of the issues regarding medication use by pregnant or breast-feeding women, see Chapter 33, “Obstetrics and Gynecology.”

## Pregnancy

Fetal exposure to medications is common, especially during the first trimester. Because approximately 50%–65% of all pregnancies in the United States are unplanned (Koren et al. 1998; Rosenfeld and Everett 1996), the fetus may be exposed to a variety of drugs during the first trimester before the mother is aware of her pregnancy. Even during an established pregnancy, surveys estimate that 80% of women take prescription medications and 21%–33% are exposed to psychotropic drugs (Barki et al. 1998; Doering and Stewart 1978). For any woman of childbearing age, all drugs should be considered for their safety in pregnancy and breast-feeding.

Fetal risks associated with drug use during pregnancy include teratogenicity, direct toxicity, perinatal effects, and possible long-term effects on behavior and development. Known and possible risks of pharmacotherapy, however, must be balanced against the risks to the fetus from withholding therapy. Exacerbation of the mother’s psychiatric illness may endanger the fetus in utero through maternal self-harm, suicide, malnutrition, lack of proper prenatal care, or excessive exposure to risks through impulsivity, delusions, disorientation, or denial of the pregnancy. Treatments for psychotic and bipolar disorders in severely ill patients should not be discontinued during pregnancy because of the fetal risks associated with the high incidence of relapse (Faedda et al. 1993).

Physiological changes associated with pregnancy alter drug pharmacokinetics and complicate therapy. In general, drug levels decline during pregnancy because of increases in renal elimination, volume of distribution, and cardiac output (Ward 1995, 1996). Over the course of the pregnancy, lithium clearance doubles (Schou et al. 1973) and TCA elimination increases 1.6 times (Wisner et al. 1993). Drug levels should be monitored during the pregnancy, and dosage should be adjusted to maintain a therapeutic response consistent with the lowest effective dose. During the early postpartum period, these physiological changes reverse. As maternal drug elimination returns to normal, any dosage adjustment required during pregnancy should be gradually reversed.

At parturition, the delivery of maternal drug to the neonate is discontinued and neonatal withdrawal symptoms may appear. Neonatal benzodiazepine withdrawal symptoms include irritability, tremor, diarrhea, vomiting, hypertonicity, and high-pitched crying (Rementeria and Bhatt 1977). Symptoms of TCA withdrawal in neonates include irritability, abdominal cramps, insomnia, tachycardia, tachypnea, and cyanosis. SSRIs have also been associated with a neonatal withdrawal syndrome (irritability, constant crying, shivering, increased tonus, eating and sleeping difficulties, and convulsions) (Nordeng et al. 2001). When possible, tapering and discontinuation of benzodiazepines and TCAs over a few weeks before delivery has been recommended to prevent neonatal withdrawal (Miller 1991, 1994), but this must be balanced against the risk of postpartum depression. Discontinued medications should be reinstated postpartum.

Neonates exposed to SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) late in the third trimester have developed complications requiring prolonged hospitalization, respiratory support, and tube feeding. Such complications can arise immediately upon delivery. Reported clinical findings have included respiratory distress, cyanosis, apnea, seizures, temperature instability, feeding difficulty, vomiting, hypoglycemia, hypotonia, hyperreflexia, tremor, jitteriness, irritability, and constant crying (Nordeng et al. 2001). These features are consistent with either a direct toxic effect of SSRIs and SNRIs or possibly a drug discontinuation syndrome. When treating a pregnant woman with an antidepressant during the third trimester, the physician should carefully consider the potential risks and benefits of treatment.

## Breast-Feeding

During the postpartum period, women are at risk for the development of depression, mania, or psychosis. More than 60% of mothers breast-feed their infants (Llewellyn

and Stowe 1998), and many will wish to do so while taking psychotropic medications. If informed that a medication is incompatible with breast-feeding, a mother may covertly breast-feed and discontinue her medication. Recurrence of the psychiatric disorder not only is dangerous for the mother but may place the infant at greater risk than that posed by breast-feeding while the mother is taking medication.

Unfortunately, case reports are the only source of adverse psychotropic effects during breast-feeding; there are no clinical trials of drug effects in breast-fed infants. With a few exceptions, psychotropic drugs seem to be relatively safe in breast-feeding. The American Academy of Pediatrics (2001) has classified medications according to the evidence supporting their safety in breast-feeding. Most psychotropic agents, however, are classified as “drugs for which the effect on nursing infants is unknown but may be of concern” (American Academy of Pediatrics 2001, p. 779) because of lack of clear data.

The use of medications during pregnancy and breast-feeding, including the risks, benefits, and treatment alternatives, must be discussed with the patient. Failure to fully inform may result in the patient discontinuing treatment because of excessive fear of risk to the fetus.

Increasing evidence suggests that most psychotropic medications are safe in pregnancy and breast-feeding. However, there are concerns about the anticonvulsant mood stabilizers, lithium, low-potency antipsychotics, and benzodiazepines. Concerns about psychotropic drug use in pregnancy and breast-feeding are listed below (compiled from American Academy of Pediatrics Committee on Drugs 2000; Burt et al. 2001; Ernst and Goldberg 2002; Gjere 2001; and Ward and Zamorski 2002).

## Risks of Psychotropic Drug Use During Pregnancy and Breast-Feeding

### *Antipsychotics*

#### • **Pregnancy:**

- *Typical agents*—Not associated with any evidence of teratogenic, behavioral, emotional, or cognitive abnormalities.
- *Low-potency drugs*—Can cause neonatal tachycardia, gastrointestinal dysfunction, sedation, and hypotension for a few days after birth. Best avoided so as to minimize anticholinergic, hypotensive, and antihistaminic effects.
- *High-potency drugs*—Preferred despite the risk of fetal EPS. Incidence of fetal EPS (hyperactivity, hyperreflexia, abnormal movements, tremor, hand flapping, and crying that may persist for several months) is dose related.

- *Atypical agents*—Insufficient human data for recommendation.
- *Depot preparations*—Avoid because of long duration of action.
- **Breast-feeding:** Compatibility of antipsychotics with breast-feeding is unknown. Clozapine may be of concern because of possible agranulocytosis, sedation, and seizures (Iqbal et al. 2001). Sedating drugs such as chlorpromazine may produce drowsiness and lethargy in the infant. Monitor the neonate for antipsychotic side effects such as sedation, muscle rigidity, or tremor (Burt et al. 2001).

### Antidepressants

- **Pregnancy:**
  - *TCA*s—Not associated with evidence of teratogenic effects. Avoid maprotiline because of increased maternal seizure risk. Neonatal TCA withdrawal symptoms include seizures, irritability, abdominal cramps, insomnia, tachycardia, tachypnea, and cyanosis.
  - *SSRIs*—Fluoxetine not associated with teratogenic effects. Other SSRIs do not appear to be teratogenic from limited human data.
  - *MAOIs*—Avoid because of hypotensive effects and potential for drug and food interactions.
- **Breast-feeding:** Compatibility with breast-feeding is unknown. Sedating drugs may cause neonatal lethargy. Limited case reports suggest that fluoxetine, paroxetine, and sertraline are relatively safe (Burt et al. 2001).

### Antiparkinsonian Agents

- **Pregnancy:**
  - *Anticholinergics*—Not recommended for the treatment of EPS during pregnancy. Associated with increased risk of congenital anomalies, complications of pregnancy, and neonatal adverse effects (Gjere 2001). Akathisia can be treated during pregnancy with propranolol or atenolol.
- **Breast-feeding:** Anticholinergic drugs and amantadine are not classified.

### Mood Stabilizers

- **Pregnancy:**
  - *Lithium*—Teratogenic potential is less than earlier thought. First-trimester exposure associated with a 10-fold increase in Ebstein anomaly, a rare (1 in 20,000) cardiovascular malformation. Cardiac ultrasonography at 18–20 weeks is recommended.
  - *Carbamazepine and valproate*—Associated with neural tube defects—carbamazepine (~1%) and valproate (~1% to 2%)—and fetal hydantoin syndrome (facial dysmorphism, cleft lip and palate, cardiac de-

fects and digit hypoplasia). Screening for neural tube defects (amniocentesis and serum alpha-fetoprotein) before week 20 is advised. To minimize risk, all women of childbearing age should consume 0.4 mg folate daily. Women taking valproate or carbamazepine should supplement with 4 mg folate daily when planning to start pregnancy. Carbamazepine and valproate may cause transient vitamin K deficiency, resulting in neonatal clotting disorders. This risk can be minimized by supplementing with 20 mg oral vitamin K from week 36 to delivery, plus 1 mg intramuscularly to the newborn.

- *Gabapentin, lamotrigine, topiramate:* Insufficient human data for recommendation. There is evidence of fetal toxicity (gabapentin) and teratogenicity (topiramate) in animal studies. Lamotrigine decreases folate in rats; consider folate supplementation (see previous item).
- **Breast-feeding:** Carbamazepine and valproate are compatible with breast-feeding; monitor for possible neonatal hepatotoxicity. Avoid breast-feeding if patient is taking lithium. High levels of lithium are present in breast milk, and therapeutic serum levels are found in breast-fed infants (Chaudron and Jefferson 2000), with reports of neonatal electrocardiographic changes and hypotonia (Ernst and Goldberg 2002). For lamotrigine, gabapentin, and topiramate, compatibility with breast-feeding is unknown. Lamotrigine may be of concern.

### Anxiolytics and Sedative-Hypnotics

- **Pregnancy:**
  - *Benzodiazepines*—May be associated with a twofold increase in orofacial clefts. Neonatal benzodiazepine withdrawal (irritability, tremor, diarrhea, vomiting, hypertonicity, and high-pitched crying) may occur.
  - *Other anxiolytics/sedatives*—Insufficient data for recommendation.
- **Breast-feeding:** Compatibility with breast-feeding is unknown. Sedating drugs may cause neonatal lethargy.

### General Guidelines for Psychotropic Drug Use in Pregnancy and Breast-Feeding

General guidelines for psychotropic drug use in pregnancy and breast-feeding (adapted from Fait et al. 2002; Newport et al. 2002; and Ward and Zamorski 2002) include the following:

1. For any woman of childbearing age, carefully select all drugs for their safety in pregnancy and breast-feeding.

2. Remember that the benefit of any medication to the mother must outweigh the risk to the fetus.
3. Discuss with the mother the risks and benefits of using psychotropic medications while pregnant or breast-feeding.
4. Avoid all drugs during pregnancy and breast-feeding if possible, including over-the-counter and herbal medicines.
5. Use the lowest effective dose of a short-half-life agent.
6. Prefer monotherapy to combination therapy.
7. Select established drugs with known effects in pregnancy and breast-feeding rather than agents with little supporting data.
8. Select medications for minimum teratogenic and behavioral toxicity.
9. Monitor clinical response and drug levels where possible during pregnancy. Adjust dosage as necessary to maintain therapeutic effect. At delivery, slowly return drug dose to prepregnancy levels.
10. Minimize drug exposure for the nursing infant by instructing the mother to take medication just after breast-feeding or before the infant is due for a long sleep (American Academy of Pediatrics 2001). SSRI levels peak in breast milk at 8–9 hours postdose. Infant exposure can be minimized if the milk during this period is “pumped and dumped” (Newport et al. 2002).
11. Consider electroconvulsive therapy for treatment of depression and especially for psychotic depression.

## Conclusion

---

Rapid developments in medical care in general, and psychopharmacology in particular, challenge clinicians to remain current with new agents, new indications for established agents, and potential pharmacokinetic and pharmacodynamic interactions in a polypharmacy environment, which also includes over-the-counter and herbal preparations. In this chapter we have discussed the many key considerations relevant to the use of psychopharmacological agents in complex medically ill patients and during pregnancy and lactation. Detailed adverse effects, toxicities, drug interactions, and alternate administration routes for each major psychotherapeutic drug class have been described. We have endeavored to provide the most up-to-date information possible by making extensive use of Internet resources. Many of these Internet sources are cited in the reference section, and we encourage their general use as a means of following developments in this area.

## Psychosocial Treatments

---

Jennifer W. Kaupp, Ph.D.

Nathalie Rapoport-Hubschman, M.D.

David Spiegel, M.D.

**WHEN DESCARTES UTTERED** his famous dictum “*cogito ergo sum*,” separating mind from body, he did medicine a favor. At the time, the Church forbade autopsies because they were considered damaging to the soul. By declaring the soul distinct, Descartes freed doctors to examine the body and thereby helped to advance medical science. Now, however, the idea that mind and body are separate is holding medicine back from fully exploring the interactions among mind, brain, and body. It constrains our knowledge of how depression and anxiety complicate illnesses such as heart disease and cancer, and it obscures the obvious fact that medical treatment must encompass care as well as cure—involve the person with the illness and not just the disease in the body.

The psychosomatic medicine psychiatrist brings to the medical setting expertise in medicine, neurobiology, psychiatry, psychopharmacology, psychotherapy, and a working knowledge of psychosocial resources (Kaplan et al. 1994), as well as an appreciation of individual patients from a biopsychosocial perspective (Gabbard 1994; Gabbard and Kay 2001). Psychosocial interventions with the medically ill differ from standard psychotherapy in several important ways. Patients are generally referred by primary care physicians or specialists for distress associated with medical illness (Postone 1998), premorbid psychiatric disturbance (Hay and Passik 2000; Weitzner et al. 1999), or somatic symptoms with no medical foundation (Abramowitz et al. 2002; Ehlert et al. 1999; Hay and Passik 2000; Richter 1999). The methodology, timing, and goals of psychosocial interventions with the medically ill are determined by the interaction among disease factors (onset, etiology, course, prognosis, stigma) and medical treatment (disfiguring, painful, aversive, palliative,

complex) (Goodheart and Lansing 1997); the nature of emotional distress (anxiety, depression, disorientation, posttraumatic stress) (Andrykowski et al. 1998, 2000; Bauer and Whybrow 1999; Block 2000; Cordova et al. 2000; Guthrie 1996; Kaplan et al. 1994; Malt and Tjemsland 1999; Tjemsland et al. 1996a); availability of social support (Blechner 1997; Goodheart and Lansing 1997; Kaplan et al. 1994); psychological characteristics of the patient (premorbid psychopathology, personality traits, intelligence) (Blechner 1997; Gabbard 1994; Goodheart and Lansing 1997; Kaplan et al. 1994; McWilliams 1994); and response to the illness (usual coping skills, denial, hostility, dependency) (Andersen 2002; Diabetes Control and Complications Trial Research Group 1993; Fitzpatrick 1999; Gonder-Frederick et al. 2002; Goodheart and Lansing 1997).

In this chapter, we review the types of stress and distress that commonly affect patients with medical illness, psychological factors unique to these patients, and the psychotherapies that have been developed and evaluated to treat their symptoms and enhance their coping styles. There is growing evidence that a variety of psychotherapeutic strategies in individual and group formats are helpful in reducing distress, anxiety, and depression among the medically ill. Techniques employed include psychodynamic, supportive-expressive, and interpersonal psychotherapies, hypnosis, family therapy, cognitive-behavioral therapy (CBT), and psychoeducation. Psychotherapy is also discussed elsewhere in this book with respect to specific psychiatric disorders such as depression (Chapter 9, “Depression”), anxiety (Chapter 12, “Anxiety Disorders”), and somatoform disorders (Chapter 13, “Somatization and Somatoform Disorders”); in the specialty and

subspecialty chapters; and in regard to its use in pain management (Chapter 36, "Pain") and palliative care (Chapter 40, "Palliative Care").

## Stress and Distress Among the Medically Ill

---

Serious medical illnesses are often complicated by anxiety and depression, stress, adjustment disorder, interpersonal problems, and lack of social support for patients and their families (Andersen 2002; Holahan et al. 1995; Krumholz et al. 1998; Spiegel 1996; van Marle and Holmes 2002). Although these psychosocial factors appear to be outside the immediate realm of medicine, they have a profound impact on the patient's quality of life, symptom severity, disability level (Saravay 1996), and survival (Krumholz et al. 1998).

Psychosocial distress has been documented in almost all diseases studied, as reviewed in earlier chapters of this textbook (Kosslyn et al. 2000). Emotional disturbance, particularly anxiety and depression, may be an acute reaction to the diagnosis and treatment of catastrophic illness (Alter et al. 1996; Andrykowski and Cordova 1998; Andrykowski et al. 1998, 2000; Green et al. 1998; Guthrie 1996; Holahan et al. 1995; Smith et al. 1999; Spiegel 1996; Sutor et al. 1998; Tjemslund et al. 1996a, 1996b); a response to coping with a chronic medical disorder (Guthrie 1996; Kaplan et al. 1994); or an early indication of onset of diseases such as Parkinson's disease or pancreatic cancer (Maxmen and Ward 1995). Even for patients who do not develop Axis I psychiatric disorders, serious medical illness can be understood as a series of stressors that can elicit psychological and physiological stress responses (Koopman et al. 1998; Spiegel 2001).

Most individuals react to serious, life-threatening illness with a combination of emotions. Anxiety, experienced at somatic, cognitive, and emotional levels, is typically heightened during an illness (Guthrie 1996; Januzzi et al. 2000). Anxiety may be normal or pathological, acute or chronic, a state or a trait (Kaplan et al. 1994). Psychiatric consultation may be requested for critically ill or injured medical inpatients who are acutely highly anxious or in a regressed state (Kaplan et al. 1994). An intervention combining pharmacotherapy, emotional support, and reassurance from medical staff may be indicated (Kaplan et al. 1994). Chronic anxiety, on the other hand, can be a response to vague and unknown threats to the body, fear of separation or lack of support, shame and guilt, or helplessness (Abramowitz et al. 2002; Ehlert et al. 1999; Gottschalk 1978; Gottschalk and Gleser 1969; Kaplan et al. 1994; Richter 1999). Close collaboration between physician and psychiatrist, pharmacotherapy, and psycho-

therapy (CBT, brief or long-term psychodynamic) are recommended for the clinical management of these patients (Abramowitz et al. 2002). Does the medical patient have a history of childhood abuse or neglect underlying chronic anxiety? Supportive-expressive dynamic therapy that helps the patient examine reactions to medical illness, explore intrapsychic processes, and discuss and integrate abuse memories is suggested for long-term symptom reduction (Blechner 1997; Gabbard 1994; Goodheart and Lansing 1997; Herman 1992; Kaplan et al. 1994; McWilliams 1994, 1999; Postone 1998). Is chronic anxiety a function of a cancer patient's realistic concerns about recurrence, diminished functioning, or helplessness in the face of death? Educational and supportive interventions would be indicated. Interventions with the medically ill, regardless of the clinician's theoretical orientation, must be flexible enough to address illness-related problems as they arise during the course of the patient's illness (Blechner 1997; Goodheart and Lansing 1997; Postone 1998; Spiegel 1996; Spiegel and Clasen 2000).

Treatment for comorbid depression, common in many chronic illnesses, will also vary as a function of disease factors and patient characteristics. For example, vegetative signs of depression, often attributed to the patient's medical illness and left untreated (Spiegel 1996; Spiegel and Giese-Davis 2003), can resolve with antidepressants (Block 2000; Nemeroff and Schatzberg 1998). Psychotherapy emphasizing social support, emotional expression, cognitive restructuring, and improved coping skills is effective in treating the psychosocial problems in depressed medically ill patients (Sutor et al. 1998).

## Coping Skills Deficits

---

Medical patients are confronted with novel situations arising from the illness itself or from the demands of the treatment, including the need to preserve a reasonable emotional balance, maintain a sense of competence and mastery, sustain relationships with family and friends, and prepare for an uncertain future (Moos and Schaefer 1987). People with medical conditions may need help to improve existing coping skills or to learn new, more adaptive skills. Those who cannot adapt to the stresses of illness and medical care will have difficulty maintaining adequate levels of emotional, physical, and social functioning. The adaptive tasks needed to adjust to the illness may require new and unfamiliar ways of coping (e.g., learning to express emotions, mobilizing social support, increasing role flexibility) (Goodheart and Lansing 1997; Kaplan et al. 1994).

Adaptive coping has been divided into three types: information focused, emotion focused, and problem focused (Moos and Schaefer 1987; Valentiner et al. 1994). Problem-focused coping skills are important in helping the patient live with the illness and manage its treatment. Emotional adjustment to the illness is also essential. Research in the past decade suggests that medical patients are particularly inclined to use emotion-oriented strategies to reduce the high levels of distress caused by their illness, although many employ a wide range of strategies in stressful situations (Dunkel-Schetter and Westlake 1995; Newman et al. 1990). Some studies have shown that emotion-oriented and avoidant strategies may be less adaptive in the long run than task-oriented and approach strategies (De Ridder and Schreurs 2001). However, the impact of these coping strategies appears to depend on the specific constraints imposed by the circumstances of the illness. Recent studies suggest no specific coping strategy is more relevant than others in the context of medical illness (i.e., coping is situation-specific) (Folkman and Moskowitz 2000; Lazarus and Folkman 1984). A broad coping skills repertoire consisting of both problem- and emotion-focused strategies increases the probability of a constructive response to the particular demands of a stressful medical situation (Taylor 1999). This may explain the superior results of multicomponent psychosocial interventions that involve a broad repertoire of coping skills training, expanding patients' coping abilities in a flexible manner.

## Timing of Intervention

---

Scheduling psychotherapeutic support at key moments during the course of an illness would seem extremely important. However, the literature specifically related to the timing of psychotherapeutic interventions is scarce. When is it appropriate to propose a psychological intervention to medical patients? Immediately following diagnosis, after acute medical treatment ends, just after relapse, during the chronic phase of the illness, during the terminal period, or when specific problems arise? What is the efficacy of early psychotherapeutic interventions? Obviously, the specific characteristics and course of various illnesses make it difficult to propose universally applicable answers.

The time of diagnosis is often overwhelming for the patient, who is also preoccupied with obtaining and assimilating diagnostic information and making treatment decisions. Because the patient's usual cognitive and emotional processes may be overwhelmed, this phase of intense distress is generally not an ideal time for proposing

psychological treatment, although crisis management can be beneficial for a newly diagnosed patient in an acute state of anxiety (Goodheart and Lansing 1997).

When the acute phase is completed, patients have more time to participate in treatment, may sometimes feel abandoned by the medical team that provided acute care, and/or may have postponed coming to grips with the meaning of the illness. Although illness-related issues may be one treatment focus, patients also present with psychosocial or interpersonal problems unrelated to illness, so it is important to avoid attributing all emotional symptoms to the medical illness (Blechner 1997; Goodheart and Lansing 1997; Postone 1998). Other issues come to the fore in the terminal stage of an illness. Depressive illness in a dying patient may be misunderstood as a normal reaction to imminent death; however, depressive symptoms can be relieved with antidepressants (Block 2000). A supportive dynamic intervention consisting of reviewing the life lived; addressing depression, anxiety, loneliness, loss, or fears about protracted and painful death; and preparing for death has been beneficial for many patients (e.g., late-stage AIDS patients) (Blechner 1997). Even some patients with AIDS-related dementia have responded favorably to supportive therapy (Blechner 1997).

Timing is also a consideration for patients undergoing acute medical interventions (e.g., surgery, cardiac catheterization). For example, when a chronic illness or malignancy necessitates amputation of a limb, a preoperative session with a psychiatrist may reduce the patient's distress following surgery (Fitzpatrick 1999). Postsurgical interventions are strongly recommended in the case of traumatic amputation (Fitzpatrick 1999). Psychosocial interventions immediately following surgery (Kuchler et al. 1999) and 2 months after diagnosis (McCorkle et al. 2000) have been beneficial in maintaining quality of life and increasing survival among cancer patients. In the case of diabetes, several researchers have suggested that family-based interventions may be scheduled early in the course of the disease to improve long-term metabolic control in pediatric patients (Anderson and Brackett 2000). Other studies suggest, however, that later intervention, even several years after diagnosis, is more efficacious when implemented at particular junctures during the course of the illness or when specific problems or complications arise (Grey et al. 1995; Kovacs et al. 1992).

## Types of Interventions

---

Various psychotherapeutic treatments have been developed and evaluated for the broad array of psychiatric symptoms

among the medically ill. Clearly, the appropriate treatment for depressive symptoms associated with cancer or heart disease will differ from psychotherapy for conversion disorder or early dementia in terms of therapeutic interventions and goals. Furthermore, variables unique to individual patients such as developmental history, stage in the life span and current roles, family history, extent and quality of emotional and social support, educational level, economic resources, cultural norms, and access to mental health services collectively shape psychosocial interventions (Blechner 1997; Goodheart and Lansing 1997; Kaplan et al. 1994). The efficacy of psychotherapeutic treatments for depression and anxiety in medically ill patients—particularly group therapy, supportive and interpersonal therapies grounded in psychodynamic theory, brief therapy, family therapy, behavioral and cognitive-behavioral methods, and psychoeducation—has been supported by numerous outcome studies (see Compas et al. 1998; Craighead et al. 1998; Niederehe and Schneider 1998).

## Group Psychotherapy

Group intervention in a variety of forms has become an increasingly popular, effective, and efficient means of providing psychosocial support for the medically ill (Spiegel et al. 2000). Groups of different types reflect theoretical approaches that include the psychodynamic, existential, educational, and cognitive-behavioral, among others (Yalom 1995).

Clinical trials have demonstrated the benefits of group therapy for breast cancer patients (Andersen 2002; Classen et al. 2001; Fawzy et al. 2003; Goodwin et al. 2001), with notable reductions in pain and emotional distress and, in some cases, increased survival time (Kogon et al. 1997; Spiegel 2001; Spiegel et al. 1989), although not in others (Goodwin et al. 2001). Although group therapy has shown considerable success as an adjunctive treatment for cancer, HIV, heart disease, and other chronic illnesses (Allan and Scheidt 1998; Beresnevaite 2000; Classen et al. 2001; Kaplan et al. 1994; Spiegel 2001; Spiegel and Classen 2000; Stauffer 1998), some patients may not feel comfortable in a group setting. For example, patients treated for testicular cancer indicated a preference for individual rather than group psychotherapy (Moynihan et al. 1998). Group therapy may not be the treatment of choice for medically ill patients with severe psychopathology or brain damage (Levenson 1995; McWilliams 1999). Groups may be contraindicated for some patients with severe character pathology because their maladaptive interpersonal style can disrupt group process, alienating group members and therapists alike (Levenson 1995). In such

cases, the stress of serious medical illness would be compounded by removal from a support group. Although reactions to catastrophic illness may differ for individuals with preexisting psychopathology, such patients share with their emotionally healthy counterparts the need for support in dealing with diagnosis and treatment, changes wrought by disease, social isolation, and existential issues, whether offered individually or in a group.

Common elements of group intervention for the medically ill are described in the following subsections.

### *Social Support*

Psychotherapy, especially in groups, can provide a new social network with the common bond of facing similar problems. At a time when the illness makes a person feel isolated, when many others withdraw out of awkwardness or fear, group psychotherapeutic support provides a new and important social connection. Indeed, the very thing that strains other social relationships is the ticket of admission to such groups, providing a surprising intensity of caring among members from the very beginning. Furthermore, members find that the process of giving help to others enhances their own sense of mastery of the patient role and increases their self-esteem, giving meaning to an otherwise meaningless tragedy.

### *Emotional Expression*

The expression of emotion is important in reducing social isolation and improving coping, although it is an aspect of medical patient adjustment that is often overlooked or suppressed. A repressive coping strategy reduces expression of positive as well as negative emotion. Emotional suppression also reduces intimacy in families, limiting opportunities for direct expression of affection and concern. The use of the psychotherapeutic setting for dealing with painful affect also provides an organizing context for handling its intrusion. When unbidden thoughts involving fears of dying intrude, they can be better managed by patients who know that there is a time and a place during which such feelings can be expressed, acknowledged, and handled. Disease-related dysphoria is more intense when amplified by isolation, leaving the patient to feel that he or she is deservedly alone with the sense of anxiety, loss, and fear that he or she experiences. Being in a group in which many others express similar distress normalizes their reactions, making them less alien and overwhelming.

### *Detoxifying Dying: Processing Existential Concerns*

Death anxiety in particular is intensified by isolation, in part because we often think of death in terms of separa-

tion from loved ones. There are powerful psychotherapeutic techniques that directly address such concerns (Yalom 1980). Yalom (1980) described the ultimate existential concerns as death, freedom, isolation, and meaninglessness. Rather than avoiding painful or anxiety-provoking topics in attempts to “stay positive,” this form of group therapy addresses these concerns head-on with the intent of helping group members better use the time they have left. The goal is to help those facing the threat of death see it from a new point of view. When worked through, life-threatening problems can come to seem real but not overwhelming. Facing even life-threatening issues directly can help patients shift from emotion-focused to problem-focused coping. The process of dying is often more threatening than death itself. Direct discussion of death anxiety can help to divide the fear of death into a series of problems: loss of control over treatment decisions, fear of separation from loved ones, anxiety about pain, and so on. Discussion of these concerns can lead to addressing, if not completely resolving, each of these issues. Even the process of grieving can be reassuring at the same time that it is threatening. The experience of grieving others who have died of the same condition constitutes a deeply personal experience of the loss that will be experienced by others after one’s own death.

### ***Reorganizing Life Priorities and Living in the Present***

Acceptance of the possibility of illness shortening one’s life carries with it an opportunity for reevaluating life priorities. Facing the threat of death can aid in making the most of life. This attitude can help patients take control of those aspects of their lives they can influence, while grieving and relinquishing those they cannot. For cancer patients who are anticipating their imminent death and its impact on their loved ones, adjustment may be aided by a change from past- or future-focused orientation to a present-focused orientation more congruent with the reality of their foreshortened future. In addition, progress in reappraisal of life goals, reorganization of priorities, and perception of the benefits of the cancer experience may also mediate improvement in symptoms and enhance quality of life.

### ***Enhancing Family Support***

Group psychotherapeutic interventions can also be quite helpful in improving communication, identifying needs, increasing role flexibility, and adjusting to new medical, social, vocational, and financial realities confronting patients and their families. The group format is especially helpful for such tasks because problems expressing needs

and wishes can be examined among group members as a model for clarifying communication in the family. For example, a patient who expresses dissatisfaction with support from her husband can be helped to clarify her requests for assistance and to deal with her ambivalence about needing help. Also, groups for family members of the medically ill have been conducted, helping them to manage their own emotional responses and develop active coping strategies for dealing with their family member’s illness (Koopman et al. 1994; Spiegel and Classen 2000).

### ***Improving Communication With Physicians***

Support groups can be quite useful in facilitating better communication with physicians and other health care providers. Groups provide mutual encouragement to get questions answered, to participate actively in treatment decisions, and to consider alternatives carefully.

### ***Symptom Control***

Many group as well as individual psychotherapy programs teach specific coping skills designed to help patients reduce cancer-related symptoms such as anxiety, anticipatory nausea and vomiting, and pain. Techniques that can be employed in the group setting include specific self-regulation skills such as self-hypnosis, meditation, bio-feedback, and progressive muscle relaxation. Hypnosis is widely used for pain and anxiety control in cancer to attenuate the experience of pain and suffering and to allow painful emotional material to be examined. Group sessions involving instruction in self-hypnosis provide an effective means of reducing pain and anxiety.

### ***Implementation of Group Process Goals***

Implementation of the themes discussed above can be facilitated by training group therapists to shift from a content to a process orientation, recognizing that their “patient” is the group itself and that group therapy is not merely a collection of individual therapeutic interactions. This means learning to keep the group’s focus on the here and now, tracking the flow of emotion rather than pursuing completion of the content of discussions, maintaining an atmosphere in which all members feel that they are full participants with equal opportunities to share experience and maintain their points of view, and transforming shared problems into strategies for active coping.

**Personalization.** Leaders are taught to bring group discussions “into the room” by keeping the focus on interactions occurring among group members rather than directing discussion toward people and events outside the group. Thus, when one patient discusses how she feels

that she is a burden to her husband, the discussion is better directed toward the questions “Do you feel like a burden to the group?” “Do other group members feel you are a burden?”

**Affective expression.** Leaders should “follow the affect” in the room rather than the content. If a silent group member shows signs of emotion, the leader should respectfully direct attention toward him or her: “You seem upset now—what are you feeling?” Expression of emotion produces vulnerability, and it is important to make sure that those who express feelings are heard and acknowledged.

**Supportive group interactions.** The leader is responsible for starting and ending the group on time and seeing that there are few interruptions of the group time. Each member should be made to feel that his or her problems are as important as anyone else’s problems. It is necessary to inquire about missing members and to make sure that very silent members have a chance to talk. Also, it is critical to avoid scapegoating—allowing the group to fix on one patient as a displacement from dealing with their own problems. Leaders must remember that their “patient” is the group, not just a series of individuals.

**Active coping.** As problems are discussed, it is helpful for the leader to direct the group toward a means of responding to the problems rather than merely accumulating a series of unresolved difficulties or avoiding discussing them. Finding a means of addressing problems reduces the helplessness engendered by the problems.

### **Summary**

Group therapy for the medically ill involves enhancing social support; encouraging emotional expression and processing; confronting existential concerns; improving relationships with family, friends, and physicians; and building coping skills. Such skills include taking a more active stance toward disease-related problems and learning techniques such as self-hypnosis for pain control. Group leaders emphasize the here and now, personalizing discussion by making the group interaction itself the focus of discussion. Thus, group relationships, feelings, and coping experiences intensify learning and solidarity.

### **Individual Psychodynamic Therapy**

A large body of literature underscores the importance of human interaction in the lives of medically ill patients and their families. Lack of social support is predictive of psychiatric morbidity (Klausner and Alexopoulos 1999), dis-

ease course, treatment compliance (Christensen and Ehlers 2002; Gonder-Frederick et al. 2002), and increased mortality in the medically ill (Christensen and Ehlers 2002; House et al. 1988; Krumholz et al. 1998; Reynolds and Kaplan 1990; Reynolds et al. 1994; Smith and Ruiz 2002; Valentiner et al. 1994). Social isolation, perceived lack of social and emotional support, and interpersonal conflicts are risk factors for coronary disease and increased mortality in post-myocardial infarction (MI) patients (Berkman et al. 1992; Krumholz et al. 1998; Smith and Ruiz 2002). Lack of social support has also been implicated in anxiety and depression in caregivers of elderly and seriously medically ill loved ones (Donnelly et al. 2000; Gabbard 1994). Unfortunately, severe medical illness, especially when progressive or terminal, can lead to relationship problems with family and friends and loss of important sources of emotional and social support when most needed (Rolland 1989). Therefore, interventions based on theories that emphasize the innately human need for relationship—psychodynamic and object relations theories (Bemporad and Vasile 1990; Gabbard 1994; Kaplan et al. 1994; Maxmen and Ward 1995; McWilliams 1999) and interpersonal theories (Bemporad and Vasile 1990; Craighead et al. 1998; Donnelly et al. 2000; Gillies 2002; Guthrie 1996; Sullivan 1953)—are discussed in some detail (Compas et al. 1998; Gabbard 1994; Guthrie 1996; Kaplan et al. 1994; Levenson 1995; Milrod et al. 2000; Niederehe and Schneider 1998).

Clinical and empirical evidence support the benefits of psychodynamic psychotherapy for patients with cancer (Donnelly et al. 2000; Fitzpatrick 1999; Hay and Passik 2000; Postone 1998), HIV/AIDS (Blechner 1997), diabetes (Goodheart and Lansing 1997; Moran et al. 1991), irritable bowel syndrome (Guthrie 1996; Guthrie et al. 1991), rheumatoid arthritis (Alpay and Cassem 2000; Goodheart and Lansing 1997), and other chronic medical conditions (Goodheart and Lansing 1997). Patients with personality disorders, treatment-resistant somatic symptoms, and chronic medical illnesses may be good candidates for brief or long-term psychodynamic therapy (Compas et al. 1998; Gabbard 1994; Guthrie 1996; Kaplan et al. 1994; Levenson 1995; Milrod et al. 2000; Niederehe and Schneider 1998). Long-term supportive dynamic therapy is appropriate for patients with complex chronic medical illnesses because it improves patient management, service utilization, treatment compliance, anxiety management, and support for the patient and the family (van Marle and Holmes 2002). For example, a dynamic intervention with rheumatoid arthritis patients combining supportive techniques during an acute attack with interpretive, insight-oriented techniques in between has been effective in symptom management (Kaplan et al.

1994). Psychodynamic therapy has also been useful in treating anxiety and depression in medically ill elderly patients (Niederehe and Schneider 1998; Stern and Lovestone 2000; Thompson et al. 1987). Dynamic principles can inform interventions for patients with brain damage or early dementia by addressing the impaired self and altered object relationships (Gabbard 1994) and in terminal illness by easing a patient's loneliness and isolation (Blechner 1997; Donnelly et al. 2000).

### *Individual Supportive-Expressive Therapy*

Supportive interventions are indicated for patients who are newly diagnosed with a life-threatening illness, acutely ill, terminal, cognitively impaired, seriously mentally ill, or lacking the ego strength and psychological-mindedness necessary for more expressive techniques (Bemporad and Vasile 1990; Gabbard 1994; Kaplan et al. 1994). The primary goal of supportive psychotherapy during an acute crisis is to return the patient to premorbid functioning by strengthening existing defenses, providing ego support and reality testing, and encouraging more adaptive object relationships (Gabbard 1994; Kaplan et al. 1994). Supportive interventions are designed to help the patient identify and express affect, cope with treatment demands, strengthen support systems, explore existential issues, and restore hope (Spiegel and Yalom 1978; Spiegel et al. 2000).

The unavoidable experiences of loss (of life, health, mobility, self-esteem, body parts, sense of the self as healthy), abandonment (because relationships often change when one becomes seriously ill), helplessness, and fear that accompany serious medical illness are major sources of distress (Spiegel and Yalom 1978; Spiegel et al. 2000). Supportive therapy provides a forum for medically ill patients to express anger and fear, grieve losses, and learn to live fully in spite of medical illness (McWilliams 1999; Spiegel and Yalom 1978; Spiegel et al. 2000).

Although transference and countertransference reactions, defensive operations, and resistances should be internally monitored throughout the sessions, these processes may never be interpreted in supportive interventions (Gabbard 1994; Kaplan et al. 1994; van Marle and Holmes 2002). However, even in a clearly supportive therapy it may be necessary to confront and interpret intrapsychic processes (e.g., resistance, defensive denial) that interfere with medical treatment and the well-being of the patient (Postone 1998).

Finally, therapists should be cautious about infantilizing medically ill patients with disproportionately supportive interventions. Unhealthy dependency can be avoided by terminating patients who are stable, using more expressive interventions as the acute phase passes, or offering brief or long-term psychodynamic therapy to

patients who are interested in and able to benefit from insight (Kaplan et al. 1994; van Marle and Holmes 2002).

### *Individual Psychodynamic Treatment With Patients With Serious Medical Illness*

This discussion is focused on psychodynamic interventions with cancer patients, although these principles are applicable to patients with a broad range of illnesses. Comorbid anxiety (Andrykowski and Cordova 1998; Andrykowski et al. 1998, 2000; Koopman et al. 2002; Malt and Tjemsland 1999; Tjemsland et al. 1996a) and depression (Derogatis et al. 1983; Evans et al. 1999; Spiegel 1996; Spiegel and Giese-Davis 2003; Spiegel et al. 1994; Van't Spijker et al. 1997) have been well documented in cancer patients, although diagnosis and treatment may also activate unconscious abandonment fears, dependency conflicts, control issues, and existential concerns (Postone 1998). Psychosocial treatments for cancer patients include crisis intervention during the acute stages of disease followed by supportive-expressive therapy, psychoeducation (Blechner 1997; Goodheart and Lansing 1997; Postone 1998; van Marle and Holmes 2002), and case management as needed (Blechner 1997; Donnelly et al. 2000; Postone 1998). Psychiatrists who move comfortably between illness-related concerns, supportive interventions, and in-depth explorations of psychological functioning are most effective (Blechner 1997; Postone 1998).

From the moment of diagnosis, cancer patients are faced with multiple losses. The stress of diagnosis and treatment activates a regressed state in most patients and old conflicts and primitive defenses in others (Postone 1998). Invasive or noxious medical treatments can evoke trauma memories, triggering flashbacks or dissociative states in patients who are survivors of childhood abuse (Hay and Passik 2000; Postone 1998). Clinical judgment will determine the appropriate balance between supportive and expressive interventions during the early phase of treatment.

Beyond the acute phase, treatment can shift to insight-oriented interventions for patients who are motivated, psychologically minded, and in reasonably stable emotional and physical health (Gabbard 1994; Kaplan et al. 1994; Postone 1998). Expressive therapy with the medically ill incorporates exploration of idiosyncratic meanings the patient has attached to the illness; interpretation of here-and-now experiences in the transference; clarification and interpretation of unconscious processes underlying current distress, maladaptive behaviors, and interpersonal problems; and supportive intervention at critical junctures during the course of illness (Gabbard 1994; Kaplan et al. 1994; Postone 1998) The real object relationship, vital because the psychiatrist has provided

the patient with ego support, encouragement, and acceptance during crises, may overshadow the development of transference (Postone 1998). Positive or idealized transference is probable in cancer patients, although negative transference can develop if the psychiatrist is perceived as linked to the disease (Postone 1998). Countertransference issues to be aware of include rescue fantasies, feelings of helplessness and hopelessness, and personal conflicts about mortality (Postone 1998). The goal of therapy with cancer patients is to optimize quality of life, tend to unfinished business, strengthen important relationships, and deal with death, although the long-term goal of structural personality change is not unheard of for patients with a favorable prognosis (Postone 1998).

### ***Individual Psychodynamic Intervention***

Individual psychodynamic therapy is often the treatment of choice for individuals with personality disorders (Gabbard 1994). The present discussion focuses on a multi-component intervention for medically ill patients with borderline personality disorder. A diagnosis of a serious medical disorder such as cancer can be particularly disruptive for individuals with borderline personality disorder or other personality disorders (Hay and Passik 2000). For a patient with premorbid limitations to the observing ego, interpersonal deficits, abandonment fears, emotional dysregulation, and impulsivity (McWilliams 1994), the heightened anxiety associated with a frightening medical diagnosis can cause severe disequilibrium resulting in regressive defenses, diminished reality testing, intensified aggression and hostility, and aggravated interpersonal problems (Hay and Passik 2000). Coping with illness, hospitalization, and treatment is especially daunting for individuals who were in all probability raised in the context of chaos, neglect, and abuse (Hay and Passik 2000). Based on childhood history, these vulnerable patients expect to be abandoned, and the defenses against their intolerable anxiety and ambivalence and their splitting and other manipulative behaviors are highly disruptive in the medical setting (Hay and Passik 2000).

Psychiatrists can more effectively manage behaviors that typically disrupt treatment teams by working closely with both the patient and the medical staff (Hay and Passik 2000). Educating hospital staff about borderline pathology (etiology, abandonment fear, defenses); encouraging collaboration; providing a forum that supports the work of the treatment team and allows expression of frustration; choosing a single prescribing physician for analgesia; and encouraging staff to place strict limits on the patient's manipulative or aggressive behaviors, impulsivity, and boundary violations may forestall problems if implemented early (Hay and Passik 2000).

A multidimensional intervention that is highly structured and symptom focused is recommended (Clarkin et al. 1999; Gabbard 1994). The patient's physical and emotional well-being will be optimized by early treatment of comorbid psychiatric symptoms and pain and by tracking and intervening in the event of self-destructive acts (treatment sabotage, substance abuse, suicidal ideation, cutting), manipulateness (demanding, rejecting, entitlement), defensive behaviors (splitting, good staff/bad staff), aggression, and impaired reality testing (medical noncompliance driven by denial) (Hay and Passik 2000). Therapy will be more supportive than expressive with this population, although judicious interpretation of idealized transference, self-destructive behavior, or denial will not necessarily upset the therapeutic alliance if offered empathically and skillfully (Clarkin et al. 1999; Gabbard 1994). Helping the patient understand the negative consequences of hostility in getting needs met, modeling effective communication, intervening with physicians and staff to facilitate or repair treatment relationships, and setting limits on boundary disturbances (interfering with other patients or staff) are useful additions to the psychiatrist's existing treatment protocol (Hay and Passik 2000).

### ***Brief Psychodynamic Therapy***

The supportive-expressive model presented earlier in this section can be effectively adapted to brief treatment, with similar goals and techniques depending on the nature of the presenting problem, dynamic formulation, and psychiatric and medical history (Gabbard 1994). The duration of brief dynamic therapy ranges from a single session to 1 year of weekly sessions (Gabbard 1994; Kaplan et al. 1994). There is a growing body of empirical evidence for the utility of brief dynamic therapy with medical patients (Donnelly et al. 2000; Guthrie et al. 1991). One randomized, controlled study investigating short-term dynamic psychotherapy with gastrointestinal clinic patients with irritable bowel syndrome demonstrated significant improvement in psychological and medical status posttreatment and at 1-year follow-up for patients in the treatment condition compared with those in the usual care condition (Guthrie et al. 1991). Furthermore, the psychological changes appeared to mediate the improvement in irritable bowel symptoms in anxious and depressed patients (Guthrie et al. 1991). Time-limited dynamic therapy (Levenson 1995) and interpersonal therapy (IPT) are brief dynamic interventions that have been effective in the medically ill.

### ***Interpersonal Therapy***

First developed as a brief therapy for depression, IPT has been beneficial in the treatment of anxiety, personality

disorders, dysthymia, major depression, and subclinical psychiatric disturbances in medically ill patients (Alpay and Cassem 2000; Donnelly et al. 2000; Gillies 2002). Interpersonal therapy has also been useful for treating illness-related distress and interpersonal problems in patients with cancer (Donnelly et al. 2000), AIDS (Markowitz et al. 1998), rheumatoid arthritis (Alpay and Cassem 2000), and other chronic medical illnesses (Gillies 2002). Stressing the interactive nature of depression and interpersonal problems, IPT emphasizes symptom formation, relationships and social functioning, isolation, and (to a lesser degree) the developmental origins of personality traits in a flexible, short-term (16–20 weeks) intervention (Bemporad and Vasile 1990; Gillies 2002). The therapist plays the role of patient advocate and teacher, encourages affective expression, and helps patients identify relational difficulties (Alpay and Cassem 2000; Gillies 2002).

IPT with medically ill patients differs from that with nonpatients by addressing illness-related distress with or without depression, including loved ones in the treatment, facilitating interactions with medical personnel, being open to flexible scheduling (including phone sessions), and dispensing with the “sick role” called for in manualized IPT (Donnelly et al. 2000). The role transitions forced by illness can upset a patient’s constant experience of self, with repercussions ranging from loss of self-esteem and self-worth, emotional distress, and social isolation to financial uncertainty (Donnelly et al. 2000). Treatment strategies include emotional support, strengthening adaptive defenses, improving coping methods, examining the physical and psychosocial impact of illness on the patient and the family, facilitating adaptive communication in all relationships, encouraging affective expression, and assisting the patient in gaining independence (Donnelly et al. 2000). Practical interventions include providing psychoeducation, increasing sources of social support, and helping the patient and family members cope with illness and treatment demands (Donnelly et al. 2000). The goal of treatment is reducing symptoms, improving interpersonal relationships, and optimizing medical and psychosocial care (Donnelly et al. 2000; Gillies 2002). Posttreatment booster sessions with IPT have been effective in relapse prevention (Frank et al. 1990, 1991) and are recommended for patients who are medically ill (Donnelly et al. 2000).

### **Summary**

Psychodynamic theory informs psychosocial treatments specific to the medically ill. Interventions (Kuttner 1993) will differ as a function of current diagnosis, treatment, disease course, and prognosis as these factors interact with the psychological, genetic, environmental, social, and devel-

opmental aspects of the patient (Gabbard 1994; McWilliams 1994, 1999). Expressive-supportive dynamic theory may also incorporate cognitive and behavioral techniques, psychoeducation, and physician liaison, depending on the needs of the patient (Blechner 1997; Donnelly et al. 2000; Goodheart and Lansing 1997; Postone 1998). The goal is to help patients cope with current problems, alleviate symptoms, and facilitate adaptive decisions about health care (McWilliams 1999).

### **Hypnosis**

Hypnosis is an altered state of consciousness that comprises heightened absorption in focal attention, dissociation of peripheral awareness, and enhanced responsiveness to social cues (Spiegel and Maldonado 1999).

Hypnosis has a long tradition of effectiveness in controlling somatic symptoms such as pain and anxiety (Faymonville et al. 1995; J. Holroyd 1996; Kuttner 1993). According to Patterson and Jensen (2003), in their recent authoritative review, “Randomized controlled studies with clinical populations indicate that hypnosis has a reliable and significant impact on acute procedural pain and chronic pain conditions” (p. 495).

Patients with the requisite hypnotic capacity can be taught to use self-hypnosis to reduce or eliminate pain and the tension that accompanies it (Maldonado and Spiegel 2000). Hypnotic analgesia seems to work via two mechanisms: physical relaxation and attention control. Patients in pain tend to splint the painful area instinctively, and yet this enhanced muscle tension around a painful area often increases pain. Most patients find that they can enhance their physical repose by focusing on a variety of images that connote physical relaxation, such as a sense of floating. Because hypnosis involves an intensification and narrowing of the focus of attention, it allows individuals to place pain at the periphery of their awareness by replacing it with some competing thought or sensation at the center of their attention. Thus, by focusing on a memory of dental anesthesia and spreading that numbness to the affected area, making the area warmer or cooler, substituting a sense of tingling or lightness, or focusing on sensation in some nonpainful part of the body, hypnotized individuals can diminish the amount of attention they pay to painful stimuli. Such hypnotic techniques have been shown to effectively reduce cancer pain in adults (Spiegel and Glafkides 1983) and procedural pain and other symptoms in children (Zeltzer and LeBaron 1982; Zeltzer et al. 1984). Hypnotic intervention actually alters perceptual processing in the brain, with reduced response to painful stimuli as measured by event-related potentials (Spiegel et al. 1989) and positron emission tomography (Rainville et al. 1999).

Because of its analgesic and anxiolytic properties, hypnosis is an effective tool in facilitating medical procedures. For example, Lang and colleagues (2000) demonstrated in a randomized prospective trial that the addition of training in self-hypnosis for individuals undergoing invasive radiological procedures resulted in significantly less pain and anxiety, fewer procedural complications, less use of analgesic medication, and saved an average of 17 minutes per procedure.

Hypnosis has also been effective in reducing symptoms in irritable bowel syndrome (Whorwell et al. 1984) and asthma (Morrison 1988) and in smoking control (Spiegel et al. 1993). Given the dissociative nature of many conversion symptoms, such as nonepileptic seizures (Bowman and Markand 1996), hypnosis is helpful in both their differential diagnosis and treatment (Barry and Sanborn 2001; Barry et al. 2000; Spiegel 2000). Thus, hypnosis is a particularly effective tool for symptoms among the medically ill because of its ability to help patients enhance control over mind/brain/body interactions (Greenberg et al. 1993; Kosslyn et al. 2000).

## Family Therapy

The psychosocial impact of medical illness on families cannot be overestimated. The family is an integral force in personality development; a primary source for meeting basic human needs for relationship, self-expression, and meaning; and a complex, evolving system that strives for equilibrium (Foley 1989; Rolland 1989). It is not surprising that the psychosocial problems associated with medical illness extend to family members. In fact, from a family systems perspective, medical illness, especially if it is chronic, becomes part of the system (Rolland 1989). A diagnosis of major illness will always upset a family's equilibrium, but the impact on the family system differs by diagnosis, onset (acute or chronic), course (progressive or episodic), prognosis, level of incapacitation, and the idiomatic characteristics of the family (Rolland 1989). For example, the sudden onset of acute MI requires immediate attention to the existing family structure and role changes, whereas the progressive course of diabetes or multiple sclerosis enables a slow, gradual adjustment to these systemic processes (Rolland 1989). The diagnosis of catastrophic illness in a loved one can be overwhelming for any family, and healthier families tend to return to usual functioning with social and emotional support. Conversely, the presence of preexisting problems in communication, interpersonal conflicts, and abandonment issues are intensified by the stress of medical illness (Kaplan et al. 1994).

While the patient experiences illness-related stress and dependency fears, the family is affected by the burden

of patient care, managing the household, and the existential fears associated with critical illness (Lehrer et al. 2002). Symptoms of anxiety and depression are common in family members caring for a loved one with cancer or other life-threatening disease (Donnelly et al. 2000; Kaplan et al. 1994; Marx et al. 2001). An illness with a progressive course requires constant adaptation and shifting roles as the illness advances, with little respite from symptoms (Rolland 1989). In recent years the field of psychoncology has been addressing emotional reactions, stress management, and caregiver burden in the family members of cancer patients (Holland 2002). A growing body of clinical and empirical evidence points to the utility of family therapy as a supportive intervention during the acute phase of medical illness, a preventive intervention for families at risk for psychiatric morbidity, and a therapeutic intervention for families with existing dysfunction (Bloch and Kissane 2000; Duff 2001; Goodheart and Lansing 1997; Kazak et al. 1999; Kissane et al. 1998; Lehrer et al. 2002; Radojevic et al. 1992; Shapiro 2002; Wysocki et al. 2001).

Family and couples therapies have been effective for patients and families living with cancer, asthma, cystic fibrosis, rheumatoid arthritis, type 2 diabetes, kidney disease, and somatoform disorders (Bloch and Kissane 2000; Donnelly et al. 2000; Duff 2001; Gonder-Frederick et al. 2002; Hener et al. 1996; Kazak et al. 1999; Keefe et al. 2002; Kissane et al. 1998; Kurnat and Murphy Moore 1999; Lehrer et al. 1992; Looper and Kirmayer 2002; Marchioro et al. 1996; Shapiro 2002; Wysocki et al. 2001). For example, an intervention with patients with rheumatoid arthritis treated with a combination of supportive family therapy and CBT resulted in improvements in joint swelling and pain at 2-month follow-up (Radojevic et al. 1992). A study comparing a supportive intervention, CBT, and a no-treatment control in dialysis patients and their partners found superior adjustment to home peritoneal kidney dialysis in both treatment groups (Hener et al. 1996).

## *Treatment Strategies*

Family or couples therapy addresses the family interactions that may contribute to sickness (Looper and Kirmayer 2002), such as exacerbation of asthma (Lehrer et al. 1992, 2002) or poor control of diabetes (Wysocki et al. 2001). Family therapy with the medically ill is a time-limited, problem-focused, collaborative intervention informed by the psychiatrist's theoretical orientation; the diagnosis, treatment, and phase of illness; the patient's premorbid character, life cycle stage, and family role; the impact of illness, level of adaptive coping, and quality of family support; historical beliefs about disease and death;

the role of illness in the family system (e.g., illness behavior reinforced, overindulgence or isolation of the sick family member); and the premorbid and current state of family functioning (Foley 1989; Goodheart and Lansing 1997; Nichols and Schwartz 1991; Rolland 1989). A multimodal family intervention facilitating structural change in a dysfunctional system will help family members adapt to the changing needs of the patient while remaining uncontrolled by the disease (Goodheart and Lansing 1997). Adjunct interventions such as individual therapy, outside sources of support (support groups and self-help groups), and respite care also contribute to adaptive functioning of families (Goodheart and Lansing 1997).

### *Family Therapy With Seriously Ill Children*

Serious chronic illnesses such as juvenile diabetes, some cancers, and childhood asthma tend to disrupt family systems, and family dysfunction can exacerbate the illness. Certain family dynamics have been implicated in acute asthma attacks in some children (Lehrer et al. 2002). Family dysfunction dominated by interpersonal problems, parental criticism, lack of affection, and parental psychopathology has been linked to poor treatment adherence and symptom exacerbation in asthmatic children, just as the stress of adapting to the needs of a family member with asthma can also lead to family disharmony (Lehrer et al. 2002). A child with life-threatening asthma may be overprotected by one or both parents, creating potential for secondary gain for the patient, possible exacerbation of symptoms, and sibling resentment (Rolland 1989). Fortunately, family therapy has been helpful in managing asthma in children (Duff 2001; Lehrer et al. 1992, 2002).

Serious illness interferes with normative developmental processes in children and adolescents (Goodheart and Lansing 1997). Frequent hospitalizations, restricted physical activity, and complex treatment protocols often leave sick children and adolescents feeling different from peers, particularly if the disease is visible (e.g., seizure disorders, certain cancers) (Duff 2001; Goodheart and Lansing 1997). Chronically ill children are vulnerable to developmental deficits, low self-esteem, interpersonal problems, isolation, and psychopathology (Duff 2001; Goodheart and Lansing 1997). Combined individual and family therapy addressing developmental, psychosocial, and behavioral problems in medically ill children is recommended (Duff 2001; Goodheart and Lansing 1997). Although behavioral and cognitive-behavioral techniques that focus on illness-related problems and parenting skills have been effective, a developmental approach utilizing expressive methods is more suitable for patients who are uncooperative with CBT or have severe depression and anxiety, developmental arrest, or enduring characterolog-

ical problems (Duff 2001; Goodheart and Lansing 1997). Another family systems intervention shows clinical promise in the prevention and treatment of psychosocial problems associated with asthma and cystic fibrosis (Duff 2001). This multimodal intervention, which utilizes psychoeducation; open discussion about the interactive effect of feelings, thoughts, beliefs, and behaviors; communication skills training; and examination of strengths, relationships, expectations, and roles within the family is currently under investigation (Duff 2001). The goal of therapy with sick children is to allow them to experience as much normality as possible, given the circumstances of chronic disease, treatment, emergencies, and disability, in order to help them develop normally even in this context (Goodheart and Lansing 1997).

### *Summary*

Important topics in family therapy with a medically ill member include current stressors, affective symptoms, grief and loss, communication patterns and dysfunctional interactions, and the role of the illness in the family system (e.g., illness behavior reinforced, overindulgence or isolation of the sick family member). The goal of family therapy is to establish constructive communication, improve interpersonal relationships among family members, and effect positive change in the structure of the system (Foley 1989).

### *Cognitive-Behavioral Therapy*

Whereas the psychodynamic school sees the core structures of personality and psychopathology as unconscious and not easily accessible to the patient, the cognitive-behavioral view holds that these structures are largely in the realm of awareness and available for conscious examination (Freeman 1990; Hollon and Beck 1994). In Beck's cognitive model, previous social learning, developmental history, and significant experiences lead people to form a unique set of meanings and assumptions, or cognitive schemas, about themselves, the world, and the future (Beck and Weishaar 1989; Freeman 1990; Hollon and Beck 1994). These schemas are then used to organize perception and to govern and evaluate behavior (Hollon and Beck 1994). When specific schemas are activated, they directly influence the content of a person's perceptions, interpretations, associations, and memories from a given time (Beck and Weishaar 1989; Hollon and Beck 1994). Personality is understood as a set of cognitive schemas that predispose people to certain emotional disorders (Hollon and Beck 1994). For example, depression results from cognitions of sadness and loss, whereas anxiety is a function of an exaggerated sense of fear and danger—

important differences when defining the treatment focus (Hollon and Beck 1994). Assumptions that are extreme, dysfunctional, and resistant to change are thought to underlie and maintain some psychiatric disorders.

CBT was developed as a short-term (12–20 sessions) intervention for depression targeting patients' thoughts and their relation to behavior and affect (Hollon and Beck 1994). The efficacy of CBT as a treatment for depression is well established (Craighead et al. 1998), and cognitive, cognitive-behavioral, and behavioral interventions have been beneficial in addressing psychosocial problems associated with medical illness (Hollon and Beck 1994). Symptoms of major depression have been alleviated with CBT in patients with rheumatic diseases (e.g., rheumatoid arthritis, fibromyalgia), chronic fatigue syndrome (Alpay and Cassem 2000), type 2 diabetes (Lustman et al. 1998), and elderly medically ill patients (Niederehe and Schneider 1998). Cognitive-behavioral techniques have also been effective in the management of tension headache (K.A. Holroyd 2002), hypochondriasis (Simon et al. 2001), and a range of other somatoform disorders (Looper and Kirmayer 2002). Cognitive-behavioral interventions with patients who have osteoarthritis (Keefe et al. 2002) or rheumatoid arthritis (Keefe et al. 2002; Young 1992) have resulted in improved coping (e.g., stress management and pain management) and reduced anxiety and depression. A recent review concluded that CBT is efficacious for chronic pain management in rheumatic diseases, chronic pain syndrome, and low back pain and possibly efficacious for irritable bowel syndrome and some cancers (Compas et al. 1998). CBT has yielded substantial improvements in the disease course of a number of illnesses (Emmelkamp and van Oppen 1993).

### ***Cognitive-Behavioral Therapy and Medical Illness***

CBT for medically ill patients can be adapted to meet the patient's needs at a given time. Initially, the therapy may concentrate on alleviation of symptoms of distress, anxiety, and depression (Hollon and Beck 1994). For some patients, the treatment focus may be on psychosocial issues that act as barriers to optimal care, treatment adherence, and quality of life (Hollon and Beck 1994). In that case, enhancing self-care is an important goal that can be best attained through interventions developed on the basis of social learning and self-regulation theories (Glasgow et al. 1989; Tobin et al. 1986; Von Korff and Simon 1996; Von Korff et al. 1997). Cognitive and cognitive-behavioral techniques are indicated for patients who are adjusting to diagnosis, coping with unpleasant medical procedures or chemotherapy-induced nausea, in rehabilitation following brain injury, and for HIV prevention (Hollon and Beck 1994). Cognitive-behavioral interventions with

cancer patients generally include relaxation training and instruction in stress management and coping skills (Hollon and Beck 1994), although some address the issues of health education, communication, assertiveness, management of emotions, or psychosocial support in a group format (Compas et al. 1998). There is evidence for the need to incorporate medical management, such as treatment options and compliance, into the intervention in order to optimize the likelihood of treatment success (Lustman et al. 1998). For example, in treating a depressed patient with type 2 diabetes, it is especially important to integrate diabetes-related concerns into the therapy (Lustman et al. 1998). Treating a patient with a somatoform disorder may require repeatedly helping him or her question the evidence for maladaptive assumptions and cognitive distortions that underlie physical symptoms. For example, a hypochondriacal patient who is convinced he has a life-threatening disease will anxiously check his body repeatedly and perceive even normal body sensations as danger signals portending severe illness (Kaplan et al. 1994; Salkovskis 1989).

### ***Summary***

Cognitive, behavioral, and CBT techniques have demonstrated clinical utility in treating anxiety and depression, increasing treatment compliance, and coping with diagnosis and noxious treatments in the medically ill.

## Psychoeducational Interventions

Group sessions that were held in the early 1900s for tuberculosis patients—interventions that involved educational as well as expressive components—educational interventions could be considered precursors to group psychotherapy for medically ill patients (Scheidlinger 1993). The provision of knowledge related to the illness has long been recognized as important, especially for information-focused coping. Psychoeducational interventions are designed to expand understanding of the mechanisms at work in the disease, improve treatment adherence, and enhance the sense of control and mastery a patient has over his or her disease. For example, interventions that reinforce information from the physician can be useful for patients navigating the difficult treatment regimen of diabetes or to reinforce safer-sex practices in HIV-positive patients. For noxious medical procedures, advanced information about the procedure, including what sensations to expect and why, may increase the coping abilities of the patient. Moreover, proposing cognitive or behavioral strategies to use during the procedure can further improve the patient's sense of control and adjustment (Taylor and Clark 1986). However, increased knowledge

may have negative consequences, increasing stress and worry or inducing feelings of anxiety in particular individuals (Miller 1987) or circumstances (Burger 1989).

A variety of psychoeducational interventions have been proposed for people with medical illnesses. Many target psychosocial as well as medical factors in helping patients cope with the daily stresses of illness. Although they share some similarity across diseases, particular features are often quite disease specific in terms of goals and outcomes. Purely educational interventions have not always been sufficient for promoting adjustment to illness or improving quality of life and/or medical status (Kraimaat et al. 1995). Psychoeducational interventions for medical patients are usually more effective when they combine illness-specific knowledge and cues that will assist patients in the daily management of their disease (De Ridder and Schreurs 2001) or offer emotion-focused components that help them adjust to and live through the different phases of the illness. Problem-focused interventions may be particularly appropriate for diseases such as diabetes or asthma, in which the patient is responsible for essential aspects of treatment (Diabetes Control and Complications Trial Research Group 1993). Psychological interventions enable cognitive processing of medical information, support emotional adjustment to disease-related changes in daily life, and encourage the patient to take an active and collaborative role in his or her own care (e.g., performing daily tasks required by complex medical regimens, taking part in medical decision making, and communicating effectively with doctors and family).

Psychoeducational interventions often feature a combination of education and cognitive-behavioral techniques. These interventions are generally offered in a group format, and although they share some features with group psychotherapy (provision of social support, universality, helper-therapy principle), they tend to be more structured than psychotherapy per se. The goals of psychoeducational interventions may include modifying medical knowledge, health behaviors, and beliefs and improving treatment adherence, emotional adjustment, and communication. Depending on the type of intervention and on the illness, these interventions may focus on psychosocial variables (reducing anxiety and depression, enhancing self-efficacy or quality of life) or more directly on medical status and physiological factors (improving blood glucose control, respiratory capacity, or immunological status).

## Psychosocial Treatment Outcomes

---

During the past two decades, several investigators have attempted to assess the efficacy of psychotherapy for the

medically ill. Since the early studies evaluating the impact of group psychotherapy for cancer patients (Spiegel et al. 1989), interest in psychotherapeutic interventions for medical patients has been extended to a large number of other chronic illnesses. Many different types of psychosocial interventions are now available for the medically ill, although evaluation of psychotherapy outcomes has been hampered by enormous variability between studies. Psychosocial interventions appear to benefit patients with cancer (Andersen 1992; Andersen et al. 1994; Ashby et al. 1996; D.G. Cruess et al. 2000b; Devine and Westlake 1995; Fawzy et al. 1995; Greenberg et al. 1993; Kibby et al. 1998; Linden et al. 1996; Meyer and Mark 1995; Spiegel et al. 1981, 1989), heart disease (Dusseldorp et al. 1999; Ketterer 1993; Linden et al. 1996), diabetes (Delamater et al. 2001; Gonder-Frederick et al. 2002; Moran et al. 1991), arthritis (Astin et al. 2002; Bradley and Alberts 1999; Keefe et al. 2002; McCracken and Turk 2002; Parker et al. 1993), and HIV/AIDS (Antoni et al. 1991; Chesney et al. 1996; D.G. Cruess et al. 2000a, 2000c; S. Cruess et al. 2000; Esterling et al. 1992; Kelly et al. 1993; Lutgendorf et al. 1997). We review studies focusing on psychosocial interventions in primary care patients, cancer, heart disease, diabetes, arthritis, and HIV. Our goal is to present an overview of interventions that have the potential of leading to improved psychological or medical outcomes.

## Primary Care

The need for psychosocial interventions in primary care is clear (Meredith et al. 1997; Saravay 1996; Sherbourne et al. 1996a, 1996b). Emotional distress has a negative impact on patients' medical symptoms, interferes with psychosocial functioning, and contributes to rising health care costs, yet psychiatric symptoms continue to be underdiagnosed and untreated by primary care providers (Coyne et al. 2002; Saravay 1996). A survey of depressed and anxious primary care patients found that a surprising 54.6%–72.9% receive no help from their physicians for personal or emotional problems (Evans et al. 1999). Yet negative treatment outcomes have been described in depressed primary care patients with asthma, diabetes, headache, and back pain (Koike et al. 2002). In one randomized, controlled study, depressed, chronically ill primary care patients were randomized into one of two treatment conditions (IPT or nortriptyline) or a control condition (usual physician care) (Coulehan et al. 1997). Remission of major depression was reported in 70% of the participants in both treatment conditions compared with 20% in the usual care condition at an 8-month follow-up (Coulehan et al. 1997).

## Cancer

As treatments continue to improve, cancer is becoming more a chronic than a terminal illness. However, given the progressive nature of the disease, and the fact that approximately half of all people diagnosed with cancer will eventually die of it, the provision of effective psychosocial support is even more important. During the past 20 years, a growing number of research studies (summarized in Tables 38-1 and 38-2) assessing the benefit of psychosocial interventions for cancer patients have been conducted (Andersen 1992; Andersen et al. 1994; Ashby et al. 1996; Devine and Westlake 1995; Fawzy et al. 1995; Kibby et al. 1998; Linden et al. 1996; Meyer and Mark 1995). There is clear evidence that these interventions have a positive effect on psychological distress (Ferlic et al. 1979; Gustafson and Whitman 1978; Mulder et al. 1992; Spiegel and Bloom 1983; Spiegel et al. 1981; Wood et al. 1978), coping skills (Fawzy et al. 1993), and quality of life (Spiegel and Bloom 1983; Spiegel and Glafkides 1983). Psychoeducation and cognitive-behavioral interventions for cancer patients have led to improved treatment adherence (Richardson et al. 1990), stress reduction and enhanced psychological well-being (Allen et al. 2002; Elsesser et al. 1994; Helgeson et al. 1999; Larsson and Starrin 1992; McQuellon et al. 1998), and encouraging medical outcomes (Fawzy et al. 1993; Kuchler et al. 1999; McCorkle et al. 2000; Richardson et al. 1990).

### *Treatment Adherence*

Despite the paucity of research on adherence to cancer treatment, it is an essential factor affecting disease outcome (Andersen et al. 1994). An early intervention study revealed that any one of three treatments (education, shaping of pill-taking behavior, or home visits) enhanced adherence to daily pill taking and follow-up visits (Richardson et al. 1987). Although patient knowledge was improved in each intervention group, the researchers pointed out that compliance was not directly affected by knowledge alone but rather by the behavioral components of the interventions (Richardson et al. 1987). Interventions designed to combat side effects of cancer treatment are important for improving treatment adherence (Fallowfield 1992). During the 1980s and 1990s, progressive muscle relaxation, with or without guided imagery, was considered efficacious in managing nausea and vomiting associated with chemotherapy (Carey and Burish 1988; Burish and Tope 1992). However, with newer antiemetic medications, the utility of psychological treatments in managing nausea and vomiting is less clear (Compas et al. 1998). For some patients, however, a combination of medication and behavioral techniques further reduces the nox-

ious effects of cancer treatments, especially anticipatory nausea in chemotherapy patients (Compas et al. 1998).

### *Distress*

A variety of psychosocial interventions have been helpful in reducing emotional distress in cancer patients (Allen et al. 2002; Elsesser et al. 1994; Larsson and Starrin 1992; McArdle et al. 1996). Even a minimal intervention such as a brief orientation tour led by a psychologist resulted in decreased anxiety, mood disturbance, and depressive symptoms in new medical oncology clinic patients (McQuellon et al. 1998). One study in which cancer patients received a minimal form of relaxation training resulted in significant improvement in mood and daily hassles and appraisal of radiation therapy as less threatening (Larsson and Starrin 1992). A recent randomized, controlled study of a cognitive-behavioral problem-solving intervention (an initial 2-hour in-person session followed by four telephone contacts, and a final 2-hour in-person session) for young women (age <50 years) with breast cancer resulted in improvements in mood, physical side effects, marital and sexual difficulties, and psychological problems at 4 months posttreatment (Allen et al. 2002). However, at the 8-month follow-up, treatment effects held only for women with moderate or good problem-solving ability, whereas women with high problem-solving skills received no benefit and women with low problem-solving skills were actually negatively affected by the intervention (Allen et al. 2002).

Finally, a program integrating psychoeducation, CBT, and family therapy for adolescent survivors of childhood cancer and their families has been positively received in early trials (Kazak et al. 1999). Families participate in a 1-day, 8-hour family group intervention focused on prevention of posttraumatic stress disorder, developmental deficits, and family dysfunction resulting from cancer (Kazak et al. 1999).

### *Coping*

Helgeson and colleagues (1999) compared an eight-session education-based group providing informational support and relaxation training, a peer discussion-based group, and a combination of the two for women with breast cancer. The educational intervention facilitated initial adjustment in early-stage breast cancer patients, whereas the peer discussion group resulted in adverse effects. Education increased the patients' self-esteem, body image, perceived control, and reduced uncertainty about the illness. In another study, a multimodal cognitive-behavioral stress management (CBSM) group for women with breast cancer, combining 20 therapy hours of cognitive restructuring, relaxation, coping skills, assertiveness, anger man-

**TABLE 38–1. Psychosocial interventions in cancer**

<b>Study</b>	<b>Participants</b>	<b>Diagnosis</b>	<b>Type of intervention</b>	<b>Results of intervention</b>
Richardson et al. 1987	92 patients	Multiple myeloma, leukemia, lymphoma, or Hodgkin's disease	Compare combined education; shaping of pill-taking behavior; home visit	Improved adherence to daily pill-taking and follow-up visits in the three intervention groups
Richardson et al. 1990	94 patients	Hematological malignancies, newly diagnosed	Educational intervention: 1-hour session with nurse plus pill-taking procedure; home visit to organize "cueing" system for pill taking; or both, to increase treatment compliance	Low severity of disease and high compliance predicted increased survival for the three modalities
Larsson and Starrin 1992	64 patients	Breast cancer	Minimal form of relaxation training	Improvement in daily hassles, mood, appraise radiation as less threatening
Gruber et al. 1993	13 women	Stage I breast cancer	"Enhanced" relaxation, PMR/guided imagery exercises; electromyographic biofeedback	Positive endocrine/immune (higher cell counts, blastogenesis/lower cortisol); no differences in psychological measures
Fawzy et al. 1993	68 patients	Malignant melanoma	6- to 8-week CBSM group intervention shortly after surgery	Longer survival and recurrence times in treatment group
Elsesser et al. 1994	20 patients	Cancer, heterogeneous	6-week anxiety management training, PMR/cognitive restructuring	Significant reduction in anxiety (state and trait); no differences in depression, quality of life, or cell counts
McArdle et al. 1996	272 patients	Breast cancer surgery patients	Supportive nursing versus cancer patient volunteer support (pre- and postsurgery)	Improved self-report health and depressive symptoms in nursing condition
McQuellon et al. 1998	180 patients	Cancer, heterogeneous	Orientation tour for patients new to a medical oncology clinic	Reduction of state anxiety, mood disturbance, and depressive symptoms
Helgeson et al. 1999	312 women	Breast cancer	Educational/informational support group versus peer discussion group	Educational intervention increased self-esteem, body image, perceived control
Kuchler et al. 1999	271 patients	Gastrointestinal cancer, heterogeneous	Individual/inpatient psychotherapy (coping, support, and information on transition to recovery)	Increased survival (especially among women) in treatment group
Allen et al. 2002	164 women	Stages I–III A breast cancer; age <50 years	Individual cognitive-behavioral problem solving (a 2-hour one-on-one session, four phone contacts, and a final 2-hour one-on-one session)	Improved mood at 4 months in treatment group, no difference at 8 months Best with moderate level of problem-solving ability
D.G. Cruess et al. 2000b	34 women	Stage I or II breast cancer	See Antoni et al. 2001	Reduced cortisol levels in treatment group

**TABLE 38–1. Psychosocial interventions in cancer (continued)**

<b>Study</b>	<b>Participants</b>	<b>Diagnosis</b>	<b>Type of intervention</b>	<b>Results of intervention</b>
Larson et al. 2000	41 women	Breast cancer	Two presurgery support sessions, relaxation, information, problem solving	Lower declines in interferon-gamma production postsurgery in treatment group
McCorkle et al. 2000	375 patients	Solid cancers	Patient education, emotional and social support, and monitoring of physical and emotional activity provided during 4 weeks by nurses	No difference in survival with early stage patients versus improved survival in late stage patients
Antoni et al. 2001	136 patients	In situ disease or stage I or II breast cancer	CBSM group treatment, support, relaxation training, coping skills, cognitive restructuring, assertiveness and anger management training	No improvement in distress, self-reports of positive benefits, especially in patients low in optimism

*Note.* CBSM= cognitive-behavioral stress management; PMR=progressive muscle relaxation.

**TABLE 38–2. Randomized trials examining the hypothesis that psychosocial treatment affects cancer survival time**

<b>Study</b>	<b>Cancer type</b>	<b>Sample size</b>	<b>Psychotherapeutic intervention</b>	<b>Psychological outcome</b>	<b>Survival outcome</b>
Linn et al. 1982	Lung, pancreatic, skin, sarcoma, leukemia, lymphoma	120	Individual existential psychotherapy	Improvement in depression, self-esteem, life satisfaction, alienation, locus of control	No difference
Spiegel et al. 1989	Metastatic breast	86	Supportive-expressive group therapy	Reduced anxiety and depression (POMS), improved coping, reduced pain	Hazard ratio for treatment = 0.51 (95% CI=0.31–0.82)
Richardson et al. 1990	Lymphoma, leukemia	94	Education, home visiting	Improved treatment adherence	RR = 0.39, independent of adherence
Fawzy et al. 1993	Malignant melanoma	66	Cognitive-behavioral group therapy emphasizing active coping skills training	Reduced anxiety and depression (POMS), improved coping	Improved at 4- and 10-year follow-up
Ilnyckyj et al. 1994	Breast, lymphoma, colon, ovarian	127	Heterogeneous group therapies, some leaderless	No benefit	No difference
Cunningham et al. 1998	Metastatic breast	66	Cognitive-behavioral therapy combined with supportive-expressive therapy	Increased anxious preoccupation and decreased helplessness in treatment group	No difference
Kuchler et al. 1999	Gastrointestinal	271	Individual psychotherapy at the time of diagnosis	Unreported	Hazard ratio for intervention group = 0.6 (95% CI= 0.45–0.84)
Edelman et al. 1999	Metastatic breast	124	Cognitive-behavioral therapy	Transient improvement in POMS	Interquartile range = 0.97 (0.59–1.46); no difference
McCorkle et al. 2000	Solid	375	Disease management and psychological support via three home visits and five telephone contacts	Unreported	RR of death for control subjects = 2.04 (95% CI= 1.33–3.12)
Goodwin et al. 2001	Metastatic breast	235	Supportive-expressive therapy	Improvement in distress on POMS but not EORTC; reduced pain	Hazard ratio for treatment = 1.06 (95% CI=0.78–1.45)

*Note.* CI=confidence interval; EORTC=European Organisation for Research and Treatment of Cancer Quality-of-Life Measure; POMS=Profile of Mood States; RR=relative risk.

agement training, and social support, resulted in self-reported improvements in perceived benefits from their experience with cancer (e.g., enhanced sense of purpose and meaning, better family relationships, and altered life priorities), although no improvement in distress was noted. Women who scored low on an optimism scale at baseline reported the most benefit from the intervention (Antoni et al. 2001).

A pilot study for an intervention with IPT adapted for cancer patients has been helpful for patients and their partners in early trials (Donnelly et al. 2000). Female outpatients undergoing an aggressive treatment regimen for metastatic breast cancer ( $n=14$ ) and their partners ( $n=11$ ) participated in individual telephone IPT sessions coinciding with chemotherapy and continuing 4 weeks after treatment. Therapy focused on salient psychosocial issues (distress, family concerns, coping with illness and treatment demands, relationships with medical personnel), and overall the patients rated the intervention from good to excellent. Partners reported that the telephone contact was their only outlet to help them cope with role transitions, anticipated losses, depression and anxiety, and feelings of fear, anger, and frustration (Donnelly et al. 2000).

Family grief therapy, an empirically derived preventive intervention for families of cancer patients at risk for complicated bereavement, has also shown clinical promise in preliminary investigations (Bloch and Kissane 2000; Kissane et al. 1998). The treatment focused on current problems and concerns and family dynamics; beliefs about illness, death, and grief; and expression of negative affect, with the goal of improved coping, enhanced communication, increased cohesiveness, and more adaptive family functioning (Bloch and Kissane 2000; Kissane et al. 1998). Finally, a nonrandomized trial of an intervention for adolescent survivors of childhood cancer and their families received positive feedback from participants in a preliminary trial, who reported reduced anxiety and post-traumatic stress disorder symptoms at 6-month follow-up (Kazak et al. 1999).

### **Medical Effects**

There is a small but surprising literature that raises the possibility that psychotherapeutic intervention may affect survival time as well as quality of life (Fawzy et al. 1993; Kuchler et al. 1999; McCorkle et al. 2000; Richardson et al. 1990; Spiegel et al. 1989). To date, 5 of 10 published randomized trials demonstrate such an effect (see Table 38-2) (Giese-Davis et al. 2002). To their initial surprise, Spiegel and colleagues (1989) found that 1 year (minimum) of supportive-expressive group psychotherapy resulted in a significant 18-month increase in survival time in metastatic breast cancer patients. In another study, a 6-

week cognitive-behavioral group intervention composed of education, stress management, coping skills training, and psychological support for malignant melanoma patients found significantly lower death rates at the 5–6 year follow-up in the treatment group (Fawzy et al. 1993). Interestingly, in this study, patients with higher baseline levels of distress seemed to experience lower rates of disease recurrence and death (Fawzy et al. 1993). An educational intervention aimed at increasing compliance with cancer treatment also had beneficial effects on survival in patients with newly diagnosed hematological cancer (Richardson et al. 1990). A recent study of individual psychotherapeutic support offered to a group of gastrointestinal cancer inpatients also yielded favorable results (Kuchler et al. 1999). In this study, standard care was supplemented with counseling (information on coping, transition to recovery, and emotional support) conducted at bedside by psychotherapists. At 2-year follow-up, the experimental group (especially female patients) experienced better survival than the control group (49% had died in the experimental group as opposed to 67% in the control group) (Kuchler et al. 1999). Finally, in a 4-week intervention consisting of patient education, psychological support, and implementation of a community-based network of support services, McCorkle and colleagues (2000) found improved survival in late-stage cancer patients, although no difference in survival time was found in patients with early-stage cancer.

Conversely, five other trials found no enhanced survival with psychosocial intervention. One excellent multicenter trial using supportive-expressive group psychotherapy with metastatic breast cancer patients showed reduced distress and pain but no survival advantage (Goodwin et al. 2001). However, the controversy over whether psychotherapy can increase survival should not obscure the finding that essentially every well-conducted study of psychotherapy in cancer patients—even studies showing no survival advantage—has found improved quality of life or reduced distress. Nevertheless, the potential benefits of psychotherapeutic support on cancer progression remains an important but unresolved research question (see also Chapter 24, “Oncology”).

### **Heart Disease**

Large prospective studies have shown an association among depressed affect, hopelessness, and ischemic heart disease (Anda et al. 1993) and among anxiety, phobic anxiety, and fatal coronary disease (Kawachi et al. 1994). Hostility has been linked to severity and progression of coronary artery disease as well as myocardial ischemia (Helmers et al. 1993; Julkunen et al. 1994; Suarez et al. 1998; Williams et al. 1985). There is now compelling evidence that psycho-

social factors play an important role in the development and progression of heart disease. The addition of psychosocial treatment to standard cardiac care and rehabilitation has helped reduce morbidity and mortality, psychological distress, and some biological risk factors (Dusseldorp et al. 1999; Ketterer 1993; Linden et al. 1996).

Although studies published in the 1980s suggested that psychosocial interventions were valuable additions to usual medical care (Frasure-Smith and Prince 1985; Friedman et al. 1986), recent large, well-controlled trials have not yielded significant intervention effects (e.g., no reduction in cardiac deaths) (Frasure-Smith et al. 1997; Jones and West 1996). However, the exclusive focus on cardiac recurrences and mortality may underestimate intervention effects by overlooking positive psychological outcomes (Smith and Ruiz 2002). Despite some inconclusive results about the effects of psychological interventions on medical outcomes in heart disease, the literature supports the efficacy of psychosocial interventions in attenuating stress and enhancing quality of life (Dusseldorp et al. 1999; Linden 2000; Smith and Ruiz 2002). Studies in this area are summarized in Table 38-3. For example, an individual cognitive-behavioral intervention consisting of one or more sessions of relaxation training, stress management, behavioral risk reduction, treatment compliance, and cognitive interventions (e.g., identifying sources of distress) was provided for patients entering cardiac rehabilitation after hospitalization for angina, MI, angioplasty, or coronary artery bypass grafting (Black et al. 1998). The treatment was associated with decreased rehospitalization and depression (Black et al. 1998). A randomized, controlled trial of a brief hospital intervention (three sessions led by a psychologist) that emphasized cognitive restructuring of negative beliefs about post-MI consequences and preparation of a recovery action plan found significant changes in patients' perceptions of their MIs (e.g., length of illness and post-MI consequences on life) (Petrie et al. 2002). Patients in the intervention group returned to work sooner than those in the control group and had lower rates of angina symptoms at 3-month follow-up (Petrie et al. 2002). A nonrandomized clinical study comparing a cardiac rehabilitation program consisting of exercise, stress management, and counseling with a control group receiving standard medical care resulted in decreased negative affect over the 3-month intervention time and higher rates of survival over the following 9 years for the treatment group (Denollet and Brutsaert 2001).

Several studies of different types of multicomponent cognitive-behavioral interventions have yielded promising results in terms of functional or clinical outcomes. For

example, a controlled pilot study of a stress management intervention for elderly patients with congestive heart failure resulted in significant improvement in perceived stress, emotional distress, depression, and exercise compliance (Luskin et al. 2002). A small study of patients with heart disease receiving eight 90-minute group therapy sessions that were focused on skills training to decrease antagonism (e.g., listening), cynicism (e.g., cognitive restructuring), and anger (e.g., problem-focused coping) was effective in reducing both hostility and blood pressure (Gidron et al. 1999). Blumenthal and colleagues (1997) compared the effects of a stress management intervention consisting of education, cognitive techniques, and relaxation training with those of an exercise condition in a group of patients with coronary artery disease and symptoms of ambulatory or mental stress-induced ischemia. The stress management intervention (sixteen 90-minute group sessions) was associated with a significant reduction in clinical coronary artery disease events at 2- and 5-year follow-up (Blumenthal et al. 1997). The multicomponent program developed by Ornish includes psychological interventions as one of multiple components targeting the risk factors for heart disease (stress management, aerobic exercise, very-low-fat diet, and group support) (Ornish et al. 1998). This intervention has produced a clear reduction in recurrent cardiac events and in severity of coronary artery disease, as well as evidence of improved coronary circulation, compared with standard medical care (Ornish et al. 1998). This intriguing finding is limited by the fact that patients were informed as to which arm of the study they would be entering prior to randomization. In this study, it also remains unclear which components of the multimodal program were the most influential in producing positive outcomes—the psychological components or others directly targeting risk factors for coronary artery disease such as diet or exercise (Ornish et al. 1998; see also Chapter 19, "Heart Disease").

## Diabetes

The past decade has seen a growing awareness of the importance of psychosocial factors in diabetes. The goals of treatment for diabetes have undergone radical changes resulting from the findings of the Diabetes Control and Complications Trial Research Group, which presented strong evidence that diabetes complications could be delayed or prevented should patients maintain tight control of their blood glucose levels (Diabetes Control and Complications Trial Research Group 1993; Gonder-Frederick et al. 2002). These treatment recommendations and their psychological implications have had an enormous impact on the study of psychosocial factors in diabetes (see Table

**TABLE 38–3. Psychosocial interventions in heart disease**

<b>Study</b>	<b>Participants</b>	<b>Diagnosis</b>	<b>Type of intervention</b>	<b>Results of intervention</b>
Ornish et al. 1998	48 patients	Coronary artery disease	Stress management, exercise, very-low-fat diet, group support	Reduced recurrent cardiac events, CAD severity, improved coronary circulation
Black et al. 1998	60 cardiac rehabilitation patients	Post–angina, MI, angioplasty, bypass grafting	One-on-one CBT, relaxation training, stress management for risk factor reduction and improved treatment compliance	Reduced depression in treatment groups; 35% versus 48% rehospitalized
Gidron et al. 1999	22 patients	Coronary heart disease and high level of hostility	Group CBT to modify hostility: listening, cognitive restructuring, and problem-focused coping	Reduction in hostility and blood pressure
Denollet and Brutsaert 2001	150 patients	Coronary heart disease	Multicomponent cardiac rehabilitation: exercise, stress management, and counseling	Less negative affect during 3-month treatment; improved survival for following 9 years
Luskin et al. 2002	14 patients	Congestive heart failure	One-on-one stress management intervention for elderly patients	Improvement in perceived stress, emotional distress, depression, exercise
Petrie et al. 2002	65 patients	First MI	Brief hospital intervention, cognitive restructuring and preparation of a recovery action plan	Significant changes in patient perceptions of their MI; treatment group returned to work faster; lower rate of angina at 3-month follow-up
Blumenthal et al. 1997	107 patients	CAD and ischemia during mental stress testing	Group intervention with stress management training, cognitive techniques, and relaxation training versus exercise	Reduction in clinical CAD events over 2 years of follow-up and after 5 years in group treatment condition

*Note.* CAD=coronary artery disease; CBT=cognitive-behavioral therapy; MI=myocardial infarction.

38–4 for a summary of these studies). Psychosocial factors are relevant to nearly every aspect of diabetes management (Ciechanowski et al. 2001; Fosbury et al. 1997; Glasgow and Eakin 1998; Gonder-Frederick et al. 2002; Grey et al. 1998; Lustman et al. 1998; Moran et al. 1991; Rubin et al. 1989; Van der Ven et al. 2000; Zettler et al. 1995). It is now clear that psychological interventions can have a positive impact on emotional and physical well-being (Gonder-Frederick et al. 2002), regimen adherence (Ciechanowski et al. 2001), and glycemic control in people living with diabetes (Delamater et al. 2001; Fosbury et al. 1997; Gonder-Frederick et al. 2002; Grey et al. 1998; Lustman et al. 1998; Moran et al. 1991; Rubin et al. 1989; Van der Ven et al. 2000; Zettler et al. 1995).

CBT has proved to be an effective treatment for comorbid depression in diabetes patients (Fosbury et al. 1997; Gonder-Frederick et al. 2002; Grey et al. 1998; Lustman et al. 1998; Rubin et al. 1989; Van der Ven et al. 2000; Zettler et al. 1995). A randomized, controlled trial comparing 10 weeks of individual CBT plus diabetes education with diabetes education alone in depressed patients with type 2 diabetes resulted in greater remission of major depression in the CBT group posttreatment and at 6-month follow-up (Lustman et al. 1998). Other investigators have shown that brief, group-based CBT targeting diabetes-specific issues (e.g., anxiety about complications, relationship problems, beliefs about diabetes that represent barriers to self-care) has shown decreased diabetes-related distress and improved emotional well-being and metabolic control (Van der Ven et al. 2000). Another cognitive approach, cognitive-analytic therapy, has been tested in patients with poorly controlled type 1 diabetes (Fosbury et al. 1997). The intervention, which addressed psychosocial difficulties contributing to self-management problems, resulted in improved interpersonal relationships and glycemic status (Fosbury et al. 1997).

Coping skills training and stress management for adolescents with diabetes have been successful in reducing diabetes-related stress, enhancing social interactions and quality of life, and improving metabolic control (Grey et al. 1998). Similarly, coping skills training in adults effectively decreases diabetes-related anxiety and avoidance behaviors, enhances coping ability and emotional well-being, and improves self-care and glycemic control (Rubin et al. 1989; Zettler et al. 1995). Nonetheless, Gonder-Frederick and colleagues (2002) noted in their recent review that the long-term impact of CBSM on lifestyle factors crucial to the management of the diabetes regimen (such as diet and exercise) has been minimal thus far. Inconsistencies in the effectiveness of psychosocial interventions studied may be due to limited scope, level of competence of the clinicians, and factors specific to the

patients. Brief, goal-directed therapy may not be adequate for overwhelmed chronic medically ill patients.

Long-standing psychosocial problems, dysfunctional interpersonal style, and maladaptive personality traits can interfere with medical management of illness (Ciechanowski et al. 2001; Goodheart and Lansing 1997; Moran et al. 1991). For example, diabetic patients who have an insecure attachment style, particularly a dismissing style, are more likely than patients with secure attachment to be treatment noncompliant, have a poor relationship with medical personnel, and have poor glycemic control (Ciechanowski et al. 2001). The impact of emotional problems, environmental stressors, and intrapsychic processes on medical management of illness has been studied in a small, controlled treatment trial with hospitalized child and adolescent brittle diabetes patients (Moran et al. 1991). Intensive psychoanalytic psychotherapy (three to five sessions per week for 15 weeks) and medical management, compared with medical management alone, was found to produce a notable improvement in glycemic control at posttreatment and 1-year follow-up (Moran et al. 1991). The psychoanalytic treatment protocol was based on the individual participants' medical and psychological assessment, social factors (family, education), and intrapsychic and interpersonal conflicts thought to underlie poor treatment compliance (Moran et al. 1991). The authors concluded that abnormal blood glucose control interfered with daily living, and that multimodal inpatient treatment (psychoanalytic therapy, dynamically informed parental and staff support, and close collaboration with the physician) led to long-term change in this brittle diabetes population (Moran et al. 1991; see also Chapter 23, "Endocrine and Metabolic Disorders").

## Arthritis

A number of studies, summarized in Table 38–5, have demonstrated the importance of psychosocial interventions for arthritis patients (Alpay and Cassem 2000; Astin et al. 2002; Bradley and Alberts 1999; Keefe et al. 2002; Leibing et al. 1999; Lorig et al. 1985; McCracken 1991; Mullen et al. 1987; Parker et al. 1993; Sharpe et al. 2001). Although the early studies focused mainly on arthritis pain (Bradley and Alberts 1999; McCracken 1991; Parker et al. 1993), emphasis has recently shifted toward a broader range of arthritis-related problems. Psychosocial interventions currently address issues such as psychological disturbance, interpersonal distress, and physical functioning (Alpay and Cassem 2000; Keefe et al. 2002). Psychoeducation and cognitive-behavioral interventions have led to substantial benefits in the management of arthritis (Lorig et al. 1985; Mullen et al. 1987), resulting in dimin-

**TABLE 38–4. Psychosocial interventions in diabetes**

<b>Study</b>	<b>Participants</b>	<b>Diagnosis</b>	<b>Type of intervention</b>	<b>Results of intervention</b>
Lane et al. 1993	38 patients	Type 2 diabetes	Biofeedback assisted relaxation training	Improved glycosylated hemoglobin level, no improvement in glucose tolerance
Zettler et al. 1995	17 patients	Diabetes	Group CBT (exposure, relaxation and cognitive restructuring)	Reduced fear of long-term complications, improved acceptance of diabetes and metabolic control
Aikens et al. 1997	22 patients	Type 2 diabetes	Relaxation training (PMR/imagery)	No difference
Fosbury et al. 1997	26 patients	Type 1 diabetes, poorly controlled	Cognitive analytic therapy versus diabetes education	Improved interpersonal problems and glycemic control in treatment group, maintained at 9-month follow-up
Grey et al. 1998	65 adolescents	Type 1 diabetes	Intensive insulin therapy with coping skills training versus insulin treatment	Improved glycemic control, diabetes self-efficacy, quality of life in treatment group
Lustman et al. 1998	51 patients	Type 2 diabetes with major depression	One-on-one CBT	Remission of depression greater (85% in CBT group, 27.3% in control group); improved glycemic control with treatment
Snoek et al. 2001	24 patients	Type 1 diabetes, poorly controlled	Group CBT	Improved glycemic control
Surwit et al. 2002	108 patients	Type 2 diabetes	Group diabetes education program with or without stress management training	Significant reduction in glycosylated hemoglobin level at 1-year follow-up in the stress management group

*Note.* CBT=cognitive-behavioral therapy; PMR=progressive muscle relaxation.

**TABLE 38–5. Psychosocial interventions in arthritis**

<b>Study</b>	<b>Participants</b>	<b>Diagnosis</b>	<b>Type of intervention</b>	<b>Results of intervention</b>
Lorig et al. 1989	707 patients	Osteoarthritis and rheumatoid arthritis	Psychoeducation, lay-leaders: illness and treatment, nutrition and exercise, training in relaxation, problem-solving, communication	Improved knowledge, increased adaptive behaviors, and reduced pain
Kelley et al. 1997	70 patients	Rheumatoid arthritis	Oral emotional disclosure: 15 minutes on 4 consecutive days	Immediate increase in negative mood, better physical functioning, decreased affective disturbance at 3 months
Leibing et al. 1999	55 patients	Rheumatoid arthritis	12 weekly sessions of CBT	Reduction in passive, emotion-focused coping; helplessness, depression; anxiety; affective pain; and fluctuation of pain
Sharpe et al. 2001	53 patients	Rheumatoid arthritis (onset <2 years)	CBT intervention	Reduced depressive symptoms posttreatment and at follow-up; reduced C-reactive protein levels; improved joint involvement
Smyth et al. 1999	112 patients	Rheumatoid arthritis	Written exercise of emotional disclosure	Reduced disease severity

*Note.* CBT=cognitive-behavioral therapy.

ished psychological distress, improved marital adjustment, and reduced disease-related symptomatology (e.g., joint swelling and fatigue) (Astin et al. 2002; Keefe et al. 2002). Interpersonal therapy has been effective in treating major depression in patients with rheumatological diseases (Alpay and Cassem 2000).

Several studies have shown that CBT is more effective in managing some disease-related symptoms of rheumatoid arthritis than some standard treatments such as physical or occupational therapy (Leibing et al. 1999; Radojevic et al. 1992; Sharpe et al. 2001). A recent randomized, controlled study of patients with rheumatoid arthritis found improvements in pain fluctuation, affect, coping, and emotional stability as well as a slower progression of disease course in the treatment group (12 weekly sessions of CBT) (Leibing et al. 1999). In a blind, randomized, controlled study with early stage rheumatoid arthritis patients (less than 2 years post-diagnosis), a multicomponent CBT intervention consisting of education, relaxation training, attention diversion, goal setting, pacing, problem solving, cognitive restructuring, assertiveness and communication, and management of high-risk situations was compared with a control group receiving standard care (Sharpe et al. 2001). The treatment produced significant reduction in depressive symptoms and improvement in joint involvement at 6-month follow-up (Sharpe et al. 2001). A reduction in C-reactive protein levels (a sensitive measure of disease activity in rheumatoid arthritis) was found in the intervention group posttreatment, although this disappeared at follow-up (Sharpe et al. 2001).

A different type of stress management approach has shown interesting results in arthritis patients. Emotional disclosure, a model in which individuals write or talk privately about a stressful life event, disclosing their intimate thoughts and feelings, led to decreased physiological activity and better self-reported health in healthy people (Pennebaker and Beall 1986; Pennebaker et al. 1988). A recent quantitative review indicated that emotional disclosure is associated with significant improvement in physical health, psychological well-being, and physiological and general functioning (Kelley et al. 1997; Smyth 1998; Smyth et al. 1999; Spiegel 1999). A study of oral emotional disclosure for persons with rheumatoid arthritis found significantly less physical dysfunction and affective disturbance in participants in the disclosure condition compared with control participants at 3-month follow-up (Kelley et al. 1997). In this case, however, the intervention did not lead to any group differences in pain or joint condition. Immediate increases in negative mood were experienced by disclosure patients following the intervention, although participants with more negative mood at baseline experienced the best long-term improvement in

joint condition (Kelley et al. 1997). This paradigm has also been applied to written emotional disclosure exercises with arthritis patients (Smyth 1998; Smyth et al. 1999).

Despite the promising results of these interventions, a recent literature review failed to confirm the superior efficacy of cognitive-behavioral interventions over other interventions (Astin et al. 2002). For arthritis-related outcomes such as pain and disability, long-term effects of the interventions seemed difficult to maintain, whereas depression and joint tenderness may further improve over time (Astin et al. 2002). Identifying the mechanisms of action of psychosocial interventions is obviously complex. In arthritis, however, it appears that patients' enhanced self-efficacy may be a pivotal factor in achieving and maintaining important treatment gains (Lorig et al. 1989; see also Chapter 25, "Rheumatology").

## HIV/AIDS

Psychosocial interventions have been used as an adjunct to medical treatment and have benefited emotional health as well as physiological parameters in people with HIV/AIDS (Antoni et al. 2000a, 2000b, 2001; Chesney et al. 1996; D.G. Cruess et al. 2000a, 2000c; Kalichman et al. 1995; Kelly 1998; Kelly et al. 1993; Lutgendorf et al. 1997, 1998; Mulder et al. 1994; Spiegel and Classen 2000; Spiegel et al. 1981; Treisman et al. 2001).

Interventions designed to decrease distress, improve coping mechanisms, influence disease progression (Chesney et al. 1996), increase self-efficacy, and decrease perceived anxiety, depressed mood, hostility, anger, and somatization (Antoni et al. 1991; Antoni et al. 2001; Chesney et al. 1996; S. Cruess et al. 2000; Kelly et al. 1993; Lutgendorf et al. 1997, 1998; Mulder et al. 1994) have met with success (see Table 38-6 for a summary of relevant studies). These studies frequently have employed cognitive and/or behavioral approaches, CBSM, and IPT. The interventions described, using an individual or group format, include relaxation skills training and practice, cognitive restructuring, instruction in self-monitoring of environmental stressors, social skills training, and interpersonal psychotherapy.

Two studies compared different psychotherapy approaches for individuals with HIV (Kelly et al. 1993; Mulder et al. 1994). Kelly et al. (1993) compared eight sessions of group-based CBSM, supportive-expressive group therapy (Spiegel and Classen 2000; Spiegel et al. 1981), and a control group (individual counseling on demand) in depressed men with HIV/AIDS. The authors (Kelly et al. 1993) found that both the CBSM and the supportive-expressive groups had reduced depressed mood, hostility,

**TABLE 38–6. Psychosocial interventions in HIV**

<b>Study</b>	<b>Participants</b>	<b>Diagnosis</b>	<b>Type of intervention</b>	<b>Results of intervention</b>
Antoni et al. 1991	47 healthy gay men	Asymptomatic	CBSM intervention, anticipating HIV test results for 5 weeks; adjust to HIV status, lifestyle needs during following 5 weeks	Treatment group had less anxiety or depression after notification; decreased CD4 and NK cell counts in response to the HIV-positive diagnosis in control group
Kelly et al. 1993	68 men	HIV/AIDS; moderate depression	Group CBSM versus socially supportive group therapy	Reduced depressed mood, hostility, somatization in CBSM and socially supportive groups; reduced psychiatric symptoms and anxiety in socially supportive group; reduced illicit drug use in CBSM group; socially supportive group therapy superior to CBSM in reducing psychological distress at 3 months
Mulder et al. 1994	39 men	Asymptomatic HIV-positive	Group CBSM, group experiential therapy, or wait-list control	CBSM and experiential therapy decreased POMS-defined total mood disturbance and Beck Depression Inventory scores
Chesney et al. 1996	149 gay men	HIV-positive	Coping effectiveness training (problem-focused or emotion-focused), HIV education group, or wait-list control	Increased self-efficacy and decreased perceived stress with coping effectiveness training; no differences among conditions in changes in CD4 count or symptoms
Lutgendorf et al. 1997	40 men	Symptomatic HIV-positive	Group CBSM	Decreased dysphoria, anxiety, total distress, and HSV-2 antibody titers in CBSM group; no difference in CD4 count
Antoni et al. 2000a	73 gay men	HIV-positive	10-week CBSM intervention	CBSM decreased anxiety, anger, total mood disturbance, perceived stress; decreased urinary norepinephrine predicted a slower decline in CD8 count at 6- to 12-month follow-up in CBSM group
Antoni et al. 2000b	59 gay men	HIV-positive	CBSM intervention	Decreased depressed mood paralleled by reductions in urinary free cortisol
D.G. Cruess et al. 2000c	30 gay men	HIV-positive	Weekly relaxation training sessions in a 10-week group-based CBSM intervention	Decreases in mood disturbance and anxiety related to reductions in pre-session salivary cortisol levels; reduced cortisol levels in early sessions associated with more frequent relaxation practice
D.G. Cruess et al. 2000a	65 gay men	Symptomatic HIV-positive	Group CBSM	Increased urinary free testosterone levels associated with reduced distress

*Note.* CBSM = cognitive-behavioral stress management; HSV-2 = herpes simplex virus type 2; POMS = Profile of Mood States.

and somatization. Whereas the CBSM group had reduced illicit drug use, the social support group experienced a reduction in overall psychiatric symptoms and anxiety. The social support group was superior to the CBSM group in reducing psychological distress and maintaining treatment gains at 3-month follow-up (Kelly et al. 1993). Mulder and colleagues (1994) compared group-based CBSM with experiential therapy (17 sessions over 15 weeks) for HIV-positive men. Men in both conditions experienced decreased distress, although no differences were noted between the two treatments with regard to coping, social support, or emotional expression (Mulder et al. 1994).

In a 3-month coping effectiveness training intervention based on Lazarus and Folkman's (1984) stress and coping theory, a group of HIV-positive homosexual men were taught to match coping strategies to stressors (e.g., emotion-focused strategies for uncontrollable stressors and problem-focused coping strategies for controllable stressors) (Chesney et al. 1996). Men in the coping effectiveness training condition reported less perceived stress, reduced emotional distress, and improved self-efficacy (Chesney et al. 1996). A recent study using the National Institute of Mental Health Treatment of Depression Collaborative Research Program four-group design (IPT, CBT, support with imipramine, support only) with depressed HIV-positive patients found that patients in both the IPT and the support with imipramine conditions had more symptom reduction than did those in the CBT and support-only conditions (Markowitz et al. 1998).

Several studies suggest that psychological interventions have the potential to improve not only psychological well-being but also biological parameters for people with HIV/AIDS (Antoni et al. 2000a, 2000b; D.G. Cruess et al. 2000a, 2000c; S. Cruess et al. 2000). Interventions characterized by a strong emphasis on relaxation (CBSM, relaxation techniques, and cognitive-behavioral packages) have been demonstrated to have positive psychosocial effects while effecting modulations in biological variables in HIV-positive patients, including reduction in cortisol levels, increase in urinary free testosterone levels, reduction in 24-hour urinary norepinephrine output, reduction in herpes simplex virus type-2 antibody titers, and changes in CD8 counts. Such neuroendocrine and immunological changes are currently considered positive biological system markers of HIV status (Antoni et al. 2000a, 2000b; D.G. Cruess et al. 2000a, 2000c; S. Cruess et al. 2000; Lutgendorf et al. 1997; Schneiderman et al. 2001).

One randomized, controlled study of a 10-week CBSM intervention targeting homosexual and bisexual men awaiting notification of HIV status focused on anticipation of HIV test results for the first 5 weeks and on ad-

justing to HIV status and lifestyle needs during the following 5 weeks (Antoni et al. 1991). The intervention group had increased CD4 (T-helper) cell counts and CD56 (natural killer) cells (Antoni et al. 1991). Another randomized, controlled study investigated a CBSM intervention that included 10 sessions of education about stress and the benefits of relaxation, cognitive restructuring, coping skills and assertiveness training, anger management, and identification of social supports for symptomatic HIV-positive men (Lutgendorf et al. 1998). The CBSM group had significant improvement in cognitive coping strategies (positive reframing and acceptance of the illness) and social supports (attachment and alliance formation). Men in the intervention group also had significant decreases in self-reported dysphoria, anxiety, and total distress. Although neither group showed changes in CD4 counts, the intervention group had decreases in herpes simplex virus type 2 antibody titers, a parameter that may be a marker of immunocompetence (Lutgendorf et al. 1998). Two other studies using the same model of CBSM showed decreases in depressed mood that were closely paralleled by reductions in urinary free cortisol (Antoni et al. 2000b; D.G. Cruess et al. 2000c). In the study by Cruess and colleagues (2000c), greater reductions in cortisol during early sessions were associated with more frequent relaxation practice at home.

Consultation psychiatry is integral in the treatment of patients with HIV/AIDS who have chronic mental illness, personality disorders, and addiction. Difficulties include risky sexual practices, continued drug abuse and needle sharing, limited access to treatment, treatment noncompliance, and a range of psychosocial problems associated with living on the fringes of society (poverty, homelessness, isolation) (Clark and Everall 1997; Kalichman et al. 1995; Treisman et al. 2001; see Chapter 28, "HIV/AIDS").

## Conclusion

---

There is considerable evidence that a variety of psychotherapeutic interventions provide substantial benefits for people in various stages of coping with medical illness (Compas et al. 1998). Techniques ranging from intensive individual psychotherapies to group, psychoeducational, and family approaches can enhance coping, reduce distress, improve adherence to medical treatment, diminish pain, and facilitate optimal functioning. Furthermore, better adjustment to illness may translate into a reduction of the cost of care (reduction in utilization of medical services, reduction in medication needs) (Lang and Rosen 2002; Sobel 1995). Further research should enable a bet-

ter identification of the most efficient interventions and allow researchers to identify which components of these interventions are the most promising with respect to the type and stage of illness and the specific needs of patients. More study is needed to better understand psychophysiological mechanisms affected by psychotherapeutic interventions. However, it is clear that psychotherapeutic techniques are effective complements to modern biotechnological medical treatment, particularly in improving quality of life.

## Electroconvulsive Therapy

---

Keith G. Rasmussen, M.D.

Teresa A. Rummans, M.D.

Teresa S.M. Tsang, M.D.

Roxann D. Barnes, M.D.

**THE CORNERSTONES IN** the management of medically ill patients receiving electroconvulsive therapy (ECT) include the following: 1) careful pretreatment identification, assessment, and stabilization of medical comorbidity; 2) proper treatment technique (anesthesia, muscle paralysis, continuous oxygenation, electrocardiographic monitoring, and rational use of cardioprotective agents); 3) vigilant assessment of the patient's medical status between treatments; and 4) identification and management of treatment-emergent medical complications.

In this chapter, we focus on the first two of these cornerstones. Management of ECT-induced medical complications, whether in the ECT suite or between treatments, is beyond the scope of this chapter. The importance of careful management is illustrated in a 1968 case report (Husar and Pachter 1968) in which an elderly man with known heart disease received ECT without cardiac assessment or electrocardiographic monitoring, resulting in myocardial infarction (MI), cardiac arrest, and death. In the modern era, with sophisticated cardiac imaging techniques and better treatments (both before and during ECT), along with continuous electrocardiography and pulse oximetry during the treatment, the outcome likely would have been quite different.

ECT has been a core component of the psychiatrist's treatment armamentarium for more than 60 years. ECT is an extremely safe procedure; average death rates due to treatment are estimated to be approximately 1 per 10,000 patients treated (American Psychiatric Association 2001). Nonetheless, medical comorbidity in ECT patients is so common that the ECT clinician should be familiar with strategies to prevent morbidity and mortality.

Ideally, prospective controlled trials would establish the safety and efficacy of ECT in patients with a given medical disorder, but such trials are impractical and unlikely. However, a substantial number of case reports and series, combined with extensive clinical experience, allow for rational and prudent risk-reduction strategies in ECT practice. In this chapter, we treat organ systems separately; for more extensive reviews of other aspects of ECT practice (e.g., electrode placement, stimulus intensity), the reader is referred to recent ECT texts and practice guidelines (Abrams 2002; American Psychiatric Association 2001). The *Journal of ECT* (formerly *Convulsive Therapy*) contains many case reports of the use of ECT in literally dozens of illnesses. In this chapter, we assume the reader is generally familiar with ECT practice, including the indications for ECT, aspects of modern ECT technique, and the routine pre-ECT workup (which includes a comprehensive medical and psychiatric history, physical examination, basic laboratory screen, and electrocardiogram). We provide recommendations for additional investigations and interventions for patients with various medical conditions.

### Cardiovascular Disorders

---

The potent effects of ECT on cardiovascular physiology have been well characterized for several decades. Unfortunately, the same cannot be said for risk-reduction strategies in such patients. In this section, we review the available literature and provide prudent recommendations. We first review ECT's cardiovascular effects, which are

relevant to the care of the cardiac patient receiving ECT. Following that, we outline specific considerations for patients with particular cardiac conditions. For most patients with known or suspected cardiovascular illness, pretreatment consultation with a cardiologist is recommended.

## Cardiac Physiology of ECT

### *Hemodynamic Effects*

Anesthetic medications can cause a decrease or increase in cardiac output, depending on the type of agent selected. Typically in ECT, a barbiturate anesthetic is used, with an approximately 25% increase in pulse rate and a 13% decrease in cardiac output immediately after anesthesia (Wells and Davies 1987). After the electrical stimulus, there is a vagally (i.e., parasympathetically) mediated short-lived bradycardia, occasionally with asystole of several seconds (Rasmussen et al. 1999). If the electrical stimulus is suprathreshold (i.e., strong enough to cause a seizure), this initial parasympathetic phase is rapidly replaced by a sympathetically mediated tachycardia and rise in blood pressure during the seizure (Rasmussen et al. 1999). Accordingly, there is also a transient sharp rise in plasma catecholamine levels (Gravenstein et al. 1965). During the seizure, the rate pressure product (the product of heart rate and systolic blood pressure, a measure of myocardial workload) often increases severalfold (Huang et al. 1989; Rasmussen et al. 1999; Rumi et al. 2002), and cardiac output increases by 81% (Wells and Davies 1987). These effects generally subside within a few minutes to an hour. In the immediate postictal phase, if no antimuscarinic premedication (e.g., glycopyrrolate or atropine) has been given, there is often transient bradycardia, followed again by a smaller increase in heart rate that typically reverts to prestimulus levels within a few minutes. A mild increase in heart rate may persist over the preanesthesia baseline depending on the half-life of the antimuscarinic premedication if given. Thus, from a hemodynamic standpoint, the factor that is most relevant to cardiac patients is the sympathetically mediated sharp increase in myocardial workload, which may pose significant risk for patients with coronary artery disease (CAD), dysrhythmias, or congestive heart failure (CHF).

If the electrical stimulus is not of sufficient intensity to cause a seizure (referred to in ECT practice as a subconvulsive, or subthreshold, stimulus), then the initial parasympathetically mediated bradycardia/asystole will not be replaced by the sympathetically mediated phase; there have been rare reports of prolonged asystole requiring resuscitative efforts, especially in patients who have not been given antimuscarinic premedication or who have

been given beta-blockers (Burd and Kettl 1998; Decina et al. 1984; Tang and Ungvari 2001; Wells et al. 1988). This is especially important in patients with cardiac disease who may not tolerate several-second asystoles well (Zielinski et al. 1993). Thus, the use of antimuscarinic premedication is encouraged in ECT, especially if the patient has received beta-blockade or when a stimulus titration procedure is to be used to determine seizure threshold, in which case subconvulsive stimuli are expected (Abrams 2002; American Psychiatric Association 2001).

### *Electrocardiographic Effects*

Several studies have examined electrocardiographic changes associated with ECT. Troup et al. (1978) performed 12-hour Holter monitoring in ECT before and after treatment in young, cardiovascularly healthy patients. A slight increase in QTc interval occurred just postictally in some patients, but a return to baseline was noted a few minutes later. The authors found no increase in ventricular or atrial premature contractions in the 12-hour post-ECT period. Kitamura and Page (1984) also performed Holter monitoring 12 hours before and after ECT in 13 patients with a mean age of just more than 50 years. No malignant ventricular dysrhythmias were noted. However, rate-dependent ST-segment depressions were observed which subsided by 1 hour post-ECT. The increase in heart rate caused by the seizure returned to prestimulus levels (i.e., postanesthesia, which included use of atropine) within 4 minutes. Hejtmancik et al. (1949) found a mean decrease in QTc interval of 38 milliseconds just after the seizure. Deliyannis et al. (1962) performed continuous electrocardiographic monitoring in ECT patients before, during, and for 2 minutes after the seizure. During the seizure itself, ST-segment depression of 1–4 mm was seen in 15 of 20 patients; increased T-wave amplitude, premature atrial complexes (PACs), and premature ventricular complexes (PVCs) were also common. Postictally, there was immediate bradycardia with frequent PACs and PVCs, varying degrees of atrioventricular block or nodal rhythms, and ST-segment depression, all of which resolved within a few minutes. These findings are consistent with sympathetic stimulation during the seizure, followed by vagal response immediately after. Guttmacher and Greenlund (1990) performed 24-hour Holter monitoring on eight elderly subjects with stable cardiac disease (the majority with past histories of MI or heart block) who were receiving ECT. Other than the expected seizure-induced tachycardia and hypertension, which rapidly resolved, no significant electrocardiographic changes were seen.

Zvara et al. (1997) performed Holter monitoring on 19 elderly patients for at least 2 hours after two of their

ECT treatments. For each patient, there was one study with, and one without, preanesthetic administration of the ultra-short-acting beta-blocker esmolol. The purpose of the study was to determine whether pretreatment with a beta-blocker reduced electrocardiographic evidence of myocardial ischemia during and after ECT. Eleven of 19 patients showed at least some ST-segment change (mostly depression) in the postictal period. Interestingly, although esmolol did potently blunt the seizure-induced tachycardia and hypertension, it had no effect on ST-segment ischemic changes. Dysrhythmias, mostly PVCs, were equally common in the postictal period with or without esmolol pretreatment.

Rumi et al. (2002) performed 24-hour ambulatory blood pressure and Holter monitoring on 47 young, healthy patients (mean age=30.3 years; range=18–40 years) without cardiac disease. Three patients (ages 23, 33, and 36 years) showed ST-segment depression of at least 1 mm before, during, and after ECT. All were demonstrated to have normal coronary arteries on subsequent angiography. Other than occasional PACs or PVCs, the Holter results were normal. Hemodynamic responses returned to baseline within 1 hour following the seizure.

Huuhka et al. (2003) performed 24-hour Holter monitoring before and after ECT in 26 elderly patients. Although there was a slight increase in bigeminy/trigeminy in the 24 hours post-ECT, there was no significant increase in the total number of PVCs. Supraventricular tachycardia increased slightly, but supraventricular extrasystoles did not, in the 24 hours post-ECT; none of the significant changes were seen in the 1-hour period post-ECT as compared with the 1-hour period pre-ECT. Nine of the patients also showed ST-segment depression of at least 1 mm in the post-ECT period, although the data on the precise timing and recovery of the ST-segments were not provided. McCully et al. (2003) performed 12-lead electrocardiograms on a series of 53 ECT patients at baseline before ECT and again after the first, fourth, and final treatments. Transient ECG changes, mostly T-wave amplitude changes, were seen in approximately one-third of the patients. Rasmussen et al. (2004) performed 3-hour Holter monitoring on 11 ECT patients (mean age 45 years) before the first treatment and after the last treatment in an ECT series. No significant changes were seen in frequency of dysrhythmias or in the ST segments.

The dysrhythmic changes described in the paragraphs above can be divided into those that are sympathetically mediated (e.g., PVCs in the context of tachycardia) and those that are parasympathetically mediated (e.g., ventricular ectopy during periods of bradycardia, nodal rhythms). In general, it is not uncommon, even in young, healthy patients, to see a variety of brief, rapidly resolving electro-

cardiographic changes during and shortly after the seizure in P-R, QTc, and ST-T wave as well as PACs, PVCs, paroxysmal supraventricular tachycardia (PSVT), and short, nonhemodynamically significant runs of ventricular tachycardia. In the immediate postictal time period, with the relative parasympathetic predominance, it is not uncommon to see vagally mediated changes such as junctional rhythms and PVCs in the face of bradycardia. These latter phenomena are less intense when antimuscarinic premedication is used.

Transient, benign T-wave inversions are also occasionally seen in ECT and can occur in the absence of myocardial compromise (Cockey and Conti 1995; Gould et al. 1983). Khoury and Benedetti (1989) found that 23% of ECT patients showed increased T-wave amplitude lasting an average of 6 minutes during and after the seizure. There has been some controversy as to whether these common, transient ECG changes in ECT represent benign, neurally mediated phenomena or myocardial ischemia. Most ECG changes are felt to be neurally mediated and probably benign (Deliyiannis et al. 1962), requiring no specific intervention. Close attention to proper pretreatment ventilation can largely abate many of these changes (McKenna et al. 1970). Changes in myocardiospecific enzymes suggesting ischemia generally do not occur with ECT (Dec et al. 1985). Some echocardiographic findings (reviewed later in the chapter), however, suggest that myocardial ischemia can occur with ECT. Obviously, if serious atrial or ventricular dysrhythmias occur, or if there is evidence of hemodynamic compromise, immediate treatment is important.

### *Echocardiographic Effects*

There are at least eight reports in which transthoracic echocardiographic assessment was performed in the peri-ictal period in ECT. Mensah et al. (1990) reported two cases in which pretreatment echocardiogram revealed left ventricular intracardiac thrombi. There were no apparent complications with full courses of ECT in either case. However, no post-ECT echocardiographic assessment was undertaken.

Messina et al. (1992) performed baseline and immediate postictal echocardiograms on 11 patients. All baseline studies were normal. Immediately postictally, 5 of the patients had transient new regional wall motion abnormalities (all hypokinesis; no akinesis or dyskinesis). Of these 5 patients, 3 had electrocardiographic evidence of 1 mm downsloping or horizontal ST-segment depressions associated with the presence of regional wall motion abnormalities; 1 had peaked T-waves; and 1 had normal electrocardiographic results during hypokinesis. The other 6 patients had normal postictal electrocardiograms. As the

echocardiographic and electrocardiographic changes occurred with doubling of the rate–pressure product, the authors interpreted them as ischemic in nature. All the measures that had changed returned to baseline within a few minutes postictally, and no patient complained of angina or had an MI.

Zhu et al. (1992) treated a 77-year-old woman without known heart disease with ECT. Postictally, the electrocardiogram revealed 1–2 mm ST-segment elevations. Immediate echocardiography showed an ejection fraction of 35% with inferior wall akinesis and anteroseptal and anterior wall hypokinesis. Coronary angiogram demonstrated relatively mild atherosclerosis. During the next 2 days post-ECT, giant T-wave inversions developed in the absence of increased myocardial enzymes. Electrocardiography and echocardiography results normalized 4 days posttreatment, and no further ECT treatments were given at that time. During a depressive relapse 6 months later, ECT was again undertaken. Nitrates and diltiazem were given before the first treatment, but electrocardiography 24 hours later showed return of the giant T-wave inversions and echocardiographic abnormalities. Before each of the remaining six ECT treatments, 15 mg labetalol was given, and no electrocardiographic or echocardiographic abnormalities recurred. The authors attributed the findings to myocardial stunning; electrocardiographic ST-segment changes, T inversions, and U waves have all been associated with acute central nervous system (CNS) events (Perron and Brady 2000). The electrocardiographic changes probably reflected ischemia from marked sympathetic stimulation.

Ruwitich et al. (1994) performed two-dimensional (2-D) echocardiography immediately before and 1 minute postictally in 10 ECT patients with known CAD. Additionally, technetium Tc 99m sestamibi was injected 45 seconds after the end of the seizure, and scans were completed within 3 hours and compared with baseline thallous chloride Tl 201 stress scintigraphy in five patients in whom such a study was available. On 2-D echocardiogram, postictal wall motion abnormalities were identified in six patients (segmental in three and global in three). One patient did not have the postictal echocardiogram performed for technical reasons. Of the remaining three patients, no new abnormalities were identified. The Tc 99m sestamibi scans showed reversible (two complete, three partial) or fixed (two) defects; in the five patients with baseline scintigraphic studies, the findings were concordant in all cases. The authors concluded that myocardial ischemia is common in ECT patients with CAD and may be predictable with scintigraphy.

Eitzman et al. (1994) performed echocardiography 30 minutes postictally on a 76-year-old woman with 1-mm

ST-segment elevation 15 minutes post-ECT. The echocardiogram revealed distal septal and apical akinesis. Intravenous nitroglycerin promptly resolved the ST-segment elevation. Adenosine thallium imaging 3 days later was entirely normal. Coronary artery spasm was presumed to be the etiology of the ECT effects. Repeat echocardiogram 6 days post-ECT was normal, but transient akinesis was replicated after hyperventilation, and this was felt to support a diagnosis of coronary artery spasm. Repeat hyperventilation echocardiogram 2 days later, while the patient was taking nifedipine (a common treatment for coronary artery spasm), was normal. The patient subsequently underwent a full course of ECT treatments without electrocardiographic changes while continuing to take the nifedipine.

O'Connor et al. (1996) performed echocardiography on 13 ECT patients at baseline, after anesthetic administration, 1 minute postictally, and 15 minutes later. For each patient, one study was done with, and one without, concomitant esmolol before anesthesia. Of the 26 seizures thus monitored with echocardiography, new regional wall motion abnormalities were seen in only one (and that was with esmolol pretreatment). In contrast to the sample of Messina et al. (1992), 31% of the patients had baseline regional wall motion abnormalities (4 with inferior hypokinesis and 1 with inferior akinesis). Concomitant electrocardiography showed nonspecific ST changes, PACs, PVCs, and one three-beat run of ventricular tachycardia, none associated with wall motion abnormalities. Thus, O'Connor et al. (1996) concluded that in their sample, in contrast to the sample of Messina et al. (1992), new regional wall motion abnormalities are rare in ECT, and the common electrocardiographic changes seen postictally do not generally occur with echocardiographic evidence of ischemia. Of note, in both the O'Connor et al. (1996) and Zvara et al. (1997) studies, pretreatment with the beta-blocker esmolol was not associated with a reduction of ECT effects on echocardiogram or electrocardiogram.

Fuenmayor and colleagues (1997) performed baseline, 20-minute post-ECT, and 6-hour post-ECT echocardiography on 11 patients without cardiac disease and focused their analysis on left ventricular pump function. The mean age of the patients was 23 years. End systolic area was increased, and ejection fraction decreased 20 minutes postictally but returned to normal at the 6 hour study. No change in diastolic function was observed. The authors concluded that ECT temporarily reduces left ventricular systolic function.

Kadoi et al. (2001) performed echocardiography with an automated border detection system that allowed continuous monitoring of systolic function in nine ECT pa-

tients with American Society of Anesthesiologists (ASA) status of I or II, starting from just prior to anesthesia induction until 10 minutes postictally. Mean age was 51 years. Immediately postictally, there was a significant reduction in fractional area change of the left ventricle, indicating higher end-systolic area, suggesting impaired overall left ventricular function. However, no regional wall motion abnormalities were seen, nor were there any ST-segment changes on electrocardiography. All measures of systolic function that had changed returned to baseline within a few minutes postictally.

In the most recent study, McCully et al. (2003) performed echocardiography at baseline and approximately 20–30 minutes after the first, fourth, and final ECT treatments. Changes were transient and included new left ventricular systolic dysfunction in 15 of the sample of 53 patients. In 7 of these 15 patients, the systolic dysfunction was global. In the other 8 patients, dysfunction was regional and included the ventricular septum and anterior wall in 5; ventricular septal and inferior wall hypokinesis in 2; and isolated ventricular septal hypokinesis in 1 patient. No baseline clinical characteristics, such as medical history, age, or gender, differentiated these patients from those who did not show echocardiographic changes during ECT. Furthermore, there was no difference between the two groups in peak rate–pressure product or electrocardiographic changes during ECT. In two of the patients showing echocardiographic changes, there was nonsustained ventricular tachycardia and moderate global left ventricular dysfunction (ejection fractions of 30% and 40%). None of the patients showing echocardiographic changes suffered any cardiac events during or up to 1 month after ECT. One patient, an 84-year-old woman with preexisting left ventricular systolic function that did not change during ECT, suffered a stroke 3 days after the last treatment and subsequently died. She had no mural thrombus on the echocardiograms.

In summary, the echocardiographic studies of ECT show transiently reduced left ventricular systolic function. Although the literature is mixed, in some patients, especially those with CAD, temporary new regional hypokinesis may be induced.

### **Summary**

ECT produces temporary parasympathetic and sympathetic nervous system stimulation with expected alterations in heart rate, blood pressure, and rate–pressure product, with a brief, but substantial, increase in myocardial workload. Transient electrocardiographic and echocardiographic changes, some of which are probably ischemic and some likely neurally mediated, also occur. Echocardiographic studies of small sample sizes have shown

brief reductions in left ventricular function. Thus, for the prospective ECT patient with cardiac disease, physicians should be vigilant with regard to stabilizing and monitoring any pathological cardiovascular responses or complications.

In the following section, we turn our attention to assessment and management of ECT patients with specific cardiac conditions.

## **Congestive Heart Failure**

Special attention should be given to patients with CHF. These patients are particularly vulnerable to the stress of hyperdynamic states, such as that associated with strong sympathetic stimulation from ECT, resulting in an increase in myocardial demand and possibly transient ischemia (Fuenmayor et al. 1997; Kadoi et al. 2001). Zielinski et al. (1993) reported on a series of 40 ECT patients with a variety of cardiac diagnoses who were compared with a similarly treated age- and sex-matched group of noncardiac ECT patients. Twelve of the 40 cardiac patients had CHF (mean ejection fraction, 34.6%; range, 22%–47%), and many had other cardiac diagnoses, including conduction defects, ischemic heart disease, and rhythm disturbances. Cardiac complications were classified as major (prolonged ischemic changes on electrocardiogram, MI, prolonged dysrhythmias, or symptoms of coronary ischemia) or minor (transient dysrhythmias or ST-T wave changes without hemodynamic compromise that occurred during or shortly after the seizure). One cardiac patient in the series had an MI, but the authors did not report on whether this patient had CHF. No patient in the series died. Of the 12 patients with CHF, 3 had “major” complications: 2 had (unspecified) ischemic changes on electrocardiography, and 1 had dysrhythmias. Seven of the CHF patients had minor cardiac complications, consisting usually of transient dysrhythmias (atrial or ventricular). Finally, 2 of the CHF patients underwent ECT without cardiac complications. The authors found that in patients who were not initially pretreated with antimuscarinic medication, bradycardia and brief periods of asystole were common and preventable with subsequent atropine. The group of noncardiac patients had no major complications and a significantly lower rate of minor complications with ECT. No specific recommendations were proffered to aid in the management of CHF patients in ECT.

Unfortunately, in this and another commonly cited series (Rice et al. 1994), cardiac illnesses were treated as a homogeneous group without specific considerations for CHF, so no useful information can be gleaned from these studies with regard to management of CHF patients during ECT.

Stern et al. (1997) reported on three patients with CHF, aged 59–78 years and with ejection fractions of 20%–25%, who received ECT without any cardiac complications. The authors used nitroglycerin patch, sublingual nifedipine, and intravenous labetalol pre-ECT to lower the risk of decompensation of heart failure during the procedure. Goldberg and Badger (1993) reported on two patients with CHF and implantable cardioverter defibrillators (ICDs). The first, a 54-year-old man (unspecified ejection fraction), tolerated eight ECT treatments without consequence except for dramatic relief from depression. The second, a 65-year-old man with dilated cardiomyopathy and pre-ECT ejection fraction of 20%, had a total of four treatments. Upon recovery from the first and third treatments, he had respiratory difficulties and bouts of hypotension that responded to an intravenous pressor (ephedrine). After the fourth treatment, he developed a wide complex tachycardia without palpable pulse and was resuscitated. No further ECT was administered, but he suffered a hypotensive episode 5 days later that ultimately led to his death from progressive heart failure several days thereafter.

Gerring and Shields (1982) provided detailed outcome data on four patients with CHF who were treated with ECT for depressive illness. A 60-year-old woman with mitral stenosis received ECT without complication. A 58-year-old woman, also with mitral stenosis in addition to CHF, suffered atrial fibrillation leading to severe decompensation of the CHF after the second treatment; upon stabilization, she went on to receive another course of ECT without complication. A 71-year-old woman with a history of MI in addition to CHF had a cardiopulmonary arrest 45 minutes after her fifth treatment and died. Finally, a 69-year-old woman showed transient ventricular and atrial dysrhythmias after several of her ECT treatments, which she otherwise tolerated well.

Petrides and Fink (1996), in a series of ECT patients with atrial fibrillation, reported that one 89-year-old woman with CHF converted to sinus rhythm after receiving a course of ECT. The other case of interest in their series of CHF patients was a 76-year-old woman in atrial fibrillation who received a course of seven ECT treatments, during which she fluctuated between atrial fibrillation and sinus rhythm. The CHF did not seem to worsen.

As shown in the case series cited above, patients with CHF need to be closely monitored before and during ECT and are particularly sensitive to sympathetic stimulation. In the case of compromised left ventricular function, an increase in sympathetic stimulation with an associated increase in myocardial workload may aggravate CHF. Because of the failing heart's decreased ability to increase its contractile function, it is more sensitive than the

normal heart to increases in afterload such as those caused by the sympathetic stimulation with ECT. If the underlying pathology is ischemic heart disease, sympathetic stimulation may induce ischemia with worsening of CHF.

CHF should be optimally treated and stabilized prior to ECT treatments. Once the patient is scheduled for ECT, cardiac medications should be administered in the morning before the treatment with a small amount of water, with enough time to ensure absorption. Recent practice guidelines caution against administration of diuretic agents the morning of ECT to avoid bladder rupture or incontinence during the seizure (American Psychiatric Association 2001). However, we generally recommend administering patients' usual stable medications, including diuretics, to avoid any abrupt changes in their medical regimen. The full bladder problem can be managed simply by having the patient void just before the treatment or, if necessary, by making transient use of a urinary catheter.

The most important principles in the management of CHF patients during actual ECT include vigilance in monitoring hemodynamic status, cardiac rhythm, oxygenation, and ventilation and prompt intervention. Beta receptors are downregulated in CHF, leading to a significantly decreased ability of the patient to respond to exogenously administered catecholamines should resuscitation be required. Patients with CHF are particularly prone to malignant ventricular dysrhythmias, which are also less responsive to conventional therapy. Zielinsky et al. (1993) noted that the presence of ventricular dysrhythmias at baseline predicted post-ECT dysrhythmias, so anesthesia providers should pay particular attention to rhythm disturbances and be aware that they may be more difficult to treat in the patient with CHF. In patients with right ventricular heart failure (especially those with increased pulmonary vascular resistance from hypoxic pulmonary vasoconstriction or hypercapnia and associated respiratory acidosis), an increase in pulmonary vascular resistance can quickly increase right ventricular afterload and precipitate right ventricular failure.

Whether to use an antimuscarinic agent in the patient with CHF must be decided on a case-by-case basis. The potential for such medication to increase myocardial workload through added tachycardia and hypertension is established (Rasmussen et al. 1999). On the other hand, as discussed previously, if a patient receives a subconvulsive electrical stimulus, especially if he or she is also receiving beta-blocking medication, the risk of unopposed parasympathetic stimulation and resultant prolonged asystole is real (Burd and Kettl 1998; Decina et al. 1984; Tang and Ungvari 2001; Wells et al. 1988).

The attending anesthesiologist may elect to use other cardioprotective agents when ECT is being administered

to the patient with CHF. For example, a beta-blocker such as esmolol or labetalol may dampen the seizure-induced sympathetic stimulation. The rationale for either agent's use is that the sympathetic stimulation worsens arterial compliance and increases vascular resistance. Because cardiac function is already borderline, even small increases in the impedance of the arterial vasculature can acutely drop cardiac output. Lessening the tachycardia with a beta-blocker reduces myocardial oxygen demand, increases diastolic filling time, and optimizes preload. On the other hand, with an intermediate-duration agent such as labetalol, or long-acting agents such as metoprolol or propranolol, effects lingering after the treatment may predispose to undesirable hypotension. Other strategies include preload reduction (e.g., nitrates), peripheral vasodilators (e.g., hydralazine), and calcium channel blockade (e.g., verapamil or diltiazem).

Finally, intertreatment assessment in patients with CHF is especially important, as demonstrated by the case report of a patient who died of congestive decompensation that began several days after the last ECT treatment (Goldberg and Badger 1993). Daily rounds should include not only assessment of mood and cognitive status but inquiries about symptoms of CHF (e.g., shortness of breath, orthopnea) and physical examination for signs of CHF (e.g., gallops, jugular venous distension, peripheral edema, pulmonary crackles). Any new or worsening findings should prompt careful evaluation and, if necessary, halting of ECT (even if temporarily) to stabilize the patient. Deterioration of left ventricular function over time may also occur without obvious symptoms, and thus patients with CHF should be periodically assessed by a cardiologist.

### Coronary Artery Disease/ Post-Myocardial Infarction

In case series cited earlier (Gerring and Shields 1982; Petrides and Fink 1996; Rice et al. 1994; Zielinski et al. 1993), numerous patients with CAD—some with remote history of MI—underwent ECT without major complications. Unfortunately, there are few reports in which patients with precisely defined severity of CAD were prospectively followed for any effects of ECT. In the echocardiographic/sestamibi study by Ruwitch et al. (1994), ECT did not cause any clinical complications (e.g., angina, MI, clinically significant depression of ventricular dysfunction). Nonetheless, the electrocardiographic and echocardiographic studies mentioned previously showed that in patients undergoing ECT, especially those with preexisting CAD, ischemic changes were often noted on electrocardiogram and/or echocardiogram. Thus,

although the risks of significant morbidity in ECT are probably small, caution is advised in the treatment of patients with CAD. Pre-ECT cardiac testing may be necessary depending on the initial assessment.

Applegate (1997) reviewed the evaluation of patients with ischemic heart disease scheduled to undergo ECT, with emphasis on the 1996 American College of Cardiology/American Heart Association Task Force guidelines, including optimization of the patient's anti-ischemic regimen. Other than the small study by Ruwitch et al. (1994), in which baseline scintigraphy correlated with ECT-induced sestamibi findings, no particular studies inform the ECT clinician whether cardiac imaging has predictive value for ECT complications. Whether to perform cardiac imaging in patients with CAD prior to ECT would depend on the time since the patient's last imaging study and the severity and status of their cardiac disease.

After the prospective ECT patient with CAD has had the appropriate pretreatment evaluation and stabilization, there are measures that may further reduce cardiac risk. Many studies have shown that pretreatment with a variety of antihypertensive agents (e.g., beta-blockers, calcium channel blockers, other vasodilators, or nitrates) lowers the seizure-induced rise in heart rate or blood pressure (Abrams 2002). Whether this reliably translates into actual protection against cardiac complications is unknown. In fact, Zvara et al. (1997) found no difference in electrocardiographic evidence of ischemia during and after ECT with the use of esmolol, in spite of reductions in the elevation in rate-pressure product. Castelli et al. (1995) also found that neither labetalol nor esmolol affected postictal ST-segment changes, even though both drugs blunted the heart rate and blood pressure elevations during ECT. Additionally, in one echocardiographic study, the use of esmolol did not appear to affect changes associated with ECT treatment (O'Connor et al. 1996), although the incidence of patients in that study with underlying CAD is unknown. Furthermore, given its small size (16 patients, 26 sessions) and the low incidence of new regional wall motion abnormalities (4%), it is unlikely that this study can provide much guidance with respect to the use of esmolol. However, it is interesting to compare the peak heart rate after esmolol treatment in relation to incidence of new regional wall motion abnormalities between studies. In the O'Connor et al. (1996) study, peak heart rate post-esmolol (1 mg/kg) was 77 ( $\pm$ 17) beats/minute, with an incidence of 4% new regional wall motion abnormalities. In the Messina et al. (1992) study, in which no esmolol was used, the heart rate post-ECT was 127 beats/minute with a new regional wall motion abnormality incidence of 45%. Thus, it remains uncertain whether beta-blocker pretreatment reduces morbidity associated with ECT. Given

the well-documented salutary effects of such drugs in patients with ischemic heart disease, it seems reasonable to use them in selected cases either before, during, or shortly after the treatment depending on the patient's hemodynamic status, after carefully weighing the risks and potential benefits of such treatment.

A final issue regarding ECT in the patient with CAD concerns the frequently asked question "How soon after an MI can ECT be safely performed?" Severe depression is common in the post-MI period. When the patient sinks into a state of suicidal despair, profound psychomotor retardation, or psychosis, ECT may be the preferred treatment of choice. De Silva and Bachman (1995) consider the first 3 months post-MI to be a particularly high-risk time period for ECT. However, there is no strict rule as to how soon one can perform ECT in a post-MI patient, because it depends on the severity of CAD and whether the patient is considered revascularized or stabilized. A cardiologist should be consulted. Treatment with nitrates or beta-blockade during ECT in a patient with a recent MI would seem prudent, along with the provision for longer-than-usual monitoring in the recovery room to check for late-occurring ischemic changes on electrocardiography or symptoms suggestive of myocardial ischemia or impaired ventricular function. It would not be advisable to perform ECT in a patient in the first few weeks after coronary stenting, although one must weigh the risks of ECT against those of the illness requiring ECT on a case-by-case basis.

### Dysrhythmias, Pacemakers, and Implantable Defibrillators

It is not uncommon for patients with known cardiac dysrhythmia or with a pacemaker or ICD to be referred for ECT. The most common dysrhythmia is atrial fibrillation. There are several reports of patients in atrial fibrillation who safely received ECT and who remained in atrial fibrillation (Geretsegger and Rochowanski 1987; Gerring and Shields 1982; Kitamura and Page 1984; Petrides and Fink 1996; Regestein and Reich 1985; Tancer and Evans 1989). There are also reports of patients in atrial fibrillation who converted to sinus rhythm, sometimes transiently, during ECT (Harsch 1991; Ottoway 2002; Petrides and Fink 1996). Ottoway (2002) reported on a 78-year-old man who had had four-vessel coronary artery bypass grafting 1 month prior to receiving ECT and who had rate-controlled atrial fibrillation. The first two treatments proceeded uneventfully. Electrical cardioversion was attempted just prior to the third treatment and converted the patient to sinus rhythm only for 30 seconds, whereupon he reverted back to atrial fibrillation,

and the third ECT treatment was then administered. The patient converted to sinus rhythm during the resultant seizure and remained there for the rest of his subsequent three treatments, and the depression resolved. Harsch (1991) described a patient in atrial fibrillation who converted to sinus rhythm twice during a course of ECT. Petrides and Fink (1996) reported on three patients who also converted from atrial fibrillation to sinus rhythm during ECT (albeit transiently in one case). ECT has been given after successful cardioversion for atrial fibrillation. Moriarty (1972) reported on a 62-year-old man with depression and chronic atrial fibrillation who received his first ECT session immediately after failed electrical cardioversion attempts. However, just prior to his second treatment, cardioversion was successful, and the patient went on to receive five more treatments without complication or return of atrial fibrillation. On follow-up 8 months later, he remained in sinus rhythm while taking quinidine.

Two cases of apparently new-onset atrial fibrillation occurring during ECT have also been described (O'Melia 1970; Petrides and Fink 1996). O'Melia (1970) described a previously healthy 57-year-old woman who was found to be in atrial fibrillation after her second ECT treatment. She reverted back to sinus rhythm 36 hours later, but further ECT treatments were not given. In the Petrides and Fink (1996) series, a patient with a past history of atrial flutter converted from sinus rhythm to atrial fibrillation after her sixth ECT treatment. She was then converted to sinus rhythm with medication but received no more ECT.

Atrial fibrillation newly identified before ECT should be assessed by a cardiologist for optimal management. The decision to choose rate control versus cardioversion depends on a number of factors and should be made by the cardiologist. Management of chronic atrial fibrillation would be the same whether the patient is receiving ECT or not. There are several considerations when performing ECT in a patient with chronic atrial fibrillation. First, in the appropriate patient without contraindications, therapeutic anticoagulation should be maintained throughout the course of ECT (American Psychiatric Association 2001). For the patient who is not receiving chronic anticoagulation, consideration should be given to short-term anticoagulation (e.g., with heparin) during the ECT course. Second, consideration should be given to performing a transesophageal echocardiogram to check if an atrial clot is present. Third, the patient's heart rate should remain well controlled. Fourth, any associated cardiovascular comorbidities, such as CAD, CHF, or valvular disease, must be taken into account. Fifth, consideration should probably be given to premedication with a beta-blocker before inducing the seizure to lessen sympathetic stimulation. Sixth, and perhaps most important,

close and meticulous monitoring of the patient's hemodynamic status, oxygenation, and electrocardiographic changes in response to treatment is critically important during ECT. Electrocardiographic rhythm should be inspected prior to each treatment. As the cases cited above demonstrate, conversion from atrial fibrillation to sinus rhythm is possible during ECT, thus reinforcing the need for anticoagulation. If the patient in atrial fibrillation does convert to sinus rhythm, the attending cardiologist should be notified. Finally, the patient without history of atrial fibrillation who develops this rhythm during ECT obviously should have a cardiac workup before treatment is resumed.

Atrial fibrillation is the most common, but not the only, cardiac dysrhythmia in patients referred for ECT. Because cardiac patients are predisposed to a variety of atrial or ventricular dysrhythmias, it is important to ensure that electrolytes (especially sodium, potassium, calcium, and magnesium) are normal. Electrolyte abnormalities and other metabolic perturbations (e.g., thyroid dysfunction) can be even more pro-dysrhythmic along with medications that may prolong the QT interval, including some psychotropics.

A related issue concerns the prospective ECT patient with a cardiac pacemaker or an ICD. There have been numerous case reports of patients with pacemakers who have undergone successful and uncomplicated ECT (Abiuso et al. 1978; Alexopoulos and Frances 1980; Alexopoulos et al. 1984; Ballenger 1973; Blitt and Kirschvink 1976; Dolenc et al., in press; Gibson et al. 1973; Jauhar et al. 1979; Youmans et al. 1972), as well as a few reports of patients with ICDs (Dolenc et al., in press; Goldberg and Badger 1993; Lapid et al. 2001; Pornnoppadol and Isenberg 1998). In the case by Goldberg and Badger (1993) described earlier, a man with an ICD and CHF underwent ECT and died of what appeared to be decompensated CHF. It was unlikely that the ICD contributed to the fatal outcome. In fact, with modern pacemakers and ICDs, there is no risk of electrical damage to the device during ECT, assuming proper grounding of the patient (Abrams 2002).

Pre-ECT device assessment to ensure normal functioning is advisable. It is particularly important for the ECT clinicians to know what type of pacemaker a patient has. Patients who are pacemaker-dependent should have their pacemaker assessed and programmed to an appropriate mode where necessary. Those patients with an activity-driven sensor generally will not need to have the rate response programmed off for ECT, because variation in rate between the programmed upper and lower rates should be tolerated. Furthermore, if the activity sensor does respond to either the electrical stimulus or the seizure, patient safety will not be compromised. Pacemaker

patients with minute ventilation devices will need the rate response turned off before ECT. Some practitioners have used a magnet placed on the chest above the device to convert a demand mode pacemaker to fixed mode during ECT in order to avoid spurious discharge of the device, which theoretically could occur as the result of muscle electrical activity; however, there is no evidence to support this practice (Abrams 2002).

ICDs should be turned off prior to each ECT treatment while the patient is on an electrocardiographic monitor, the latter being continued until the ICD is turned back on. All patients with ICDs or pacemakers that have been reprogrammed prior to ECT should have device assessment after the procedure. In summary, presence of a pacemaker or defibrillator does not constitute a contraindication to ECT, but cardiology consultation for appropriate assessment and management of the underlying cardiac disease and device interrogation/adjustment is required.

## Vascular Disease

A number of case reports cite safe and effective use of ECT in patients with a variety of aortic aneurysms, some after surgical correction (Abramczuk and Rose 1979; Attar-Levy et al. 1995; Chapman 1961; Devanand et al. 1990; Dowling and Francis 1993; Goumeniouk et al. 1990; Greenbank 1958; Monke 1952; Moore 1960; Pomeranze et al. 1968; Rosenfeld et al. 1988; Weatherly and Villien 1958; Wolford 1957). Assuming that there are no preexisting conditions or surgical complications, there is no specific reason to assume that patients who have had an aneurysm repair are at increased risk during ECT.

The chief concern in patients with aneurysms is the potential risk of rupture or leakage caused by the rapid rise in blood pressure during ECT. If a patient is known to have an aortic aneurysm, evaluation of the size (e.g., by ultrasound) should be undertaken prior to ECT. Consultation with a vascular surgeon would be prudent to evaluate the stability of the aneurysm and strategies for risk reduction. Pretreatment with antihypertensives before ECT anesthesia can optimize control of blood pressure and reduce arterial wall stress. Labetalol would seem to be ideal for this purpose, as it has both alpha- and beta-blockade and thus can reduce peripheral vascular resistance and attenuate the rise in blood pressure during and shortly after the seizure (McCall et al. 1991). Repetitive imaging may be necessary during the course of ECT treatments if there is any concern with respect to the stability of the aneurysm.

Hypertension is probably the most common cardiovascular condition in patients receiving ECT. Although it

seems intuitively obvious that good control of blood pressure is ideal before ECT, undue delays while waiting for complete normalization are unwarranted. In the 65-year history of ECT, reports of intracerebral hemorrhage during treatment are exceedingly rare; in fact, we are aware of only two reports, both in patients without known prior vascular instability (Rikher et al. 1997; Weisberg et al. 1991). Swartz and Inglis (1990) found that blood pressure actually went down after a course of ECT. Prudic et al. (1987) and Webb et al. (1990) both found that patients with the highest blood pressures pre-ECT had the lowest rise in blood pressure and rate–pressure product during and after the seizure. Finally, with the availability of short acting antihypertensive agents (e.g., esmolol), high blood pressure can generally be managed rapidly and effectively during the treatments.

### Miscellaneous Cardiac Conditions

Numerous reports exist of safe use of ECT in patients with various valvular abnormalities with or without prior surgical correction (Hardman and Morse 1972; Levin et al. 2000; Rasmussen 1997). If a patient has had mechanical valve replacement and has received appropriate anticoagulation, the risk of ECT treatment should not be significantly increased (assuming that no other cardiac dysfunction, such as impaired ventricular function or dysrhythmia, is present). However, if a patient has a valvular abnormality that has not been optimally treated or is newly identified, then echocardiography should be obtained.

Heart transplant patients are rarely encountered in ECT practice. There are three published cases of uncomplicated ECT in heart transplant recipients (Kellner et al. 1991a; Lee et al. 2001; Pargger et al. 1995). Because the transplanted heart is denervated, theoretically there is less risk of vagally mediated bradydysrhythmias during ECT (Lee et al. 2001). Although sympathetic innervation is also lacking, the acute seizure-induced rise in plasma catecholamines still occurs, which causes increases in pulse and blood pressure (Gravenstein et al. 1965), as was seen in the cases just referenced. One must also remember that if bradycardia is encountered during ECT in such a patient, the heart rate will not change in response to anti-muscarinic medication. If resuscitation is necessary, the drugs of choice are epinephrine or isoproterenol. Pre-ECT echocardiographic evaluation is recommended, and use of intratreatment medications such as beta-blockers or nitrates can reduce unfavorable cardiac stress. Obviously, one should only undertake ECT in a cardiac transplant patient in close consultation with the patient's cardiologist.

### Anticoagulation

There are several common indications for anticoagulation in ECT patients, including atrial fibrillation, deep venous thrombosis, and valvular replacement. Many reports exist of patients receiving therapeutic anticoagulation who underwent ECT without complications (Bleich et al. 2000; Hay 1989; Loo et al. 1985). One theoretical concern about maintaining anticoagulation during ECT is the risk of spontaneous hemorrhage during the blood pressure surge in the peri-ictal period. However, to our knowledge no cases have been reported of hemorrhage during ECT in patients receiving anticoagulation, so therapeutic anticoagulation should be continued throughout ECT. Indices of anticoagulation (i.e., the international normalized ratio for coumadin or the partial thromboplastin time for heparin) may fluctuate, especially in patients with acute illnesses or medication changes, and should be carefully monitored. The blood pressure cuff used to block the effects of muscle paralysis in assessing the motor seizure duration should not be placed on the affected limb in patients with deep venous thrombosis (e.g., a forearm should be cuffed rather than the calf).

### Neurological Disorders

---

In considering the medical risks of ECT in patients with neurological disorders, there are four main differences between the neurological and cardiovascular aspects of ECT: 1) the effects of ECT on CNS function are not as well characterized; 2) there are essentially no functional tests to assess degree of risk in a neurological patient before ECT; 3) there are no neuroprotective strategies of note, as there are in the context of cardiac disease (i.e., availability of various cardioprotective agents to blunt the cardiac effects of ECT); and 4) ECT may actually improve the underlying neurological disorder for some conditions (as discussed later in this section). One similarity with the cardiac literature is that there are virtually no controlled data informing the ECT clinician. Fortunately, a large body of case series and reports, as well as accumulated clinical experience, does provide confidence that the majority of patients with various neurological disorders can safely and effectively be treated with ECT. The few areas of probable high neurological risk are well characterized and represent a very small percentage of patients referred for ECT.

Although neurodiagnostic tests (e.g., computed tomography, magnetic resonance imaging [MRI], electroencephalography, single photon emission computed tomography, positron emission tomography) may be helpful

in diagnosing suspected neurological disease, none of these tests is routinely indicated prior to ECT (American Psychiatric Association 2001), nor do any lead to a confident ability to predict risk level with ECT. In patients with known neurological disease, the best pre-ECT assessment consists of a careful neurological exam and diagnostic tests for particular indications. In this section, before considering the various neurological disorders encountered in ECT practice, we review some of the neurophysiological effects of ECT.

## Neurophysiological Effects of ECT

A great deal of research has been conducted on the electroencephalographic, cerebral blood flow, neurometabolic, and neurohormonal effects of electrically induced seizures both in animals and humans (reviewed in Abrams 2002). The purpose of this research is to elucidate the mechanism of action of ECT as well as the underlying neurobiology of psychiatric illnesses and is beyond the scope of this chapter. Furthermore, other than perhaps the blood flow effects, none of these findings is relevant to assessing degree of risk in the prospective ECT patient with comorbid neurological disease.

The most well-characterized clinical effect of ECT on the brain is that on memory function (reviewed in Abrams 2002), which is also beyond the scope of this chapter. No laboratory tests reliably predict extent of cognitive dysfunction with ECT in neurological patients, nor are any nootropic agents available to prevent these effects.

There is a dramatic increase in cerebral blood flow during the seizure in ECT (Nobler et al. 1994), which leads to a transient increase in intracranial pressure. Thus, it would be expected that conditions already causing increased intracranial pressure would represent high-risk situations (American Psychiatric Association 2001).

## Dementia

Numerous reports indicate that ECT can be efficacious for depressive symptoms in depressed dementia patients without causing undue or long-lasting increases in memory disturbance (Rao and Lyketsos 2000). Most of these reports do not establish a dementia diagnosis separate from the cognitive dysfunction related to depression (Rasmussen et al. 2002). In fact, in routine clinical circumstances, it is often difficult to determine whether the patient with coexisting severe depression and cognitive dysfunction has a separate dementing illness or depression-related cognitive dysfunction (Stoudemire et al. 1995). A further problem with this literature is the lack of long-term cognitive follow-up in most reports.

Reynolds et al. (1987) prospectively followed depression ratings in three depressed dementia patients receiving ECT. Two of the patients enjoyed an excellent antidepressant response to ECT without cognitive worsening, whereas one patient suffered acute cognitive worsening as assessed with the Mini-Mental State Examination (MMSE) (Folstein et al. 1975) and had no antidepressant response. Gaspar and Samarasinghe (1982) treated three patients with ECT who carried diagnoses of primary dementia and depression. As with the Reynolds et al. (1987) series, two of the three patients experienced a good antidepressant effect with ECT; none of the patients seemed to have long-lasting cognitive impairment, although no systematic follow up was reported.

Nelson and Rosenberg (1991) treated 21 depressed dementia patients with ECT. Antidepressant efficacy ratings based on chart review were similar to those of a depressed ECT comparison group without dementia. Post-ECT confusion was believed to be greater in the dementia patients, although no efficacy or cognitive follow-up data were presented.

In the largest series to date, Rao and Lyketsos (2000) administered ECT in 31 depressed dementia patients: 16 with vascular dementia, 4 with Alzheimer's dementia, and 11 with dementia of uncertain cause. No outcome data were presented separately for the different dementia groups. Half of the patients experienced delirium (criteria not specified) with ECT. Two-thirds had a good antidepressant response to treatment. The MMSE score actually increased an average of 1.62 points during ECT, indicating the beneficial effect of ECT on attention after clearing of the acute posttreatment confusion. One patient had tardive seizures in the recovery room after ECT.

McDonald and Thompson (2001) reported on three dementia patients with medication-refractory mania who showed excellent benefits with index and maintenance courses of right unilateral ECT and who seemed to tolerate the treatments well from a cognitive standpoint. Grant and Mohan (2001) described four dementia patients whose agitation and aggression were reduced with ECT.

In the most recent ECT series in patients with dementia, Rasmussen et al. (2003) treated seven patients with probable Lewy body dementia. All seven experienced acute antidepressant effects with ECT, which were sustained in three patients for several months to 2 years with maintenance ECT. Acute confusional states were common in this series.

In summary, several dozen cases of patients with dementia have been reported in the ECT literature, with approximately two-thirds showing antidepressant (or antimanic) benefit, and about half showing greater-than-usual cogni-

tive impairment. If the patient's dementia syndrome etiology is well characterized, there is no need to perform neurodiagnostic testing in preparation for ECT. If, however, there is still diagnostic uncertainty about the dementia etiology, further workup may be indicated.

The frequency with which elderly, cognitively impaired patients are referred for ECT points to the need for a large, prospective trial in patients whose dementia severity and subtype are well characterized, with long-term follow up of cognitive and psychopathological outcome. In the meantime, the ECT clinician treating such patients would be well advised to consider right unilateral or bifrontal electrode placement with twice-weekly treatment frequency. There is no evidence from the available literature that the number of treatments to achieve efficacy is different from that for patients without dementia, although the treatments may need to be halted if excessive cognitive dysfunction occurs.

Another common technical issue in treating dementia patients with ECT is whether to have the patients continue taking a cholinesterase inhibitor such as donepezil, galantamine, or rivastigmine. Such medications are commonly used in treating patients with dementia, but there has been concern over a possible interaction of such drugs with succinylcholine, which is metabolized by plasma cholinesterases (Folk et al. 2000). Theoretically, such drugs may prolong the action of succinylcholine, and practitioners have been cautioned either to discontinue such therapy before anesthesia or at least to proceed with caution (Folk et al. 2000; Heath 1997, 2003; Walker and Perks 2002). Rasmussen et al. (2003) reported that patients taking donepezil for dementia symptoms were safely treated with ECT. A further practical problem is that the half-life of the most commonly used cholinesterase inhibitor, donepezil, is so long (i.e., about 50 hours) that a complete washout would take about a week and a half, a period that is prohibitively long in treating a typical patient severely ill enough to warrant ECT treatment. A prudent approach, in our opinion, would be to continue the cholinesterase inhibitor if there has been benefit with it and proceed with ECT but remain mindful of a possible prolongation of succinylcholine action.

## Movement Disorders

In this section, we discuss the most commonly encountered movement disorders in ECT practice: Parkinson's disease and neuroleptic-induced movement disorders. The scarce literature on rare conditions such as Huntington's disease, Wilson's disease, progressive supranuclear palsy, and multiple system atrophy is also briefly reviewed.

### *Parkinson's Disease*

Several case reports, case series, and one placebo (sham-ECT)-controlled trial indicate that ECT is effective for treating depression in patients with Parkinson's disease (Rasmussen et al. 2002). An intriguing finding in this literature is that ECT may also improve motor function (Moellentine et al. 1998; Rasmussen and Abrams 1991). Common side effects of ECT in patients with Parkinson's disease include delirium and treatment-emergent dyskinesia, which probably indicate a dopaminomimetic effect (Douyon et al. 1989). The duration of ECT-related anti-parkinsonian effects has been variable. Fall et al. (1995) followed 16 nondemented, nondepressed patients with Parkinson's disease before, immediately after, and for up to 1.5 years after courses of mostly unilateral ECT. Fifteen had measurable (occasionally dramatic) improvement in the motor symptoms of Parkinson's disease. Although maintenance ECT was not used, 8 patients had sustained improvement for 3–18 months after ECT. Five patients developed severe confusional states, the duration of which was up to 2 weeks. Four of these 5 patients went on to have long-lasting (i.e., at least several months) motor improvement.

Pridmore et al. (1995) treated seven nondepressed Parkinson's disease patients with four unilateral ECT treatments. Immediate post-ECT and 2-week post-ECT ratings in all spheres of motor function indicated improvements. Four patients developed severe, although temporary, confusion. One patient developed dyskinesia, which responded to lowering of the levodopa dose. In a follow-up report on these and several other such patients who had been given index (but not maintenance) ECT, three of nine initial ECT responders had improvements lasting 2–10 weeks, whereas six of nine had improvements lasting 10–35 months (Pridmore and Pollard 1996).

There are several case reports of patients with Parkinson's disease given maintenance ECT to extend the initial motoric improvement of index courses of treatment (Aarsland et al. 1997; Fall and Granerus 1999; Hoflich et al. 1995; Serby et al. 1994; Wengel et al. 1998; Zervas and Fink 1991). Maintenance ECT seemed to prevent relapses. The frequency of such treatments was quite variable depending on the period of improvement each patient sustained. Cognitive impairment was noticeable in some cases.

In summary, ECT seems to be effective for the depression commonly encountered in patients with Parkinson's disease and may even improve the motoric signs. The duration of such benefits is unpredictable and may be extended with maintenance ECT, although the benefits need to be balanced against cognitive impairment. Acute

confusional states and dyskinesias are common during ECT and may be reduced with cautious lowering of dopamine agonist dosage. As with demented patients, we recommend that the ECT clinician consider twice, versus thrice, weekly treatment frequency and the use of electrode placements that may cause less cognitive impairment (i.e., right unilateral or bifrontal).

### *Neuroleptic-Induced Movement Disorders*

A few case series and case reports indicate variable results in patients with tardive dyskinesia (Besson and Palin 1991; Flaherty et al. 1984; Holcomb et al. 1983; Price and Levin 1978; Yassa et al. 1990). In one case, dyskinesias were induced in a Wilson's disease patient (DeQuardo et al. 1992). It is not surprising that some cases of tardive dyskinesia worsen with ECT, considering the known propensity of ECT to increase levodopa-induced dyskinesias in patients with Parkinson's disease (Douyon et al. 1989). Several cases of improvement in tardive dystonia with ECT have been reported (Kaplan et al. 1991; Kwentus et al. 1984; Postalache et al. 1995), although one case without improvement has been reported (Hanin et al. 1995).

Numerous series have documented that ECT represents a life-saving option for patients with neuroleptic-induced malignant catatonia (also known as neuroleptic malignant syndrome) who do not respond to more conservative measures (Davis et al. 1991; Mann et al. 1990; Nisijima and Ishiguro 1999; Philbrick and Rummans 1994; Scheftner and Shulman 1992; Troller and Sachdev 1999). Typically, ECT should be reserved for patients who fail to respond to withdrawal of neuroleptic medication and institution of supportive measures, such as muscle relaxants and benzodiazepines; additionally, ECT can treat both the signs of neuroleptic-induced malignant catatonia as well as catatonia, psychosis, or mood disorder as part of the underlying psychopathological condition, which are sometimes difficult to distinguish (Mann et al. 2003).

There is no particular reason to believe that ECT is unsafe in patients who have these neuroleptic-induced movement disorders, although the clinician should monitor the effects ECT may have on the movements as well as on cognitive function.

### Cerebrovascular Disease

Several isolated reports of safe use of ECT in patients poststroke have been published (DeQuardo and Tandon 1988; Weintraub and Lippmann 2000). In a large series of such patients given ECT (Currier et al. 1992; Murray et al. 1986), 32 of 34 attained an antidepressant response, and none of the patients deteriorated neurologically. Nei-

ther location nor time since stroke was associated with clinical outcome. Five of six patients showed improvement in preexisting cognitive impairment with treatment, again reflecting the enhancement in sustained attention with the antidepressant benefit of ECT.

Martin et al. (1992) treated 14 poststroke patients with ECT and compared their outcomes with those of 14 age- and sex-matched control ECT patients. They found a similar incidence of 4 of 14 in each group developing interictal delirium. All four of the poststroke patients developing delirium had caudate strokes, supporting the investigators' contention that basal ganglia lesions predispose to ECT-related delirium. The poststroke ECT patients had a good clinical response without worsening in non-cognitive neurological functions. Of note, the more ECT treatments given after the delirium became apparent, the longer the delirium lasted.

In addition to patients with a history of stroke, those with known intracerebral aneurysms or vascular malformations might be expected to have a higher than average risk of complications with ECT. At least two cases of patients safely administered ECT after cerebral aneurysm repair have been reported (Farah et al. 1996; Husum et al. 1983), and numerous cases of patients with known aneurysms that have not been surgically corrected pre-ECT have been reported; in none of those did a bleed occur (Bader et al. 1995; Drop et al. 1988; Gardner and Kellner 1998; Hunt and Kaplan 1998; Kolano et al. 1997; Najjar and Guttmacher 1998; Salaris et al. 2000; Viguera et al. 1998). Two cases of ECT-associated intracerebral hemorrhages have been reported (Rikher et al. 1997; Weisberg et al. 1991), both in patients without known pre-ECT cerebrovascular disease. Most investigators reporting on ECT in patients with known aneurysms used antihypertensive treatments to dampen the ECT-related increase in blood pressure. Drop et al. (2000) considered intracerebral aneurysms at high risk for rupture during ECT and recommended that appropriate antihypertensive measures (e.g., beta-blockade, sodium nitroprusside) and monitoring should be undertaken during ECT in such patients.

In summary, the literature on ECT in patients with histories of stroke or intracerebral aneurysm contains numerous reports of safe ECT administration. This should provide some confidence to the clinician, but caution is still warranted. Patients with hemorrhagic strokes probably present a greater risk than those with ischemic ones. Measures to control excessive blood pressure increases that do not cause a later drop in blood pressure should be considered, given stroke patients' common impairment in cerebral autoregulation of blood pressure (Drop et al. 2000). Thus, relatively short-acting antihypertensives,

such as esmolol, probably provide safer hemodynamic control than longer-acting compounds.

## Epilepsy

ECT has anticonvulsant activity, as indicated by a progressive increase in seizure threshold and decrease in seizure length during the course of treatments (Sackeim et al. 1983). In the pre-anticonvulsant era, and sporadically in the modern era, ECT has been used successfully to treat intractable epilepsy (Caplan 1946; Griesemer et al. 1997; Regenold et al. 1998; Sackeim et al. 1983; Schnur et al. 1989; Taylor 1946; Viparelli and Viparelli 1992; Wolff 1956) and even status epilepticus (Lisanby et al. 2001). These effects are short-lived, however, and the use of ECT to treat epilepsy is largely only of historical interest, with current treatments including anticonvulsant medications, surgery, and vagal nerve stimulation.

Occasional reports document that status epilepticus can occur, fortunately rarely, after ECT, even in nonepileptic patients given ECT for a mood, psychotic, or behavioral dyscontrol disorder (Grogan et al. 1995; Hansen-Grant et al. 1995; Rao et al. 1993). There are two reports of status epilepticus following ECT in epileptic patients: one patient had been administered multiple monitored ECT (Maletzky 1981), a technique no longer recommended for routine use (American Psychiatric Association 2001); the other had previously unrecognized seizures and was not receiving anticonvulsant medication during ECT (Moss-Herjanic 1967). At present, there is no evidence that spontaneous seizure frequency increases with ECT in epileptic patients. However, no large series have been published. Furthermore, it does not appear that the incidence of chronic epilepsy is increased in nonepileptic patients who receive ECT (Blackwood et al. 1980).

The more common clinical challenge is how to treat the epileptic patient whose psychopathological features indicate ECT. Surprisingly few reports describe ECT for psychiatric indications in epileptic patients (Hsiao et al. 1987). There are two cases of successful and safe ECT in depressed patients after neurosurgery for a seizure disorder (Kaufman et al. 1996; Krahn et al. 1993). In assessing risk with ECT, one must consider the etiology of the seizure disorder: a patient with seizures secondary to a brain tumor would obviously be at higher risk of complications from ECT than a patient with idiopathic epilepsy, a normal head MRI, and no focal neurological findings. Before undertaking a course of ECT in a patient with epilepsy, consultation with the patient's neurologist is advised. Pretreatment head imaging or electroencephalography is not needed unless such testing is indicated as part of the patient's neurological care.

The most common technical problem in ECT with epileptic patients is elicitation of therapeutic seizures in the face of concomitant treatment with anticonvulsant medications. We have personally treated numerous epileptic patients successfully with ECT without having to alter the patient's anticonvulsant regimen; however, occasionally patients either do not obtain seizures or have extremely short ones. In such a scenario, strategies include hyperventilation before the electrical stimulus, use of non-anticonvulsant anesthetic agents such as etomidate or ketamine, pretreatment with intravenous caffeine before anesthesia, and cautious lowering of the patient's anticonvulsant medication dosages (American Psychiatric Association 2001). The latter method brings the risk of spontaneous seizures and should be undertaken with the aid of a neurologist. At present, it is not known whether various anticonvulsant agents differentially affect seizure threshold and duration in ECT.

## Intracranial Tumors

Two early reports of dire outcomes in ECT patients found to have brain tumors following treatment led to the common belief that intracranial masses represent an absolute contraindication to ECT (Maltbie et al. 1980; Shapiro and Goldberg 1957). Mattingly et al. (1991), however, reviewed 10 cases in which presence of the tumor was known in advance of ECT (eight with meningiomas and two with metastatic breast cancer). None of the patients had focal neurological findings, increased intracranial pressure, or papilledema before treatment, nor did any of them die or experience neurological deterioration with ECT up to 1 month afterward. Several other cases of successful and neurologically uncomplicated administration of ECT to patients with meningiomas have been described (Kellner and Rames 1990; Kellner et al. 1991b; McKinney et al. 1998; Starkstein and Migliorelli 1993). Recently, a patient with increased intracranial pressure associated with a brain tumor was reported to enjoy a good therapeutic response without neurological deterioration (Patkar et al. 2000). The investigators used dexamethasone, furosemide, and beta-blockade before treatment to decrease brain edema and to blunt the increase in intracranial pressure associated with ECT. Most recently, Kohler and Burock (2001) reported a 35-year-old woman with intractable depression after two resections and radiation therapy for recurrent left frontal neurocytoma. Pretreatment MRI revealed a complex mass in the left lateral ventricle and left frontal encephalomalacia. She had mild right-sided weakness and mild transcortical expressive dysphasia. After three ECT treatments and on follow-up several months later, she was much better and without any neurological worsening.

Whether intracranial pressure was elevated pretreatment was not reported.

Presence of any CNS tumor may present an increased risk for neurological complications caused by ECT. In the absence of focal neurological signs, brain edema, mass effect, or papilledema, the risks likely are relatively small. In the presence of such findings, the increased risk may be quite high, and ECT should be considered only when no other reasonable option exists and only after consultation with a neurosurgeon or neurologist.

## Other Neurological Disorders

As discussed previously, ECT may be lifesaving in some cases of refractory neuroleptic-induced malignant catatonia (neuroleptic malignant syndrome). There have also been several reports that ECT may be effective in a variety of other states falling under the rubric of "delirium" (Stromgren 1997). However, most of the reports involve patients who would be described in the United States as having catatonic features as part of a mood or psychotic disorder (American Psychiatric Association 1999; Stromgren 1997). We agree with recent practice guidelines that ECT should not be considered effective against delirium as a global phenomenon (American Psychiatric Association 1999). However, there may be specific types of delirium in which ECT may play a role. For example, there are some reports of a beneficial effect of ECT in delirium tremens (Dudley and Williams 1972; Kramp and Bolwig 1981), although this is probably only of historical interest. Additionally, there are reports of patients with protracted delirium after traumatic brain injury who responded to ECT (Kant et al. 1995; Silverman 1964). A prudent summary statement on this issue would be that although ECT is not a primary treatment for delirium, it sometimes may be dramatically effective in cases in which, in spite of intense medical and neurological assessment and management, a patient persists with severe agitation, psychosis, or catatonic features.

Several cases have been reported of patients with multiple sclerosis receiving ECT for psychopathological states (Mattingly et al. 1992; Savitsky and Karliner 1951), with the suggestion that gadolinium-enhancing lesions on MRI before treatment may indicate a high risk for neurological deterioration (Mattingly et al. 1992). Isolated case reports and small series also describe, with greatly varying levels of detail on outcome, the safe use of ECT for psychopathological states in patients with a diversity of other neurological conditions such as cerebral palsy (Rasmussen et al. 1993), hydrocephalus with shunt (Levy and Levy 1987), spinocerebellar ataxia (Folkerts et al. 1998), Huntington's disease (Beale et al. 1997; Broth-

ers and Meadows 1955; Evans et al. 1987; Folstein et al. 1983; Heathfield 1967; Lewis et al. 1996; McHugh and Folstein 1975; Ranen et al. 1994), progressive supranuclear palsy (Barclay et al. 1996), Friedreich's ataxia (Singh et al. 2001), and multiple system atrophy (Hooten et al. 1998; Roane et al. 2000). Of course, these do not prove ECT has the same risk profile as for patients without these conditions. A prudent approach in such patients is to be cautious for signs of neurological worsening and especially for excessive cognitive side effects.

## Miscellaneous Medical Disorders

---

The heart and brain bear most of the physiological effects of ECT. Fortunately, most of the other organ systems are not substantially affected by ECT, nor do their diseases generally cause much concern for greater risk of complications during ECT. We do, however, cover some additional considerations in the following discussion.

### Pulmonary

With the obvious paralyzing effect of anesthetic medications on respiration, careful attention to airway management is of the highest importance in ECT practice, and patients with pulmonary disorders should receive special attention. For example, bronchospasm is a risk in patients with chronic obstructive pulmonary disease or asthma (Taylor 1968). Patients who are using inhalers should do so in the morning shortly before treatment. Theophylline has been associated with a risk of prolonged seizures and status epilepticus in ECT (Abrams 1997; Devanand et al. 1988; Peters et al. 1984), and discontinuation before ECT if medically safe has been recommended (American Psychiatric Association 2001), although Rasmussen and Zorumski (1993) described seven patients with therapeutic theophylline levels during ECT, none of whom developed status epilepticus. If discontinuing theophylline is medically contraindicated, then the lowest therapeutic blood level should be maintained, caffeine augmentation should be avoided, and there should be ready access to rapidly acting anticonvulsant medication (e.g., intravenous diazepam).

### Pregnancy

The two most common adverse events in pregnant women during ECT are aspiration and those related to premature labor, uterine contractions, and vaginal bleeding, although ECT can be delivered safely during pregnancy (American Psychiatric Association 2001; Ishikawa et al. 2001; Miller

1994; Walker and Swartz 1994). Safety measures to prevent aspiration include tracheal intubation and alkalinizing intragastric pH with a nonparticulate antacid. Pretreatment obstetrical assessment, preferably to include fetal ultrasound, can identify high-risk pregnancies. Non-invasive monitoring of fetal heart tones before and after the seizure can document that no fetal distress occurred. Finally, probably the most important aspect of safe ECT in pregnant women is ready availability of obstetrical intervention in case of untoward events (American Psychiatric Association 2001).

## Diabetes Mellitus

A recent large series describing patients with insulin-dependent type 2 diabetes mellitus concluded that clinically significant changes in glucose levels are rare during ECT (Netzel et al. 2002). Diabetic patients should have blood glucose levels monitored closely during the ECT course, including fingerstick checks just before treatment and probably during recovery and shortly thereafter. Typically, insulin-dependent diabetics are administered half their morning insulin doses and are treated with ECT promptly. They are then fed breakfast and given the remaining half of their insulin dose. Intravenous access should be maintained well into recovery in case glucose needs to be administered for hypoglycemic episodes in brittle patients.

## Other Considerations

Electrolyte abnormalities can lead to cardiac dysrhythmias and should be corrected. Histamine<sub>2</sub> antagonists or antacids may decrease gastric acid secretion and the risk of aspiration in patients with gastroesophageal reflux disease, gastroparesis, or obesity (as well as pregnancy, as discussed above). Patients at severe risk for aspiration may require intubation. Urinary retention from antimuscarinic agents given during ECT is quite uncomfortable for patients and can predispose to urinary tract infections and even bladder rupture if not monitored. In those patients who do experience significant urinary retention after treatments, antimuscarinics can be avoided, recognizing that the vagal effect of the electrical stimulus is not blocked and prolonged asystole can occur. Patients with severe osteoporosis or recent fractures require careful titration of muscle relaxant dosing; the adequacy of paralysis can be tested with a peripheral nerve stimulator. Extra care should be exercised in ventilating the patient with unstable cervical spine disease to avoid spinal cord injury. With the brief increase in intraocular pressure lasting a few minutes after the seizures (Edwards et al. 1990; Good et al. 2004; Saad

et al. 2000), glaucoma patients should receive their medications in the mornings before treatment, an exception being anticholinesterase drugs, which theoretically could prolong the action of succinylcholine (American Psychiatric Association 2001; Saad et al. 2000).

## Conclusion

---

ECT represents a remarkably safe and effective treatment option for depressed, manic, or psychotic patients with concomitant medical illnesses. With proper attention to pretreatment medical evaluation, rational use of cardio-protective medications during the treatments, and ongoing monitoring of medical status in between treatments, virtually all patients requiring ECT can be safely treated.

# 40 Palliative Care

---

William Breitbart, M.D.

Christopher Gibson, Ph.D.

Harvey Max Chochinov, M.D., Ph.D., F.R.C.P.C.

**ONE OF THE** most challenging roles for the psychosomatic medicine psychiatrist is to help guide terminally ill patients physically, psychologically, and spiritually through the dying process. Patients with advanced cancer, AIDS, and other life-threatening medical illnesses are at increased risk for developing major psychiatric complications and have an enormous burden of both physical as well as psychological symptoms (Breitbart et al. 2004a). In fact, surveys suggest that psychological symptoms such as depression, anxiety, and hopelessness are as frequent, if not more so, than pain and other physical symptoms (Portenoy et al. 1994; Vogl et al. 1999).

In 1999 the Academy of Psychosomatic Medicine published its position statement titled “Psychiatric Aspects of Excellent End-of-Life Care” (Shuster et al. 1999), which stressed the importance of psychiatric issues in palliative care and the need for competent psychiatric care to be an integral component of palliative care. Major textbooks provide comprehensive reviews of the interface of psychiatry and palliative medicine (Chochinov and Breitbart 2000; Lloyd-Williams 2003), and a new international journal with that focus has recently been started (Breitbart 2003b).

The importance of the psychiatric, psychosocial, and spiritual aspects of palliative care has also been recognized in reports from the American Board of Internal Medicine (Subcommittee on Psychiatric Aspects of Life-Sustaining Technology 1996), the Institute of Medicine (Field and Cassel 1997; Foley and Helband 2001), the National Comprehensive Cancer Network (Levy et al. 2003), and the U.S. Health Resources and Services Administration (O’Neill et al. 2003). Several major national and international palliative care organizations also exist, and more

than 10 national and international palliative care scientific journals have been published (Stjernsward and Clark 2004).

This chapter prepares the psychosomatic medicine practitioner to become an effective psychiatric clinician involved in the care of patients with advanced, life-threatening medical illnesses, either as a consultant to or a part of the palliative care team. In this chapter, we review basic concepts and the role of the psychiatrist in palliative care, including assessment and management of common psychiatric disorders in the terminally ill, with special attention to suicide and desire for hastened death. We describe the psychotherapies developed for use in palliative care settings and then discuss spirituality, cultural sensitivity, communication, grief and bereavement, and control of common physical symptoms.

Related topics are discussed elsewhere in this book, including advance directives and end-of-life decisions (see Chapter 4, “Ethical Issues,” and Chapter 5, “Psychological Responses to Illness”), physician-assisted suicide (see Chapter 10, “Suicidality”), terminal sedation (see Chapter 20, “Lung Disease”), dialysis discontinuation (see Chapter 22, “Renal Disease”), and pain management (see Chapter 36, “Pain”).

## Palliative Care

---

### Historical Perspectives

The term *palliation* is derived from the Latin root word *palliare*, which means “to cloak” or “to conceal.” *Pallium* also refers to the cloth that covers or cloaks burial caskets.

These root words suggest that the dying patient, although not amenable to cure, can be “cloaked” or “embraced” in the comforting arms of the caregiver. What cannot be cured can always be comforted. The nature and focus of palliative care has evolved over the past century, expanding beyond just comfort for the dying to include palliative care and symptom control that begins with the onset of a life-threatening illness and proceeds past death to include bereavement interventions for family and others.

Modern palliative care is an outgrowth of the hospice movement that began in the 1840s with Calvaires in Lyon, France, and progressed through 1900 and the establishment of the St. Joseph’s Hospice in London, finally culminating with the progenitor of all modern hospices, St. Christopher’s Hospice, established in 1967. By 1975 a large number of independent hospices had been developed in the United Kingdom, Canada, and Australia. The first hospice in the United States was established in 1974 in Connecticut. Soon after, the U.S. government established limited Medicare coverage for hospice benefits. This period also saw the establishment of the first “palliative care” program at Royal Victoria Hospital in Montreal, founded by Balfour Mount and his colleagues. This period of evolution from the traditional stand-alone, home-based hospice also saw the development of hospital-based pain and palliative care consultation services such as the pain service established in 1978 by Kathleen Foley at the Memorial Sloan-Kettering Cancer Center. Modern palliative care thus evolved from the hospice movement into a mixture of academic and nonacademic clinical care delivery systems that had components of home care and hospital-based services (Stjernsward and Papallona 1998).

## Defining Palliative Care

The Palliative Care Foundation (1981) defined *palliative care* as “active compassionate care of the terminally ill at a time that their disease is no longer responsive to traditional treatment aimed at cure or prolongation of life, and when the control of symptoms is paramount” (p. 10). According to this definition, palliative care applies primarily at the end of life. In 1990, the World Health Organization (WHO) defined *palliative care* as

the active total care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms, and of psychological, social and spiritual problems, is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families. Many aspects of palliative care are also applicable earlier in the course of the illness in conjunction with anti-cancer treatment. (p. 2)

This definition is the first to suggest applicability even at stages of disease that precede the end of life.

In 1995, the Canadian Palliative Care Association published its definition of *palliative care*:

Palliative care, as a philosophy of care, is the combination of active and compassionate therapies, intended to comfort and support individuals and families who are living with a life-threatening illness. During periods of illness and bereavement, palliative care strives to meet physical, psychological, social and spiritual expectations and needs, while remaining sensitive to personal, cultural and religious values, beliefs and practices. Palliative care may be combined with therapies aimed at reducing or curing illness, or it may be the total focus of care. (p. 3)

This definition is perhaps the most expansive to date. It suggests not only that palliative care is applicable at all stages of life-threatening disease (intensifying once cure is no longer possible) but that psychological, social, spiritual, and cultural issues are elements of palliative care as important as the control of pain and other physical symptoms. According to the WHO, palliative care 1) affirms life and regards dying as a normal process; 2) views the dying process as a valuable experience; 3) neither hastens nor postpones death; 4) provides relief from pain and other symptoms; 5) integrates psychological and spiritual care; 6) offers a support system to help patients live as actively as possible until death; 7) helps family cope with illness and bereavement; and 8) is multidisciplinary, including physicians, nurses, mental health professionals, clergy, and volunteers (World Health Organization 1990, 1997, 1998).

## Palliative Care Programs/ Models of Care Delivery

Fully developed model palliative care programs ideally include all of the following components: 1) a home care program (e.g., hospice program); 2) a hospital-based palliative care consultation service; 3) a day care program or ambulatory care clinic; 4) a palliative care inpatient unit (or dedicated palliative care beds in hospital); 5) a bereavement program; 6) training and research programs; and 7) Internet-based services. It is estimated that there are currently more than 3,000 hospices in the United States and over 300 hospital-based pain and palliative care services. In addition, there are 4 academic medical school-affiliated departments of palliative medicine, and 10 pain and palliative medicine fellowship training programs in the United States.

## Death in America

---

To understand and treat psychiatric issues in the dying patient today, one must have an appreciation of why, when, where, and how Americans now die.

### Where and How Do Americans Die?

Although two Gallup polls, conducted in 1992 and 1996, found that 9 of 10 terminally ill patients with less than 6 months to live would prefer to die at home (Foreman 1996; National Hospice Organization 1996; Seidlitz et al. 1995), today most Americans die in institutions, surrounded by medical caregivers.

The SUPPORT clinical trial (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) (SUPPORT Principal Investigators 1995) and other studies have suggested that a technological imperative characterizes Western medical practice, including care of the dying. SUPPORT found substantial shortcomings in the care of seriously ill hospitalized patients—including poor communication between physicians and dying patients and implementation of overly aggressive treatment, often against patients' wishes. The findings of this study emphasized the need for greater skills and education in end-of-life issues as well as increased communication with and support of dying patients. Perhaps the most perturbing conclusion from this study is that in general, Americans are dying not good deaths but bad deaths, characterized by needless suffering and disregard for patients' or families' wishes or values.

The concept of death trajectories (see Figure 40–1) has been used to describe the unique as well as relatively predictable patterns of approaching death (Field and Casse 1997). Some people die suddenly and unexpectedly, as shown in Figure 40–1A (e.g., cardiac arrest). Among those with forewarning of death, many have a steady and relatively predictable decline, as shown in Figure 40–1B (e.g., advanced cancer). There is a third pattern (Figure 40–1C) of long periods of chronic illness punctuated by crises, any of which may result in death (e.g., AIDS, congestive heart failure, or chronic obstructive pulmonary disease). Each type of death trajectory brings with it a unique set of problems and illustrates the challenges of determining prognoses for patients with life-threatening illnesses.

### What Is a “Good” Death?

A meaningful dying process is one throughout which the patient is physically, psychologically, spiritually, and emotionally supported by his or her family, friends, and care-

givers. Weisman (1972) described four criteria for what he called an “appropriate death”: 1) internal conflicts, such as fears about loss of control, should be reduced as much as possible; 2) the individual's personal sense of identity should be sustained; 3) critical relationships should be enhanced or at least maintained, and conflicts should be resolved, if possible; and 4) the person should be encouraged to set and attempt to reach meaningful goals, even though limited, such as attending a graduation, a wedding, or the birth of a child, as a way to provide a sense of continuity into the future.

## Role of the Psychiatrist

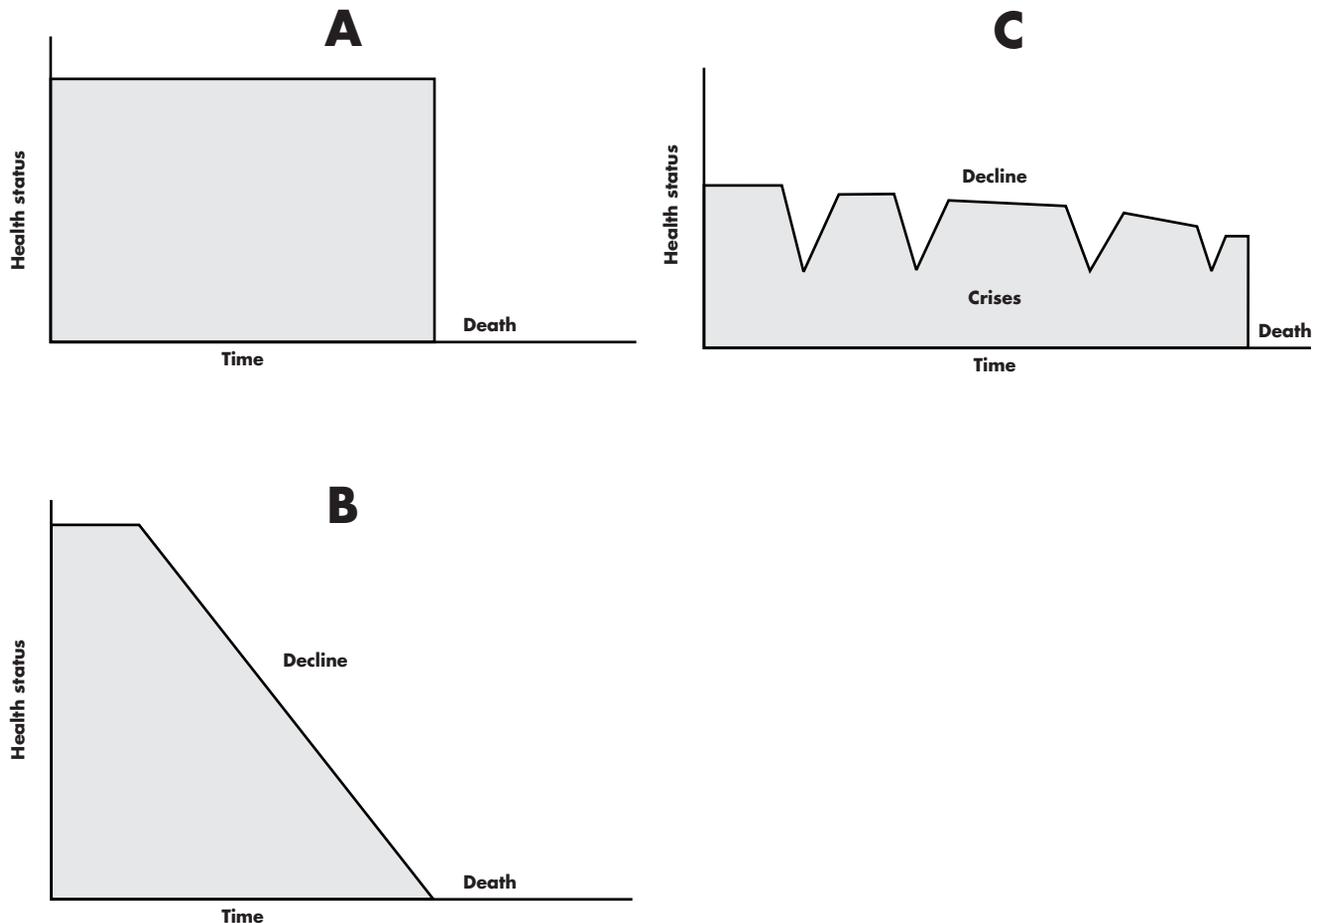

---

The traditional role of the psychiatrist is broadened in several ways in the care of the dying patient. Psychosomatic medicine psychiatrists can provide expert care and teaching about the management of depression, anxiety, delirium, and pain in terminally ill patients (Breitbart and Holland 1993; Chochinov and Breitbart 2000). Psychiatrists can also play an important role in the management of social, psychological, ethical, legal, and spiritual issues that complicate the care of dying patients. The psychiatrist can provide assistance in dealing with the existential crisis posed by a terminal diagnosis. Through discussions with the primary care physician, the patient and family may have begun to confront the reality that the disease is no longer curable or controllable. The psychiatrist can help the patient deal with the prognosis and explore treatment options, including palliative care. The psychiatrist's unique expertise in the care of the dying patient is to diagnose and treat comorbid psychiatric disorders that may complicate the course of illness as well as evaluate and intervene regarding suicide risk.

The psychiatrist helps resolve conflicts among patient, family, and staff by opening lines of communication and helping families to deal with the strong emotions that surround the imminent death of a loved one. Conflicts with the physician and staff are common because the clinicians are also stressed; resolution of these conflicts is a critical intervention for the patient's physical and psychological well-being.

Psychotherapeutic interventions for patients and families who are experiencing anticipatory grief are also important. During the bereavement period, the family may turn to the psychiatrist who participated in the patient's care and who shares memories of the patient for continuing support.

The psychiatrist also has an ethical role in encouraging discussion of end-of-life decisions regarding treatment, withholding resuscitation, and life support. The ca-

**FIGURE 40-1. Prototypical death trajectories.**

(A) Sudden death from an unexpected cause. (B) Steady decline from a progressive disease with a “terminal” phase. (C) Advanced illness marked by slow decline with periodic crises and “sudden” death.

capacity of the patient to make rational judgments and the proxy’s ability to make an appropriate decision for the patient may require psychiatric evaluation. The decision to withdraw life support is highly emotional and may require psychiatric consultation (Subcommittee on Psychiatric Aspects of Life-Sustaining Technology 1996). The psychiatrist’s role can include teaching the medical staff about the psychological issues involved in care of dying patients, including how to deliver bad news and discuss do-not-resuscitate (DNR) orders and other treatment preferences with the patient or with family when the patient is unable to make such decisions (Misbin et al. 1993).

## Psychiatric Disorders in the Palliative Care Setting

Patients with advanced disease, such as advanced cancer, are particularly vulnerable to psychiatric disorders and

complications (Breitbart et al. 1993, 1995, 2004a; Minagawa et al. 1996). The incidence of specific psychiatric disorders in advanced diseases is discussed in earlier chapters in this volume, for example, cancer (Chapter 24, “Oncology”), heart failure (Chapter 19, “Heart Disease”), chronic obstructive pulmonary disease (Chapter 20, “Lung Disease”), end-stage renal disease (Chapter 22, “Renal Disease”), and AIDS (Chapter 28, “HIV/AIDS”).

### Anxiety Disorders

The terminally ill patient presents with a complex mixture of physical and psychological symptoms in the context of a frightening reality, making the identification of anxious symptoms requiring treatment challenging (see also Chapter 12, “Anxiety Disorders”). Patients with anxiety complain of tension or restlessness, or they exhibit jitteriness, autonomic hyperactivity, vigilance, insomnia, distractibility, shortness of breath, numbness, apprehension, worry, or rumination. Often the physical or somatic

manifestations of anxiety overshadow the psychological or cognitive ones and are the symptoms that the patient most often presents (Holland 1989). The consultant must use these symptoms as a cue to inquire about the patient's psychological state, which is commonly one of fear, worry, or apprehension.

The assumption that a high level of anxiety is inevitably encountered during the terminal phase of illness is neither helpful nor accurate. In deciding whether to treat anxiety during the terminal phase of illness, the clinician should consider the patient's subjective level of distress as the primary impetus for the initiation of treatment. Other considerations include problematic patient behavior such as noncompliance due to anxiety, family and staff reactions to the patient's distress, and the balancing of the risks and benefits of treatment (Payne and Massie 2000).

### *Prevalence*

Prevalence of anxiety disorders among terminally ill cancer and AIDS patients ranges from 15% to 28% (Kerrihard et al. 1999). Prevalence studies of anxiety, primarily in cancer populations, report a higher prevalence of mixed anxiety and depressive symptoms rather than anxiety alone (Payne and Massie 2000). Prevalence of anxiety increases with advancing disease and decline in the patient's physical status (Rabkin et al. 1997). Brandberg et al. (1995) reported that 28% of advanced melanoma patients were anxious compared with 15% of control subjects. The prevalence of anxiety disorders in HIV/AIDS has been reported to range from 0% to 39% (Kerrihard et al. 1999). As disease progresses, patients' anxiety may include fears about the disease process, the clinical course, possible treatment outcomes, and death. In addition, anxiety may result from fear of increasing social stigma as the medical illness becomes more evident as well as from fear of the increasing financial consequences of treatments.

As outlined in Table 40-1, anxiety can occur in terminally ill patients as an adjustment disorder, a disease- or treatment-related condition, or an exacerbation of a pre-existing anxiety disorder (Kerrihard et al. 1999; Massie 1989). Adjustment disorder with anxiety is related to adjusting to the existential crisis and the uncertainty of the prognosis and the future (Holland 1989). When faced with terminal illness, patients with preexisting anxiety disorders are at risk for reactivation of symptoms. A generalized anxiety disorder or panic disorder is apt to recur, especially in the presence of dyspnea or pain. Persons with phobias will have an especially difficult time if the disease or treatment confronts them with their fears (e.g., claustrophobia, fear of needles, fear of isolation). Post-traumatic stress disorder (PTSD) may be activated in dying patients as they relate their situation to some prior

near-death experience, such as the Holocaust, a combat experience, or a cardiac arrest, and the terror associated with that experience.

### *Assessment*

As noted in Table 40-1, symptoms of anxiety in the terminally ill patient may arise from a medical complication of the illness or treatment (Breitbart et al. 1993, 1995; Holland 1989; Payne and Massie 2000). Hypoxia, sepsis, poorly controlled pain, drug reactions such as akathisia, and withdrawal states often present as anxiety. In the dying patient, anxiety can represent impending cardiac or respiratory arrest, pulmonary embolism, sepsis, electrolyte imbalance, or dehydration (Strain et al. 1981).

During the terminal phase of illness, when patients become less alert, there is a tendency to minimize the use of sedating medications. It is important to consider the need to slowly taper benzodiazepines and opioids, which may have been sustained at high doses for extended relief of anxiety or pain, in order to prevent acute withdrawal states. Withdrawal states in terminally ill patients often manifest first as agitation or anxiety and become clinically evident days later than might be expected in younger, healthier patients due to impaired metabolism.

Despite the fact that anxiety in terminal illness commonly results from medical complications, it is important to consider psychological factors that may play a role, particularly in patients who are alert and not confused (Holland 1989; Payne and Massie 2000). Patients frequently fear the isolation and separation of death. Claustrophobic patients may fear the idea of being confined and buried in a coffin. These issues can be disconcerting to consultants, who may find themselves at a loss for words that are consoling to the patient.

### *Pharmacological Treatment*

The pharmacotherapy of anxiety in terminal illness has been extensively reviewed (Breitbart et al. 1993, 1995; Holland 1989; Payne and Massie 2000) and is similar in most respects to its treatment in the medically ill in general (see Chapter 12, "Anxiety Disorders," and Chapter 37, "Psychopharmacology"). In this subsection, we note selected aspects specific to the terminally ill.

Dying patients can be administered diazepam rectally when no other route is available, with dosages equivalent to those used in oral regimens. Rectal diazepam (Twy-cross and Lack 1984) has been used widely in palliative care to control anxiety, restlessness, and agitation associated with the final days of life. Neuroleptics are perhaps the safest class of anxiolytics in patients for whom there is legitimate concern regarding respiratory depression or compromise. The utility of antidepressants for anxiety disorder

**TABLE 40-1. Anxiety in terminally ill patients**

<b>Types of anxiety</b>	<b>Causes</b>
Reactive anxiety/adjustment disorder	Awareness of terminal condition Fears and uncertainty about death Conflicts with family or staff Do-not-resuscitate order discussion
Disease- and treatment-related anxiety	Poor pain control Related metabolic disturbances Hypoxia Hypoglycemia Electrolyte imbalance Delirium Sepsis Bleeding Pulmonary embolus
Substance-induced anxiety	Anxiety-producing drugs Corticosteroids Antiemetics Metoclopramide Prochlorperazine Bronchodilators Withdrawal Opioids Benzodiazepines Alcohol
Preexisting anxiety disorders General anxiety disorder Panic Phobias Posttraumatic stress disorder	Exacerbation of symptoms related to fears and distressing medical symptoms

ders is often limited in the dying patient because these agents require weeks to achieve therapeutic effect.

Opioid drugs such as the narcotic analgesics are primarily indicated for the control of pain but are also effective in the relief of dyspnea and associated anxiety (Bruera et al. 1990). Continuous intravenous infusions of morphine or other narcotic analgesics allow for careful titration and control of respiratory distress, anxiety, pain, and agitation (Portenoy et al. 1989). Occasionally one must maintain the patient in a state of unresponsiveness in order to maximize comfort. When respiratory distress is not a major problem, it is preferable to use the opioid drugs solely for analgesia and to add more specific anxiolytics to control concomitant anxiety.

### ***Nonpharmacological Treatment***

Nonpharmacological interventions for anxiety and distress include supportive psychotherapy and behavioral interventions that are used alone or in combination (see discussion later in this chapter and in Chapter 12, "Anxiety

Disorders," and Chapter 38, "Psychosocial Treatments"). Brief supportive psychotherapy is often useful in dealing with both crises and existential issues confronted by the terminally ill (Massie et al. 1989). Inclusion of the family in psychotherapeutic interventions should be considered, particularly as the patient with advanced illness becomes increasingly debilitated and less able to interact.

Relaxation, guided imagery, and hypnosis may help reduce anxiety and thereby increase the patient's sense of control. Many patients with advanced illness are still appropriate candidates for the use of behavioral techniques despite physical debilitation. The utility of such interventions for a terminally ill patient is limited by the degree of mental clarity of the patient (Breitbart et al. 1995). In some cases, techniques can be modified so as to include even mildly cognitively impaired patients. This involves the therapist taking a more active role by orienting the patient, creating a safe and secure environment, and evoking a conditioned response to his or her voice or presence. A typical behavioral intervention for anxiety in a terminally

ill patient would include a relaxation exercise combined with some distraction or imagery technique. The patient is first taught to relax using passive breathing accompanied by either passive or active muscle relaxation. When in a relaxed state, the patient is taught a pleasant, distracting imagery exercise. In a randomized study comparing a relaxation technique with alprazolam in the treatment of anxiety and distress in non-terminally ill cancer patients, both treatments were demonstrated to be quite effective for mild to moderate degrees of anxiety or distress. Alprazolam was more effective for greater levels of distress or anxiety and had more rapid onset of beneficial effect (Holland et al. 1987). Of course, relaxation techniques can be prescribed concurrently with anxiolytic medications in highly anxious terminal patients.

## Depression

See also Chapter 9, "Depression," for additional information.

### *Prevalence*

Two recent studies of the prevalence of major depression in terminally ill cancer patients in palliative care units suggest that the prevalence of depression in patients during the last weeks to months of life ranges from 9% to 18% (Breitbart et al. 2000; Wilson et al. 2000). Family history of depression and history of previous depressive episodes further increase the patient's risk of developing a depressive episode. Recent reports suggest that loss of meaning and low scores on measures of spiritual well-being are associated with higher levels of depressive symptoms, suggesting that the relationship between existential distress and depression in terminal illness warrants further investigation (Nelson et al. 2002). Many studies have also found a correlation between depression, pain, and functional status (Breitbart 1989b). In addition, evaluation of depression must also include an examination of treatments and physical conditions that may be the cause of depression. Corticosteroids (Stiefel et al. 1989), chemotherapeutic agents (vincristine, vinblastine, asparaginase, intrathecal methotrexate, interferon, interleukin) (Adams et al. 1984; Denicoff et al. 1987; Holland et al. 1974; Young 1982), amphotericin (Weddington 1982), whole brain radiation (DeAngelis et al. 1989), central nervous system (CNS) metabolic-endocrine complications (Breitbart 1989a), and paraneoplastic syndromes (Patchell and Posner 1989; Posner 1988) can all cause depressive symptoms.

### *Assessment*

Depressed mood and sadness can be appropriate responses as the terminally ill patient faces death. These emotions

can be manifestations of anticipatory grief over the impending loss of one's life, health, loved ones, and autonomy. Despite this, major depression is common in the palliative care setting, where it has been underdiagnosed and undertreated. Minimization of depressive symptoms as "normal reactions" by clinicians and the difficulties of accurately diagnosing depression in the terminally ill both contribute to the underdiagnosis of depression, and undertreatment is due in part to the concern that severely medically ill patients will not be able to tolerate the side effects of antidepressants (Block 2000). Strategies for accurately diagnosing depression in seriously medically ill patients are reviewed in Chapter 9, "Depression." Their application in terminally ill patients in a palliative care facility is exemplified by Chochinov et al. (1994).

The diagnosis of a major depressive syndrome in a terminally ill patient, as in medically ill patients in general, often relies more on the psychological or cognitive symptoms of major depression than the neurovegetative symptoms. The strategy of relying on the psychological symptoms of depression for diagnostic specificity is itself not without problems. How is the clinician to interpret feelings of hopelessness in the dying patient when there is no hope for cure or recovery? Feelings of hopelessness, worthlessness, or suicidal ideation must be explored in detail. Although many dying patients lose hope for a cure, they are able to maintain hope for better symptom control. For many patients hope is contingent on the ability to find continued meaning in their day-to-day existence. Hopelessness that is pervasive and accompanied by a sense of despair or despondency is more likely to represent a symptom of a depressive disorder. Such patients often state that they feel they are burdening their families unfairly, causing them great pain and inconvenience. Those beliefs are less likely to represent a symptom of depression than if the patient feels that his or her life has never had any worth or that the illness is punishment for evil things he or she has done. Even mild and passive forms of suicidal ideation are very often indicative of significant degrees of depression in terminally ill patients (Breitbart 1987, 1990).

Chochinov et al. (1997) studied brief screening instruments to measure depression in the terminally ill, including a single-item interview assessing depressed mood ("Have you been depressed most of the time for the past 2 weeks?"), a two-item interview assessing depressed mood and loss of interest in activities, a visual analogue scale for depressed mood, and the Beck Depression Inventory. Semistructured diagnostic interviews served as the standard against which the screening performance of the four brief screening methods was assessed. Most noteworthy, the single-item question correctly identified the

diagnosis of every patient, substantially outperforming the questionnaire and visual analogue measures.

Passik and colleagues demonstrated that the Zung Depression Rating Scale could be used effectively by oncologists and nurses as a rapid screening tool for depression in patients with advanced cancer and that oncologists could be trained to diagnose and initiate further evaluation and treatment of clinical depression (Dugan et al. 1998; McDonald et al. 1999; Passik et al. 1998, 2000, 2001).

### *Pharmacological Treatment*

Antidepressant medications are the mainstay of management for gravely ill patients meeting diagnostic criteria for major depression (Block 2000; Wilson et al. 2000) and have established efficacy (Massie and Popkin 1998; Wilson et al. 2000). Pharmacotherapy of depression in the medically ill is reviewed in detail in Chapter 9, "Depression," and Chapter 37, "Psychopharmacology," and in this discussion we note specific aspects relevant to palliative care. Factors such as prognosis and the time frame for treatment may play an important role in determining the type of pharmacotherapy for depression in the terminally ill. A depressed patient with several months of life expectancy can afford to wait the 2–4 weeks it may take to respond to a standard antidepressant. The depressed dying patient with less than 3 weeks to live may do best with a rapid-acting psychostimulant (Block 2000; Homsy et al. 2001; Tremblay and Breitbart 2001). Patients who are within hours to days of death and in distress are likely to benefit most from the use of sedatives or narcotic analgesic infusions. For the terminally ill, antidepressants are usually initiated at approximately half the usual starting dose because of the patients' sensitivity to adverse effects.

Psychostimulants are particularly helpful in the treatment of depression in the terminally ill because they have a rapid onset of action and energizing effects and typically do not cause anorexia, weight loss, or insomnia at therapeutic doses. In fact, at low doses, stimulants may actually increase appetite (see also Chapter 9, "Depression," and Chapter 37, "Psychopharmacology"). Abuse is almost always an irrelevant concern in the terminally ill, and stimulants should not be withheld on the basis of a patient's prior history of substance abuse. Occasionally, treatment with a selective serotonin reuptake inhibitor (SSRI) and a psychostimulant may be initiated concurrently so that depressed patients may receive the immediate benefits of the psychostimulant drug while waiting the necessary weeks for the SSRI to work. At that point the psychostimulant may be withdrawn. Methylphenidate and dextroamphetamine are usually initiated at low doses (2.5–5 mg in the morning and at noon). The benefits can be assessed

during the first 1–2 days of treatment and the dose gradually titrated (usually to no greater than 30 mg/day total). An additional benefit of stimulants is that they have been shown to reduce sedation secondary to opioid analgesics and provide adjuvant analgesic effects (Bruera et al. 1987). Pemoline comes in a chewable tablet form that can be absorbed through the buccal mucosa and thus can be used by patients who have difficulty swallowing or have intestinal obstruction, and it appears to be as effective as methylphenidate or dextroamphetamine in the treatment of depressive symptoms in terminally ill cancer patients (Breitbart and Mermelstein 1992). Pemoline can be started at a dose of 18.75 mg in the morning and at noon and increased gradually over a period of days. Patients typically require 75 mg/day or less. Pemoline should be used with caution in patients with liver impairment.

### *Nonpharmacological Treatment*

Depression in cancer patients with advanced disease is optimally managed with a combination of supportive psychotherapy, cognitive-behavioral techniques, and antidepressant medications (Wilson et al. 2000). Psychotherapeutic interventions, in the form of either individual or group counseling, have been shown to effectively reduce psychological distress and depressive symptoms in advanced-stage cancer patients (Massie et al. 1989; Spiegel and Bloom 1983; Spiegel et al. 1981). Cognitive-behavioral interventions such as relaxation and distraction with pleasant imagery also have been shown to decrease depressive symptoms in patients with mild to moderate levels of depression (Holland et al. 1987).

Supportive psychotherapy for the dying patient consists of active listening with supportive verbal interventions and the occasional interpretation (Peck et al. 1983). Despite the seriousness of the patient's plight, it is not necessary for the psychiatrist or psychologist to appear overly solemn or emotionally restrained. Often the psychotherapist is the only person among all of the patient's caregivers who is comfortable enough to converse lightheartedly and to allow the patient to talk about his or her life and experiences rather than focus solely on impending death. The dying patient who wishes to talk or ask questions about death should be encouraged to do so freely, with the therapist maintaining an interested, interactive stance.

Psychotherapies other than supportive psychotherapy have been described as potentially useful in the treatment of depressive symptoms and distress in palliative care patients. Chochinov and Breitbart (2000) extensively reviewed interpersonal, existential, life narrative, and group psychotherapies in palliative care. Recently, several novel psychotherapies have been developed and are being

tested in the treatment of depression, hopelessness, loss of meaning, and demoralization; these new modalities include meaning-centered psychotherapy (Breitbart 2002) and dignity-conserving care (Chochinov 2002), both of which are described later in this chapter.

## Suicide, Assisted Suicide, and Desire for Hastened Death

Suicide, suicidal ideation, and desire for hastened death are all important and serious consequences of unrecognized and inadequately treated clinical depression (see also Chapter 10, "Suicidality"). Although clinical depression has been demonstrated to be a critically important factor in desire for hastened death (through suicide or other means), understanding more fully why some patients with a terminal illness wish or seek to hasten their death remains an important element in the practice of palliative care. Despite the continued legal prohibitions against assisted suicide in the United States (except Oregon), a substantial number of patients think about and discuss those alternatives with their physicians, family, and friends (Rosenfeld 2000).

### *Suicide*

Factors associated with increased risk of suicide in patients with serious medical illnesses are reviewed in Chapter 10, "Suicidality," and elsewhere (Breitbart 1987, 1990).

Cancer patients commit suicide most frequently in the advanced stages of disease (Bolund 1985; Farberow et al. 1963; Fox et al. 1982; Louhivuori and Hakama 1979). With advancing disease the incidence of significant pain increases, and uncontrolled pain is a dramatically important risk factor for suicide (Bolund 1985; Farberow et al. 1971).

Hopelessness is a key variable linking depression and suicide in the terminally ill. Chochinov et al. (1998) demonstrated that hopelessness was correlated more highly with suicidal ideation in terminally ill cancer patients than was level of depression. In Scandinavia, the highest incidence of suicide was found in cancer patients who were offered no further treatment and no further contact with the health care system (Bolund 1985; Louhivuori and Hakama 1979). Being left to face illness alone creates a sense of isolation and abandonment that is critical to the development of hopelessness.

The prevalence of organic mental disorders reaches as high as 85% during the terminal stages of illness (Massie et al. 1983). Although early work suggested that delirium was a protective factor in regard to suicide among cancer patients (Farberow et al. 1963), clinical experience has found confusional states to be a major contributing factor in impulsive suicide attempts, especially in the hospital setting (see Chapter 10, "Suicidality").

Loss of control and a sense of helplessness in the face of terminal illness are important factors in suicide vulnerability. *Control* refers to the helplessness induced by symptoms, deficits due to the illness or its treatments, and the excessive need on the part of some patients to be in control of all aspects of living or dying. Farberow et al. (1971) noted that patients who were accepting and adaptable were much less likely to commit suicide than those who exhibited a need to be in control of even the most minute details of their care. However, it is not uncommon for terminal illness to induce a great sense of helplessness even in those who are not typically controlling individuals, for example through loss of mobility, paraplegia, loss of bowel and bladder function, amputation, aphonia, sensory loss, and inability to eat or swallow. Most distressing to patients is the sense that they are losing control of their minds, especially when they are confused or sedated by medications. The risk of suicide is increased with such impairments, especially when accompanied by psychological distress and disturbed interpersonal relationships (Farberow et al. 1971).

Fatigue in the form of emotional, spiritual, financial, familial, communal, and other resource exhaustion increases risk of suicide in patients with terminal illness (Breitbart 1987). Increased survival in cancer, AIDS, chronic obstructive pulmonary disease, congestive heart failure, and other diseases is accompanied by increased numbers of hospitalizations, complications, and expenses. Symptom control thus becomes a prolonged process with frequent advances and setbacks. The dying process also can become extremely long and arduous for all concerned. It is not uncommon for both family members and health care providers to withdraw prematurely from the patient under these circumstances. A suicidal patient can thus feel even more isolated and abandoned. The presence of a strong support system for the patient that may act as an external control of suicidal behavior reduces risk of suicide significantly.

### *Suicidal Ideation*

It is widely held that most terminally ill patients experience occasional thoughts of suicide as a means of escaping the threat of being overwhelmed by their illness ("If it gets too bad, I always have a way out") and will reveal this to a sensitive interviewer. However, some studies suggest that suicidal ideation is relatively infrequent and is limited to those who are significantly depressed (Achte and Vanhokouen 1971; Brown et al. 1986; Silberfarb et al. 1980). Among a cohort of cancer patients with pain, suicidal ideation was found in just 17% (Breitbart 1987). The actual prevalence of suicidal ideation may be considerably higher, because patients may be less likely to dis-

close these thoughts to a research interviewer than in a well-established doctor–patient relationship.

### ***Assessment and Management of the Suicidal Terminally Ill Patient***

Assessment and management of suicidal ideation in the medically ill are discussed in Chapter 10, “Suicidality.” Some physicians, nurses, and other caregivers fail to intervene for suicidal ideation in the terminally ill, either because they think it is rational (“I would feel that way too”) or because they think that intervention is futile (“He’s going to die anyway”). This is a serious error for several reasons. Suicide can be very traumatic to family and health care givers, even in the terminally ill. Patients often reconsider and reject the idea of suicide after they have an opportunity to express underlying issues to an attentive physician, particularly fears of loss of control over aspects of their death. Suicidal ideation is often driven by unbearable symptoms that may not have been recognized and should become the focus of palliative care.

Psychiatric hospitalization can sometimes be helpful but is usually not desirable in the terminally ill patient. Thus, the medical hospital or home is the setting in which management most often takes place. Although it is appropriate to intervene when medical or psychiatric factors are clearly the driving force in a cancer patient’s suicide, there are circumstances when usurping control from the patient and family with overly aggressive intervention may be contraindicated. This is most evident in those with advanced illness for whom comfort and symptom control are the primary concerns.

Ultimately, palliative care clinicians are not able to prevent all suicides in terminally ill patients for whom they provide care. Intervention should emphasize an aggressive attempt to prevent suicide that is driven by the desperation of physical and psychological symptoms, such as uncontrolled pain and unrecognized or untreated delirium or depression. Prolonged suffering caused by poorly controlled symptoms can lead to such desperation, and it is the appropriate role of the palliative care team to provide effective management of physical and psychological symptoms as an alternative to desire for death, suicide, or request for assisted suicide by patients. (Requests for assisted suicide are covered in Chapter 10, “Suicidality.”)

### ***Desire for Hastened Death***

Desire for hastened death may be thought of as a unifying construct underlying requests for assisted suicide or euthanasia, as well as suicidal thoughts in general. Several studies have demonstrated that depression plays a significant role in the terminally ill patient’s desire for hastened

death. Chochinov et al. (1995) found that 45% of terminally ill patients in a palliative care facility acknowledged at least a fleeting desire to die, but these episodes were mostly brief and did not reflect a sustained or committed desire to die. However, 9% reported an unequivocal desire for death to come soon and indicated that they held this desire consistently over time. Among this group, 59% received a diagnosis of depression, compared with a prevalence of 8% in patients who did not endorse a genuine, consistent desire for death. Patients with depression were approximately six to seven times more likely to have a desire for hastened death than patients without depression. Patients with a desire for death were also found to have significantly more pain and less social support than those patients without a desire for death.

Breitbart et al. (2000) studied the relationships among depression, hopelessness, and desire for death in terminally ill cancer patients. Seventeen percent of the patients were classified as having a high desire for death (; Rosenfeld et al. 1999, 2000), and 16% met criteria for a current major depressive episode. Of the patients who met criteria for major depressive episode, 47% were classified as having a high desire for hastened death; only 12% of those without a desire for death met criteria for depression. Thus, patients with major depression were four times more likely to have a high desire for hastened death. In addition, Breitbart et al. (2000) found that both depression and hopelessness, characterized as a pessimistic cognitive style rather than an assessment of one’s poor prognosis, appear to be synergistic determinants of desire for hastened death. No significant association with the presence or the intensity of pain was found.

Desire for hastened death also appears to be a function of psychological distress and social factors such as social support, spiritual well-being, quality of life, and perception of oneself as a burden to others. Recent data suggest that among dying patients the “will to live,” as measured with a visual analogue scale, tends to fluctuate rapidly over time and is correlated with anxiety, depression, and shortness of breath as death approaches (Chochinov et al. 1999).

Treatment of depression can reduce the wish for hastened death and also increase desire for life-sustaining medical therapies (Ganzini et al. 1994). When it is practical to do so, in severely depressed patients—particularly those who are hopeless—decisions about withdrawal of treatment should be discouraged until after treatment of their depression.

### ***Interventions for Despair at the End of Life***

The response of a clinician to despair at the end of life as manifest by a patient’s expression of desire for death or

request for assisted suicide has important and obvious implications for all aspects of care and affects patients, family, and staff (Breitbart et al. 2004a). These issues must be addressed both rapidly and thoughtfully, offering the patient a nonjudgmental willingness to discuss the factors contributing to the kind of suffering and despondency that leads to such a desire for death. Such despair has been variably described as “spiritual” suffering, “demoralization,” loss of “dignity,” and “loss of meaning” (Breitbart 2002; Cherny 2004; Chochinov et al. 2002b; Greenstein and Breitbart 2000; Kissane et al. 2001; Rousseau 2000). Specific therapeutic approaches for despair at the end of life are described in detail in the section on “Psychotherapy Interventions in Palliative Care” later in the chapter.

Most palliative care clinicians believe that aggressive management of physical and psychological distress will prevent wishes for hastened death or requests for assisted suicide. For example, there is a general consensus that major depression can be effectively treated in the context of terminal illness. However, no research has yet addressed whether such treatment for depression directly influences desire for hastened death. There are currently two large trials in cancer and AIDS populations examining this specific question (Breitbart et al. 2000). Because depression and hopelessness are not identical constructs (although highly correlated), it is important to empirically test clinical interventions.

## Delirium

---

Delirium is discussed in detail in Chapter 6, “Delirium”; in this discussion we focus on aspects most relevant to palliative care. In addition to its own adverse effects, delirium can interfere dramatically with the recognition and control of other physical and psychological symptoms such as pain in later stages of illness (Breitbart and Sparrow 1998; Bruera et al. 1992; Coyle et al. 1994; Fainsinger et al. 1991).

### Prevalence

Delirium is the most common and serious neuropsychiatric complication in patients with advanced illnesses such as cancer and AIDS, particularly in the last weeks of life, with prevalence rates ranging from 25% to 85% (Breitbart 2001; Breitbart et al. 1996a; Bruera et al. 1992; Fainsinger et al. 1991; Levine et al. 1978; Massie et al. 1983; Murray 1987). Pereira et al. (1997) found the prevalence of cognitive impairment in cancer inpatients to be 44%, and just prior to death, the prevalence rose to 62%. Lawlor et al. (2000a) reported that whereas 42% of advanced cancer patients had delirium upon admission to their pal-

liative care unit, terminal delirium occurred in 88% of patients before their deaths.

In a recent study of terminally ill cancer patients, Breitbart et al. (2002) found that 54% of patients recalled their delirium experience after recovery from delirium. Factors predicting delirium recall included the degree of short-term memory impairment, delirium severity, and the presence of perceptual disturbances (the more severe, the less likely recall). Patients, spouses or other caregivers, and nurses each rated distress related to the episode of delirium. The most significant factor predicting distress for patients was the presence of delusions. Patients with hypoactive delirium were just as distressed as patients with hyperactive delirium. Spouse distress was predicted by the patients’ Karnofsky Performance Status (the lower the Karnofsky score, the worse the spouse distress), and nurse distress was predicted by delirium severity and perceptual disturbances.

### Assessment

Delirium, in contrast with dementia, is classically conceptualized as a reversible process. Reversibility of delirium is often possible even in the patient with advanced illness, but it may not be reversible in the last 24–48 hours of life, with the outcome probably attributable to irreversible processes such as multiple organ failure occurring in the final hours of life. In the palliative care literature, delirium occurring in the last days of life is often referred to as “terminal restlessness” or “terminal agitation.” Unfortunately, delirium is often underrecognized or misdiagnosed and inappropriately treated or untreated in terminally ill patients.

Instruments available for diagnosing and monitoring severity of delirium are described in Chapter 6, “Delirium.” Of those, the Memorial Delirium Assessment Scale (MDAS) is one specifically validated in hospitalized inpatients with advanced cancer and AIDS (Breitbart et al. 1997). The MDAS is a 10-item tool useful both for diagnostic screening and for assessing delirium severity among patients with advanced disease. Lawlor and colleagues (2000b) found that a cutoff score of 7 out of 30 yielded the highest sensitivity (98%) and specificity (76%) for a delirium diagnosis in advanced cancer patients in a palliative care unit.

### Reversible Versus Irreversible Delirium

The standard approach to managing delirium outlined in Chapter 6, “Delirium,” remains relevant in the terminally ill, including a search for underlying causes, correction of those factors, and management of the symptoms of delir-

ium (Breitbart 2001; Breitbart et al. 2000). The ideal and often achievable outcome is a patient who is awake, alert, calm, cognitively intact, not psychotic, and communicating coherently with family and staff. In the terminally ill patient who develops delirium in the last days of life (terminal delirium), the management differs, presenting a number of dilemmas, and the desired clinical outcome may be significantly altered by the dying process.

Delirium can have multiple potential etiologies (see Table 40–2). In patients with advanced cancer, for instance, delirium can be due to the direct effects of cancer on the CNS, indirect CNS effects of the disease or treatments (medications, electrolyte imbalance, failure of a vital organ, infection, vascular complications), and/or pre-existing CNS disease (e.g., dementia) (Bruera et al. 1992; Lawlor et al. 2000a). Given the large numbers of drugs cancer patients require and the fragile state of their physiological functioning, even routinely ordered hypnotic agents may be enough to tip patients over into delirium. Narcotic analgesics, especially meperidine, are common causes of confusional states, particularly in the elderly and terminally ill.

In confronting delirium in the terminally ill or dying patient, a differential diagnosis should always be formulated as to the likely etiology. However, there is an ongoing debate as to the appropriate extent of diagnostic evaluation that should be pursued in a dying patient with a terminal delirium (Breitbart 2001). Most palliative care clinicians would undertake diagnostic studies only when a clinically suspected etiology can be identified easily, with minimal use of invasive procedures, and treated effectively with simple interventions that carry minimal burden or risk of causing further distress. Diagnostic workup in pursuit of an etiology for delirium may be limited by either practical constraints such as the setting (home, hospice) or the focus on patient comfort, so that unpleasant or painful diagnostics may be avoided. Most often, however, the etiology of terminal delirium is multifactorial or may not be determined. Bruera et al. (1992) reported that an etiology is discovered in less than 50% of terminally ill patients with delirium. When a distinct cause is found for delirium in the terminally ill, it may be irreversible or difficult to treat. Studies in patients with earlier stages of advanced cancer have demonstrated the potential utility of a thorough diagnostic assessment (Bruera et al. 1992; Coyle et al. 1994). When such diagnostic information is available, specific therapy may be able to reverse delirium. One study found that 68% of delirious cancer patients could be improved, despite a 30-day mortality of 31% (Lawlor et al. 2000a). Another study found a cause in 43% of the patients evaluated, and of these, one-third of the episodes of cognitive failure improved (Bruera et al. 1992).

**TABLE 40–2. Causes of delirium in patients with advanced disease**

**Direct central nervous system (CNS) causes**

Primary brain tumor  
Metastatic spread to CNS  
Seizures  
CNS infection

**Indirect causes**

Hyperthermia  
Organ failure  
  Uremia  
  Hepatic encephalopathy  
  Congestive heart failure  
  Pulmonary failure  
    Pulmonary edema  
    Pulmonary emboli  
Electrolyte imbalance  
Treatment side effects from  
  Chemotherapeutic agents  
  Steroids  
  Radiation  
  Narcotics  
  Anticholinergics  
  Antiemetics  
  Antivirals  
Infection  
  Sepsis  
  Opportunistic infections  
Hematological abnormalities  
  Severe anemia  
  Disseminated intravascular coagulopathy (DIC) and other hypercoagulable states  
Nutritional deficiencies  
Paraneoplastic syndromes

A recent prospective study of delirium in patients on a palliative care unit found that the etiology of delirium was multifactorial in the great majority of cases (Lawlor et al. 2000a). Although delirium occurred in 88% of dying patients in the last week of life, delirium was reversible in approximately 50% of episodes. Causes of delirium that were most associated with reversibility included dehydration and psychoactive or opioid medications. Hypoxic and metabolic encephalopathies were less likely to be reversible in terminal delirium.

Therefore, even in terminal delirium a diagnostic workup should include basic assessment of potentially reversible causes of delirium while minimizing any investigation that would be burdensome for the patient. A full physical examination should be conducted to assess for evidence of sepsis, dehydration, or major organ failure. Medications that could contribute to delirium should be

reviewed. Oximetry can rule out hypoxia, and one set of blood draws can screen for metabolic disturbances (e.g., hypercalcemia) and hematological abnormalities (e.g., anemia, leukocytosis). Imaging studies of the brain and assessment of the cerebrospinal fluid may be appropriate in some instances if they have the potential to identify lesions amenable to palliative treatment (e.g., radiosensitive CNS metastases).

## Interventions

### *Pharmacological*

Pharmacotherapy of delirium is reviewed in detail in Chapter 6, "Delirium." Low doses of neuroleptic medication are usually sufficient in treating delirium in the terminally ill, but high doses have sometimes been required (Fernandez et al. 1989). Haloperidol remains the drug of first choice and may be given orally or parenterally. Delivery of haloperidol by the subcutaneous route is utilized by many palliative care practitioners (Bruera et al. 1992; Twycross and Lack 1983).

Many palliative care clinicians are using low dosages of risperidone (e.g., 0.5–1.0 mg bid) or olanzapine (2.5–20 mg/day in divided doses) in the management of delirium in terminally ill patients, particularly in those who have demonstrated intolerance to the extrapyramidal side effects of the classic neuroleptics (Breitbart 2001). However, there is less experience with (and few data on) using atypical antipsychotics for delirium, and most are unavailable for parenteral administration. Breitbart and colleagues (2002b) recently published a large open trial of olanzapine for the treatment of delirium in hospitalized patients with advanced cancer. Olanzapine was highly effective, resolving delirium in 76% of patients with no extrapyramidal side effects. Poorer response to treatment occurred in those with age over 70, history of dementia, and hypoactive delirium. Sedation was the most common side effect.

Although neuroleptic drugs are generally very beneficial in reducing agitation, anxiety, and confusion in delirium, this is not always possible in terminal delirium. A significant group (at least 10%–20%) of terminally ill patients experience delirium that can only be controlled by sedation to the point of a significantly decreased level of consciousness (Fainsinger et al. 1991; Ventafridda et al. 1990). The goal of treatment in those cases is quiet sedation only. Midazolam, given by subcutaneous or intravenous infusion in doses ranging from 30 to 100 mg per 24 hours, can be used to control agitated terminal delirium (Bottomley and Hanks 1990; De Sousa and Jepson 1988). Propofol, a short-acting anesthetic agent, has also begun to be used for this purpose, given in, for example, an in-

travenous loading dose of 20 mg followed by a continuous infusion with initial doses of 10–70 mg/hour titrated up to as high as 400 mg/hour in severely agitated patients (Mercadante et al. 1995; Moyle 1995). Propofol's level of sedation may be more easily controlled, with more rapid recovery upon decreasing the rate of infusion than with midazolam (Mercadante et al. 1995).

### *Nonpharmacological*

In addition to seeking out and potentially correcting underlying causes for delirium, environmental and supportive interventions are important, as described in Chapter 6, "Delirium." In fact, in the dying patient these may be the only steps taken. The presence of family, frequent re-orientation, correction of hearing and visual impairment, reversal of dehydration, and a quiet well-lit room with familiar objects all are helpful in reducing the severity and impact of delirium in seriously ill patients. However, these interventions are less applicable in the last days of life, and there is little likelihood that they would prevent terminal delirium.

## Controversies in the Management of Terminal Delirium

Several aspects of the use of neuroleptics and other pharmacological agents in the management of delirium in the dying patient remain controversial in some circles. Some view delirium as a natural part of the dying process that should not be altered and argue that pharmacological interventions are inappropriate in the dying patient. In particular, some who care for the dying view hallucinations and delusions in which dead relatives communicate with dying patients or welcome them to heaven as important elements in the transition from life to death. There are some patients who experience hallucinations during delirium that are pleasant and even comforting, and many clinicians question the appropriateness of intervening pharmacologically in such instances.

Another concern often raised is that these patients are so close to death that aggressive treatment is unnecessary. Parenteral neuroleptics or sedatives may be mistakenly avoided because of exaggerated fears that they might hasten death through hypotension or respiratory depression. There is the possibility that sedation may worsen confusion in delirium. Many clinicians are unnecessarily pessimistic about the possible results of neuroleptic treatment for delirium. They argue that since the underlying pathophysiological process (such as hepatic or renal failure) often continues unabated, no improvement can be expected in the patient's mental status.

Clinical experience in managing delirium in dying patients suggests that the use of neuroleptics in the management of agitation, paranoia, hallucinations, and altered sensorium is safe, effective, and often quite appropriate (Breitbart 2001). Management of delirium on a case-by-case basis seems wisest. The agitated, delirious dying patient should usually have a trial of neuroleptics to help restore calm. A “wait and see” approach prior to using neuroleptics may be appropriate with some patients who have a lethargic, somnolent presentation of delirium or those who are having frankly pleasant or comforting hallucinations. Such an approach must be tempered by the knowledge that a lethargic delirium may very quickly and unexpectedly become an agitated delirium that can threaten the serenity and safety of the patient, family, and staff. An additional rationale for intervening pharmacologically with patients who have “hypoactive” delirium is evidence that neuroleptics are effective in controlling the symptoms of delirium in both hyperactive as well as hypoactive subtypes of delirium (Breitbart et al. 1996a).

Finally, a very challenging clinical problem is management of terminal delirium that is unresponsive to standard neuroleptics and for which symptoms can only be controlled by sedation to the point of significantly decreased consciousness. Before undertaking interventions such as midazolam or propofol infusions, in which the aim is a calm, comfortable, but sedated and unresponsive patient, the clinician should discuss with the family (and the patient if he or she has lucid moments) the concerns and wishes for the type of care that can best honor the patient’s and family’s values. Family members should be informed that the goal of sedation is to provide comfort and symptom control and not to hasten death. Terminal sedation intended to maximize the patient’s comfort is not euthanasia. After the patient receives this degree of sedation, the family may experience a premature sense of loss, and they may feel their loved one is in some sort of limbo state, not yet dead but yet no longer alive in the vital sense. The distress and confusion that family members can experience during such a period can be ameliorated by including them in the decision making and emphasizing the shared goals of care. Sedation in such patients is not always complete or irreversible; some patients have periods of wakefulness despite sedation, and many clinicians will periodically lighten sedation to reassess the patient’s condition.

## Psychotherapy Interventions in Palliative Care

---

The potential benefits of psychotherapy for seriously medically ill patients are frequently underestimated by clini-

cians (Rodin and Gillies 2000). This bias against psychotherapeutic interventions tends to be even more pronounced in patients who are months away from death. However, psychotherapeutic interventions have been demonstrated to be useful and effective for patients struggling with advanced life-threatening medical illness. This section briefly describes different psychotherapeutic interventions and their relative applicability and efficacy for patients near the end of life. Psychotherapy in the medically ill is reviewed in detail in Chapter 38, “Psychosocial Treatment.”

### Individual Psychotherapy

Traditional insight-oriented psychotherapy has had limited application among dying patients. Insight-oriented psychotherapy is based on the development of a trusting relationship between the psychotherapist and the patient and an exploration of various unconscious conflicts and issues (Rodin and Gillies 2000). Resolution of conflicts, through a process involving interpretation, catharsis, and enhanced insight, requires time, energy, and commitment. This approach may be too demanding for most patients nearing death, but elements of psychodynamic therapy have an important role in all palliative psychotherapies. Cognitive-behavioral and interpersonal therapies have been widely studied in the medically ill. In full extended form they too may not be practical in imminently dying patients, but there are important cognitive and interpersonal elements in the specific psychotherapies as described in the following sections.

### Existential Therapies

Existential therapies explore ways in which suffering can be experienced from a more positive and meaningful perspective. *Logotherapy* is one approach with the primary tenet that one always has control over one’s attitude or outlook, no matter the enormity of the adversity. The goal is to decrease patients’ suffering and encourage them to live life to its fullest by engaging in activities that bring the greatest amount of meaning and purpose to their lives (Frankl 1959/1992). The focus is on goals to achieve, tasks to fulfill, and responsibilities toward others. Rather than covering up patients’ distress, logotherapy acknowledges and fully explores patients’ suffering (Spira 2000). Although it was not designed for patients who were imminently dying, Zuehlke and Watkins (1975) explored the use of logotherapy with six dying patients and reported them to have a greater sense of freedom to change their attitudes and to see themselves and their lives as meaningful and worthwhile.

Another form of existential therapy useful with dying patients is the *life narrative*. This treatment explores the

meaning of the physical illness in the context of the patient's life trajectory. It is designed to create a new perspective of dealing with the illness, emphasize past strengths, increase self-esteem, and support effective past coping strategies. The therapist emphatically summarizes the patient's life history and response to the illness to convey a sense that the therapist understands the patient over time (Viederman 2000; Viederman and Perry 1980). Life narrative can bolster patients' psychological and physical well-being. One study by Pennebaker and Seagal (1999) demonstrated that when patients wrote about important personal experiences in an emotional way for 15 minutes over 3 days, improvements in mental and physical health occurred. Life narrative has traditionally been used for treating depressed patients whose depression is a response to physical illness. However, the written form of this approach can be too demanding for patients at the end stage of their illness.

A similar method of intervention is the *life review*, which provides patients with the opportunity to identify and reexamine past experiences and achievements to find meaning, resolve old conflicts and make amends, or resolve unfinished business (Byock 1996; Heiney 1995; Lichter et al. 1993). The process of life review can be achieved through written or taped autobiographies, by reminiscing, through storytelling about past experiences or discussion of the patient's career or life work, and by creating family trees (Lewis and Butler 1974). Examples of other life review activities include going on pilgrimages, artistic expression (e.g., creating a collage or drawings, writing poetry), and journal writing (Pickrel 1989). Life review has traditionally been used in the elderly as a means of conflict resolution and to facilitate a dignified acceptance of death (Butler 1963). For dying patients, their stories have a special meaning. In negotiating one's way through serious illness and its treatment, the telling of one's own story takes on a renewed urgency. This approach has not, however, been widely utilized in palliative care settings.

## Group Psychotherapy

Group interventions may offer benefits less available in individual therapies, such as a sense of universality, sharing a common experience and identity, a feeling of helping oneself by helping others, hopefulness fostered by seeing how others have coped successfully, and a sense of belonging to a larger group (self-transcendence, meaning, common purpose). However, patients in advanced stages of terminal illness are often too sick to participate in group therapy. Group psychotherapeutic interventions for medically ill patients are reviewed in detail in Chapter 38, "Psychosocial Treatment."

## Emerging Psychotherapeutic Interventions in the Terminally Ill

### *Spiritual Suffering*

Palliative care practitioners have recognized the importance of spiritual suffering in their patients and have begun to design interventions to address it (Puchalski and Romer 2000; Rousseau 2000). Rousseau (2000) has developed an approach for the treatment of spiritual suffering that centers on facilitating religious expression while also controlling physical symptoms; providing a supportive presence; encouraging life review to assist in recognizing purpose, value, and meaning; exploring guilt, remorse, forgiveness, and reconciliation; reframing goals; and encouraging meditative practices. Although this approach blends basic principles common to many psychotherapies, it should be noted that this intervention contains a heavy emphasis on facilitating religious expression and confession and thus, although very useful to many patients, is not applicable to all and is not an intervention that all clinicians feel comfortable providing.

### *Meaning-Centered Psychotherapy*

Breitbart and colleagues (Breitbart 2002; Breitbart and Heller 2003; Gibson CA, Breitbart W: "Individual Meaning-Centered Psychotherapy Treatment Manual," unpublished, 2004; Greenstein and Breitbart 2002) have applied Viktor Frankl's (1955, 1963, 1969, 1988, 1992, 1997) concepts of meaning-based psychotherapy (logotherapy) to address spiritual suffering in dying patients. This "Meaning-Centered Group Psychotherapy" (Greenstein and Breitbart 2000) utilizes a mixture of didactics, discussion, and experiential exercises that focus on particular themes related to meaning and advanced cancer. It is designed to help patients with advanced cancer sustain or enhance a sense of meaning, peace, and purpose in their lives even as they approach the end of life. Gibson and Breitbart ("Individual Meaning-Centered Psychotherapy Treatment Manual," unpublished, 2004) have manualized an individual form of this therapy and are currently conducting outcome studies to determine the feasibility and efficacy of both the group and individual forms of this therapy.

### *Demoralization*

Kissane and colleagues (2001) described a syndrome of "demoralization" in the terminally ill that they propose is distinct from depression and consists of a triad of hopelessness, loss of meaning, and existential distress expressed as a desire for death. It is associated with life-threatening medical illness, disability, bodily disfigurement, fear, loss

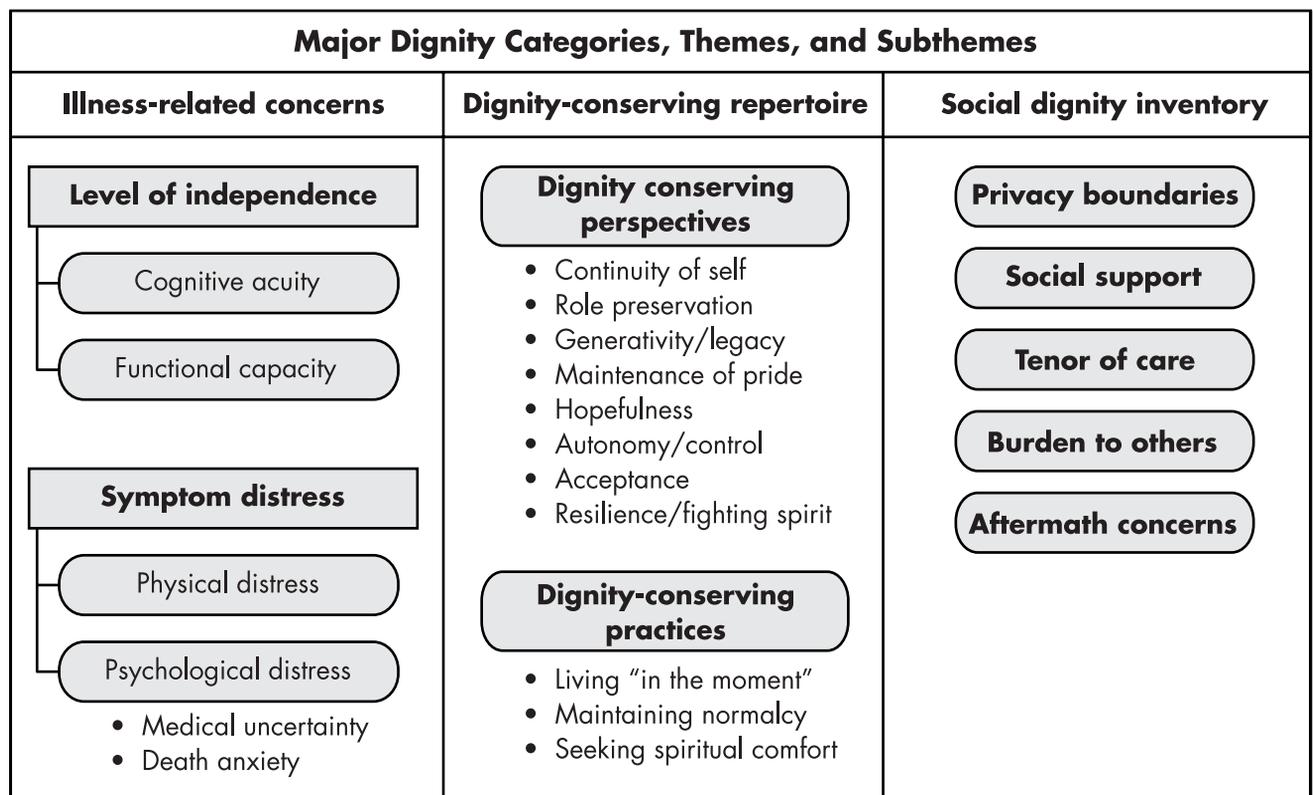

of dignity, social isolation, and feelings of being a burden. Because of the sense of impotence and hopelessness, those with the syndrome predictably progress to a desire to die or commit suicide. The authors (Kissane et al. 2001) formulated a treatment approach for demoralization syndrome that emphasizes a multidisciplinary, multimodal approach consisting of 1) ensuring continuity of care and active symptom management; 2) ensuring dignity in the dying process; 3) using various types of psychotherapy to help sustain a sense of meaning, limit cognitive distortions, and maintain family relationships (i.e., meaning-based, cognitive-behavioral, interpersonal, and family psychotherapy interventions); 4) using life review and narrative and attention to spiritual issues; and 5) administering pharmacotherapy for comorbid anxiety, depression, and delirium.

### **Dignity-Conserving Care**

Ensuring dignity in the dying process is a critical goal of palliative care. Despite use of the term *dignity* in arguments for and against a patient's self-governance in matters pertaining to death, there is little empirical research on how this term has been used by patients who are nearing death. Chochinov et al. (2002a, 2002b) examined how dying patients understand and define *dignity* in order to

develop a model of dignity in the terminally ill (see Figure 40–2). A semistructured interview was designed to explore how patients cope with their illness and their perceptions of dignity. Three major categories emerged, which included illness-related concerns (concerns related to the illness itself that threaten or impinge on the patient's sense of dignity), dignity-conserving repertoire (internally held qualities or personal approaches that patients use to maintain their sense of dignity), and social dignity inventory (social concerns or relationship dynamics that enhance or detract from a patient's sense of dignity). These broad categories and their carefully defined themes and subthemes form the foundation for an emerging model of dignity among the dying. The concept of dignity and the notion of dignity-conserving care offer a way of understanding how patients face advancing terminal illness and present an approach that clinicians can use to explicitly target the maintenance of dignity as a therapeutic objective.

Accordingly, Chochinov (2002) has developed a short-term dignity-conserving care intervention for palliative care patients that incorporates various facets from this model most likely to bolster the dying patient's will to live, lessen their desire for death or overall level of distress, and improve their quality of life. The dignity model establishes

**FIGURE 40–2.** Model of dignity for the terminally ill.

the importance of generativity as a significant dignity theme. As such, the sessions are taped, transcribed, and edited, and the transcription is returned to the patient within 1–2 days. The creation of a tangible product that will live beyond the patient acknowledges the importance of generativity as a salient dignity issue. The immediacy of the returned transcript is intended to bolster the patient's sense of purpose, meaning, and worth while giving them the tangible experience that their thoughts and words continue to be valued. In most instances, these transcripts will be left for family or loved ones and form part of a personal legacy that the patient will have actively participated in creating and shaping.

## Spirituality in Palliative Care

---

Addressing spirituality as an essential element of quality palliative care has been identified as a priority by medical professionals as well as by patients (Field and Cassel 1997; Moadel et al. 1999; Singer et al. 1999). Spirituality encompasses concepts of faith and/or meaning (Karasu 1999; Puchalski and Romer 2000). Viewing spirituality as a construct composed of faith and meaning is reflected in the FACIT Spiritual Well-Being Scale (Brady et al. 1999; Peterman et al. 1996). This scale generates a total score as well as two subscale scores; one corresponding to "Faith" and a second corresponding to "Meaning/Peace." Other measures that are commonly used to gauge aspects of spirituality include the Daily Spiritual Experiences Scale (Underwood and Teresi 2002) and the Spiritual Beliefs Inventory (Baider et al. 2001).

### Spirituality and Life-Threatening Medical Illness

There has been great interest in spirituality, faith, and religious beliefs and their impact on health outcomes and their role in palliative care (Baider et al. 1999; Holland et al. 1999; Koenig et al. 1992, 1998; McCullough and Larson 1999; Sloan et al. 1999). Sloan and colleagues (1999) concluded in their review of the literature that evidence of an association between religion and health was weak and inconsistent and that it was premature to promote faith and religion as adjunctive treatments. Elderly men who use religious beliefs or practices as a means of coping with physical illness appear to be less depressed than their non-religious peers (Koenig et al. 1992). Researchers theorize that religious beliefs may help patients construct meaning from the suffering inherent in illness, which may in turn facilitate acceptance (Koenig et al. 1998). Recent studies have found that religion and spirituality generally play a

positive role in patients' coping with illnesses such as cancer or HIV (Baider et al. 1999; Nelson et al. 2002; Peterman et al. 1996).

Several recent studies (Breitbart et al. 2000; McClain et al. 2003; Nelson et al. 2002) have demonstrated a central role for spiritual well-being and meaning as a buffering agent against depression, hopelessness, and desire for hastened death among advanced cancer patients. Although spiritual well-being (per the FACIT Spiritual Well-Being Scale) has a generally positive influence on the incidence of depression, hopelessness, and desire for death, it is the score on the Meaning/Peace subscale that has the most significant effect. These findings are significant in the face of what we have come to learn about the consequences of depression and hopelessness in palliative care patients. Depression and hopelessness are associated with poorer survival in cancer patients (Watson et al. 1999) and dramatically higher rates of suicide, suicidal ideation, desire for hastened death, and interest in physician-assisted suicide (Breitbart et al. 1996b, 2000; Chochinov et al. 1994, 1995, 1998). Such findings point to the need for interventions in terminal patients that address depression, hopelessness, and loss of meaning and impact on desire for death.

### Communicating About Spiritual Issues

Several factors may inhibit effective communication with patients about spirituality in a palliative care setting (Clayton 2000; Ellis et al. 1999; Post et al. 2000; Sloan et al. 1999). Promoting religion, faith, or specific religious beliefs or rituals (e.g., prayer, belief in an afterlife) in an effort to deal with patients' spiritual concerns or suffering at the end of life has limited acceptance among health care providers and is not universally applicable to all patients. Maugans and Wadland (1991) suggested that there is often a great discrepancy between physicians and patients on such issues as belief in God, belief in an afterlife, regular prayer, and feeling close to God, with physicians endorsing such beliefs or practices less than half as often as patients (none greater than 40%).

Additional barriers include lack of time on the part of the provider, lack of training, fear of projecting one's own beliefs onto the patient, and concerns about patient autonomy (Ellis et al. 1999). Finally, providers may feel that these discussions are inappropriate because they are outside of their area of expertise or intrusive to the patient's privacy (Ellis et al. 1999; Post et al. 2000; Sloan et al. 1999). However, the majority of studies have demonstrated that patients welcome these discussions (Anderson et al. 1993; King and Bushwick 1994; Maugans 1996).

Communicating effectively with patients about spirituality requires comfort in several domains. These in-

clude 1) a basic knowledge of common spiritual concerns and sources of spiritual pain for patients; 2) the principles and beliefs of the major religions common to the patient populations one treats; 3) basic clinical communication skills, such as active and empathetic listening, with an ability to identify and highlight spiritually relevant issues; and 4) the ability to remain present while patients struggle with spiritual issues in light of their mortality (Storey and Knight 2001). This final domain is often the most trying, especially for clinicians early in their career.

The American Academy of Hospice and Palliative Medicine offers the following guidelines for clinicians when communicating about spiritual issues (Doyle 1992; Hay 1996; Storey and Knight 2001). First, it is important to recognize that every patient is an individual and has a unique belief system that should be honored and respected. A patient's spiritual views may or may not incorporate religious beliefs, as *spirituality* is considered the more inclusive category. Therefore, initial discussions should focus on broad spiritual issues and then, when appropriate, on more specific religious beliefs. Caregivers should maintain appropriate boundaries and avoid discussions of their own religious beliefs because they are usually not relevant. Finally, fostering hope and integrating meaning into a patient's life is a more important aspect of providing spiritual healing than adherence to a particular belief system or religious affiliation. Methods for taking a spiritual history are reviewed elsewhere (Puchalski and Romer 2000). Formal assessment tools are also available (Kuhn 1988; Mougans 1996).

Psychosomatic medicine clinicians should be aware of the importance of spirituality and the value of pastoral care services not only for the patient but also for the family coping with a terminal illness. Referrals to chaplains are as important as referrals to any other specialist and an essential part of comprehensive care (Thiel and Robinson 1997).

## Cross-Cultural Issues in Care of the Dying

---

Ethnicity and culture strongly influence attitudes toward death and dying. A full discussion of cultural and ethnic differences in the face of life-threatening illness is beyond the scope of this chapter, but some illustrative points should be noted. Although fears of cancer and other debilitating diseases are universal (Butow et al. 1997), it appears that individuals from mainstream Western cultures generally use different coping strategies than those used in non-Western cultures (Barg and Gullatte 2001). Wide differences also exist within countries.

Blackhall et al. (1995) studied ethnic attitudes in the United States toward patient autonomy regarding disclosure of the diagnosis and prognosis of a terminal illness and toward end-of-life decision making. They found that different cultures have distinct opinions about how much information physicians should provide concerning diagnoses and prognoses. The investigators determined that African Americans (88%) and European Americans (87%) are significantly more likely than Mexican Americans (65%) or Korean Americans (47%) to believe that a patient should always be informed of a diagnosis of metastatic cancer. They also found that African Americans (63%) and European Americans (69%) are more likely than Korean Americans (35%) and Mexican Americans (48%) to believe a patient should be informed of a terminal prognosis and be actively involved in decisions concerning use of life-sustaining technology. They concluded that physicians should ask their patients whether they wish to be informed of their diagnoses and prognoses and to be involved in treatment decisions or prefer to let family members or caregivers handle such matters.

A similar study of Navajo Indian beliefs concerning autonomy in patient diagnosis and prognosis found that in the Navajo culture, physicians and patients must speak in only a positive way, avoiding any negative thought or speech (Carrese and Rhodes 1995). Because Navajos believe that language can "shape reality and control events," informing patients of a negative diagnosis or prognosis is considered disrespectful and physically and emotionally dangerous (Carrese and Rhodes 1995). As these two studies show, physicians must be careful to respect their patients' cultural beliefs in disclosing the diagnosis and prognosis of a terminal illness. Important differences between cultures include those that exist in the roles of religion (Musick et al. 1998a, 1998b), family, alternative healing traditions and folk healers (Canive and Castillo 1997; Chan et al. 2001), attitudes toward pain and suffering (Gordon 2002), beliefs about afterlife, and customs regarding the deceased's body and burial preparations (Parkes et al. 1997). At the same time, one should beware of cultural stereotypes and not assume that every member of a particular ethnic or cultural group holds identical shared values.

## Doctor-Patient Communication

---

Doctor-patient communication is an essential component in caring for a dying patient (Baile and Beale 2001; Buckman 1993, 1998; Fallowfield 2004; Parker et al. 2001; Smith 2000). A study of cancer patients' predictions regarding outcome and the treatments they chose re-

vealed that inadequate communication between cancer patients and their physicians resulted in overestimation of survival by patients and a resulting tendency to choose more aggressive treatment (Weeks et al. 1996).

In a study of oncologists' communication skills (Fallowfield et al. 1998), less than 35% reported having received any previous communication training, but most desired to learn better communication techniques. Psychosomatic medicine specialists can help improve communication skills in physicians and other health care professionals caring for dying patients. Intensive training programs in doctor-patient communication that use a variety of teaching methods, including role playing, videotaped feedback, experiential exercises, and didactics, have been demonstrated to have both short-term as well as long-term efficacy in improving communication skills among physicians (Fallowfield 2004; Maguire 1999).

One critical aspect of doctor-patient communication is how to break bad news. A useful six-step protocol for breaking bad news includes 1) getting the physical context right, 2) finding out how much the patient knows, 3) finding out how much the patient wants to know, 4) sharing information (aligning and educating), 5) responding to the patient's feelings, and 6) planning and following through (Baile and Beale 2001; Buckman 1998).

## Bereavement

Bereavement care is an integral dimension of palliative care, particularly for the 20% of bereaved individuals who develop complicated grief, for which effective therapies are available (Kissane 2004). Normal grief is an inevitable dimension of humanity, an adaptive adjustment process, and one that, with support, can be approached with courage.

Although words such as *grief*, *mourning*, and *bereavement* are commonly used interchangeably, the following definitions may be helpful:

- *Bereavement* is the state of loss resulting from death (Parkes 1998).
- *Grief* is the emotional response associated with loss (Stroebe et al. 1993).
- *Mourning* is the process of adaptation, including the cultural and social rituals prescribed as accompaniments (Raphael 1983).
- *Anticipatory grief* precedes the death and results from the expectation of that event (Raphael 1983).
- *Complicated grief* represents a pathological outcome involving psychological, social, or physical morbidity (Rando 1983).

- *Disenfranchised grief* represents the hidden sorrow of the marginalized patient, for whom there is less social permission to express many dimensions of loss (Doka 2000).

## The Nature of Normal Grief

The expression of normal grief is evident through its emotional, cognitive, physical, and behavioral features (Parkes 1998). In Lindemann's classic (1944) study of people who lost a relative in Boston's Coconut Grove Nightclub fire, he identified key features of grief including somatic distress with numbness, preoccupation with sad memories of the deceased, guilt, anger, loss of regular patterns of conduct, and identification with the deceased.

Emotional distress occurs in waves with unavoidable crying and a range of associated affects including sadness, anger, despair, anxiety, and guilt. Cognitive processes become dominated by memories, reflected in storytelling, reminiscences, and conversations about the deceased. Physical responses include numbness, restlessness, tension, tremors, sleep disturbance, anorexia, weight loss, fatigue, and painful symptoms. Finally, behavioral aspects are variously reflected in social withdrawal, wandering, searching, and seeking company and consolation.

A number of physiological changes have been identified in grief in neuroendocrine functioning (Jacobs et al. 1997), immune indices (Esterling et al. 1996), and sleep efficiency (Hall et al. 1998).

## Clinical Presentations of Grief

As the patient and family journey through palliative care, the clinical phases of grief progress from anticipatory grief through to the immediate news of the death, to the stages of acute grief, and potentially for some, to the complications of bereavement.

### *Anticipatory Grief*

Anticipatory grief generally draws the supportive family closer. In contrast, for some families difficulties emerge as they express their anticipatory grief. Impaired coping is exhibited through protective avoidance, denial of the seriousness of the threat, anger, or withdrawal from involvement. Sometimes family dysfunction is glaring. More commonly, however, subthreshold or mild depressive or anxiety disorders develop gradually as individuals struggle to adapt to unwelcome changes. Although anticipatory grief was historically suggested to reduce postmortem grief (Parkes 1975), intense distress is now well recognized as a marker of risk for complicated grief. During this phase of anticipatory grief, families that are capable of

effective communication should be encouraged to openly share their feelings as they go about the care of their dying family member or friend. Saying goodbye needs to be recognized as a process that evolves over time, with opportunities for reminiscence, celebration of the life and contribution of the dying person, expressions of gratitude, and completion of any unfinished business (Mearns 1981). These tasks have the potential to generate creative and positive emotional aspects of what is otherwise a sad time for all.

Sometimes staff will have concerns about the emotional response of the bereaved. If there is uncertainty about its cultural appropriateness, consultation with an informed cultural intermediary may prove helpful.

Caution is needed in those settings where grief could be marginalized, well exemplified by ageism (see Doka 2000). If a death is normalized because it appears in step with the life cycle, family members may receive less support and reduced permission to express many aspects of their loss.

### *Acute Grief and Time Course of Bereavement*

The sequence or phases through which the bereaved move over time are not rigidly demarcated but merge gradually one into the other (Parkes 1998; Raphael 1983). Starting with 1) initial numbness and sense of unreality, 2) waves of distress begin to occur as the bereaved experience intense pining and yearning for their lost one. Memories of the deceased trigger these acute pangs of grief. Then, as the pain of separation grows, 3) a phase of disorganization emerges as loneliness resulting from the loss sets in. Hofer (1984) described this phase aptly as a constant background disturbance of restlessness, inattention, sadness, and despair with social withdrawal that can last for several months. Eventually 4) a phase of reorganization and recovery develops as nostalgia replaces sadness, morale improves, and an altered world view is constructed.

The time course of mourning is proportional to the strength of attachment to the lost person and also varies with cultural expression, there being no sharply defined end point to grief. Just as a mother's grief following sudden infant death syndrome usually lasts longer than grief following a neonatal death, so too with adult loss—the mourning that follows many years of marriage is generally longer than that in brief relationships. Some, including older widows and widowers, may continue to display their grief for several years (Zisook and Schacter 1985). This may represent a continuing relationship with the deceased that, for some, is their choice and leads to a prolonged period of bereavement that may be quite appropriate and within the normal range of grief experience. The clinical task is then to differentiate those that remain

within the spectrum of normality from those that cross the threshold of complicated grief.

### *Complicated Grief*

Normal and abnormal responses to bereavement span a spectrum in which intensity of reaction, presence of a range of related grief behaviors, and time course determine the differentiation. Psychiatric disorders commonly complicating grief include clinical depression, anxiety disorders, alcohol abuse or other substance abuse, and psychotic disorders. When frank psychiatric disorders complicate bereavement, they are more likely to be recognized and treated than subthreshold states. Studies of the bereaved identify clusters of intense grief symptoms distinct from uncomplicated grief (Parkes 1983; Prigerson et al. 1995a, 1995b). Their recognition calls for an experienced clinical judgment that does not normalize the distress as understandable.

### *Inhibited or Delayed Grief*

Although avoidance may serve some as a temporary coping mechanism, its persistence is usually associated with relationship or other difficulties. Cultural and individual variation significantly influences grief expression; a placid external emotional response cannot be equated with internal avoidance. Empirical studies have generally identified avoidant forms of complicated grief in up to 5% of the bereaved—the grief may not always present clinically but may reappear in later years as an unresolved issue.

### *Chronic Grief*

A common form of complicated grief, chronic grief is particularly associated with overly dependent relationships in which a sense of abandonment is avoided by perpetuation of the relationship through memorialization of the deceased and maintenance of continuing bonds. Social withdrawal and depression are common. A fantasy of reunion with the deceased can cause suicide to be an increasingly attractive option. Active treatment using antidepressants and cognitive-behavioral therapy to reality test the loss and promote socialization (via activity scheduling) is often appropriate for chronic grief (keeping in mind that not all persistent grief is pathological).

### *Traumatic Grief*

When death has been unexpected or its nature in some way shocking—traumatic, violent, stigmatized, or perceived as undignified—its integration and acceptance may be interfered with by the arousal and increased distress that memories can trigger. Intensive recollections including flashbacks, nightmares, and recurrent intrusive mem-

ories cause hyperarousal, disbelief, insomnia, irritability, and disturbed concentration that distort normal grieving (Prigerson and Jacobs 2001). The shock of the death can precipitate mistrust, anger, detachment, and an unwillingness to accept its reality. These reactions at a subthreshold level are on a continuum with the full features of acute and posttraumatic stress disorders, but subthreshold states have been observed to persist for years and contribute substantial morbidity. Palliative care deaths involving profound breakdown of bodily surfaces, gross disfigurement due to head and neck cancers, or other changes eliciting fear, disgust, or mortification may generate traumatic memories in the bereaved. Schut and colleagues (1997) found that PTSD was often correlated with the perceived inadequacy of the goodbye and suggested that rituals to complete this be incorporated into related grief therapies.

### Psychiatric Disorders in Bereavement

Rates of major depression in the bereaved have varied between 16% and 50%, peaking during the first 2 months (Clayton 1990; Zisook and Schuchter 1991) and gradually decreasing to 15% across the next 2 years (Harlow et al. 1991; Zisook et al. 1994). The features of any major depressive episode following bereavement resemble major depression at other points of the life cycle (Karam 1994). There is a tendency toward chronicity, considerable social morbidity, and risk of inadequate treatment.

Anxiety disorders take the form of adjustment disorders, generalized anxiety disorder, acute and posttraumatic stress disorders, and phobias and occur in up to 30% of the bereaved (Jacobs 1993).

Individuals predisposed to alcohol or other substance use disorders are at higher risk for relapse during grief

(Jacobs 1993), as are those with psychotic disorders. The latter should not be confused with the “normal” hallucinations that can occur in grief, typically limited to the voice, sight, and/or sense of presence of the deceased.

Risk factors that, when present, can aid recognition of those at greater risk of complicated grief are summarized in Table 40–3.

### Grief Therapies

The most basic model is a supportive/expressive intervention in which the person is invited to share his or her feelings about the loss to a health professional who will listen and seek to understand the other’s distress in a comforting manner. The key therapeutic aspects of this encounter are the sharing of distress and, through the relational understanding that is acknowledged, some shift in cognitive appraisal of the reality that has been forever altered. There are multiple possible formal interventions for bereaved people, but the first question is whether an intervention is actually warranted. For most, although bereavement is painful, personal resilience will ensure normal adaptation. There can therefore be no justification for routine intervention, because grief is not a disease. Early intervention should be considered for those at risk of maladaptive outcomes and those who later develop complicated bereavement need active treatments.

The spectrum of interventions spans individual-, group-, and family-oriented therapies and encompasses all schools of psychotherapy as well as appropriately indicated pharmacotherapy. A typical intervention entails six to eight sessions over several months. In this sense, grief therapy is focused and time limited, but multimodal therapies are common. Table 40–4 lists commonly used forms of grief therapy (Kissane 2004).

**TABLE 40–3. Risk factors for complicated grief**

Category	Range of circumstances
Nature of the death	Untimely within the life cycle (e.g., death of a child) Sudden and unexpected Traumatic/shocking Stigmatized
Strengths and vulnerabilities of the caregiver/bereaved	Past history of psychiatric disorder Personality and coping style Cumulative experience of losses
Nature of the relationship with the deceased	Overly dependent Ambivalent
Family and support network	Dysfunctional family Isolated Alienated

**TABLE 40-4. Models of grief therapy**

<b>Model</b>	<b>Potential focus for application</b>	<b>Clinical issues when indicated</b>
Supportive/expressive therapy (guided grief work, crisis intervention)	Individual and/or group	Avoidance of emotional expression Inhibited or delayed grief Isolated and needing support Established psychiatric disorders including depression
Interpersonal or psychodynamic therapy	Individual and/or group	Relational issues dominate Role transition difficulties
Cognitive-behavioral therapy	Individual and/or group	Chronic grief with "stuck" behaviors Traumatic grief Posttraumatic stress disorder
Family-focused grief therapy	Family	Family either at risk or clearly dysfunctional in its relating Adolescents or children at risk
Combined pharmacotherapies with any of the psychotherapeutic models	Individual	Depressive disorders Anxiety disorders Sleep disorders

Pharmacotherapy is widely used to support the bereaved, but prescribing should be judicious. Benzodiazepines allay anxiety and assist sleep, but excessive use may interfere with adaptive mourning. Antidepressants are indicated when bereavement is complicated by major depression or panic disorder (Jacobs et al. 1987; Pasternak et al. 1991; Zisook et al. 2001).

## **Palliation of Selected Physical Symptoms**

Although the diagnosis and treatment of psychiatric disorders in the patient with advanced illness is important, pain and other distressing physical symptoms must also be aggressively treated to enhance the patient's quality of life (Foley 1985; Foley and Helband 2001). Some key points are noted in this discussion, but a comprehensive review of pharmacological and nonpharmacological interventions for common physical symptoms encountered in the terminally ill can be found in a curriculum published by the American Society of Clinical Oncology (2001) and in major palliative care texts (Chochinov and Breitbart 2000; Doyle et al. 2003).

### **Pain**

The Agency for Health Care Policy and Research (1994) published a practice guideline for management of cancer pain in the early 1990s, with more recent guidelines from the National Comprehensive Cancer Network (Benedetti et al. 2000). Breitbart et al. (2004b) provided an up-to-

date detailed discussion of the use of behavioral, psychotherapeutic, and psychopharmacological interventions for pain control in palliative care (see also Chapter 36, "Pain"). After adequate medical treatment, mild to moderate levels of residual pain can be effectively managed with behavioral techniques that are quite similar to those used for anxiety, phobias, and anticipatory nausea and vomiting. Relaxation techniques, imagery, hypnosis, biofeedback, and multicomponent cognitive-behavioral interventions have been used to provide comfort and minimize pain in adults, children, and adolescents.

### **Anorexia and Weight Loss**

Whereas physiological changes associated with terminal illness account for most of the anorexia and cachexia in the terminally ill, with additional contributions from adverse effects of treatments, psychological and psychiatric factors, including anxiety, depression, and conditioned food aversions, may also play a role (Lesko 1989). The treatment of anorexia and weight loss begins with the identification and correction of reversible causes (e.g., opioid-induced nausea, stomatitis from chemotherapy, or thrush). Progestational drugs (medroxyprogesterone or megestrol acetate) are often tried for non-specific cachexia. Appetite-stimulating antidepressants (e.g., tricyclic antidepressants, mirtazapine, trazodone) should be prescribed when the cause is major depression, but depression should never be diagnosed solely on the basis of unexplained anorexia and weight loss. Treatment of conditioned nausea and vomiting is discussed later.

## Asthenia/Fatigue

Asthenia and fatigue are extremely common in patients with advanced cancer, AIDS, and organ failure as a result of deconditioning, catabolism, malnutrition, infection, profound anemia, metabolic abnormalities, or adverse effects of treatment, but a reversible cause often cannot be identified. As with unexplained weight loss in advanced disease, there is a tendency to overdiagnose depression in the terminally ill patient with extreme fatigue.

The literature in support of the pharmacotherapy of fatigue in cancer patients is largely anecdotal, but practice guidelines are available (Mock et al. 2000). Identifiable causes should be specifically treated when possible, for example, erythropoietin for anemia. Some patients respond to corticosteroids, but the benefits tend to be fleeting and prolonged use can cause proximal myopathy. Psychostimulants have been used in the treatment of asthenia with good results (Breitbart et al. 2001; see also Chapter 28, "HIV/AIDS"). Low doses of stimulants do not appear to cause appetite suppression or weight loss and may actually improve energy and appetite in fatigued terminally ill patients.

## Nausea and Vomiting

Common causes of nausea and vomiting in cancer patients include radiation, medications, toxins, metabolic derangements, obstruction of the gastrointestinal tract, and chemotherapy. Conditioned by the experience of profound nausea and vomiting secondary to highly emetic chemotherapy agents, some patients report being nauseated in anticipation of treatment. Anticipatory nausea and vomiting used to be very frequent but has become less so with current antiemetic therapy.

Antiemetic drugs are the mainstay of managing chemotherapy-induced nausea and vomiting in patients with advanced disease. Several antiemetics (e.g., metoclopramide, prochlorperazine, promethazine) have dopamine-blocking properties and so can cause the same extrapyramidal side effects as neuroleptics, with acute akathisia and dystonia common. Extrapyramidal side effects are not a problem with newer antiemetics like ondansetron. Rapid-onset, short-acting benzodiazepines are also helpful in controlling anticipatory nausea and vomiting once they have developed (Greenberg et al. 1987). Behavioral control of anticipatory nausea and vomiting was shown to be highly effective (Barnes 1988) but has largely been replaced by antiemetic drugs.

## Conclusion

The psychosomatic medicine practitioner can play an important role in the care of patients with advanced, life-

threatening medical illnesses. Palliative care for terminally ill patients must include not only control of pain and physical symptoms but also assessment and management of psychiatric and psychosocial complications. The psychosomatic medicine practitioner working in the palliative care setting must be knowledgeable in the assessment and management of major psychiatric complications such as anxiety, depression, and delirium, and also must be adept in dealing with issues of existential despair and spiritual suffering. Cultural issues, communication issues, ethical issues, and issues of bereavement are all areas requiring attention and awareness. As part of a multidisciplinary team, the psychosomatic medicine practitioner can play an important role in the provision of comprehensive palliative care.

- von Economo's disease, 587
- Vulvodynia, 741–742
- WAIS (Wechsler Adult Intelligence Scale), 20, 448, 501, 668
- Warfarin, **438**, **876**
- Water intoxication, 504
- Water loading, in eating disorders, **321**, 321–322
- Weakness, drug-induced
- anticonvulsants, 885
  - benzodiazepines, 890
- Weapons checks in emergency department, 185
- Wechsler Adult Intelligence Scale (WAIS), 20, 448, 501, 668
- Wegener's granulomatosis, 535, 548
- Weight changes, drug-induced
- anticonvulsants, 886
  - antipsychotics, 889, 910
  - bupropion, 882
  - lithium, 884, 885
  - mirtazapine, 206, 875, 882
  - monoamine oxidase inhibitors, 264, 882
  - selective serotonin reuptake inhibitors, 155, 875, 882
  - tricyclic antidepressants, 264, 882
  - venlafaxine, 875
- Weight gain
- associated with intensive diabetes management, 498
  - during nicotine withdrawal, 410
  - in polycystic ovary syndrome, 506
- Weight loss
- after bariatric surgery, 665
  - behavioral, for binge-eating disorder, 328
  - in eating disorders, 312, 323
  - nutritional rehabilitation for, 325–327
  - management in terminally ill patients, 1000
  - for obesity hypoventilation syndrome, 345
  - for obstructive sleep apnea, 344
- Wernicke-Korsakoff syndrome, 395, 508, 709
- Wernicke's aphasia, 6, 703
- Wernicke's encephalopathy, 395, 398, 508, 709
- West Nile virus infection, 586

- Western equine encephalomyelitis, 586
- WHI (Women's Health Initiative), 751
- Whipple's disease, 713
- Wilson's disease, 141, 472, 711  
 clinical features of, 141, 711  
 course of, 152  
 depression and, 141  
 differential diagnosis of, 711  
 genetics of, 135, 711  
 investigation of, 711  
 Kayser-Fleischer rings in, 711  
 management of, 711  
 penicillamine, 152  
 neuropathology of, 141, 711
- Withdrawal states  
 from alcohol, 394–395  
 aggression and, 180  
 delirium during, 116, 180, 394–395
