TEXTBOOK OF  
**PSYCHOSOMATIC**  
**MEDICINE**

James L. Levenson, M.D.

*Official Textbook of the Academy of Psychosomatic Medicine*

**The American Psychiatric Publishing**

**Textbook of  
Psychosomatic Medicine**

## Editorial Board

**William Breitbart, M.D.**

Chief, Psychiatry Service, Department of Psychiatry and Behavioral Sciences, and Attending Psychiatrist, Pain and Palliative Care Service, Department of Neurology, Memorial Sloan-Kettering Cancer Center; Professor of Psychiatry, Department of Psychiatry, Weill Medical College of Cornell University, New York, New York

**Francis Creed, M.D., F.R.C.P., F.R.C.Psych., F.Med.Sci.**

Professor of Psychological Medicine, University of Manchester, United Kingdom; Honorary Consultant Psychiatrist, Manchester Mental Health and Social Care Trust

**Joel Dimsdale, M.D.**

Professor of Psychiatry, University of California, San Diego, San Diego, California

**Giovanni A. Fava, M.D.**

Professor of Clinical Psychology, University of Bologna, Bologna, Italy; Clinical Professor of Psychiatry, State University of New York at Buffalo, Buffalo, New York; Editor-in-Chief, *Psychotherapy and Psychosomatics*

**Donna B. Greenberg, M.D.**

Psychiatrist, Massachusetts General Hospital; Associate Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts

**Wayne Katon, M.D.**

Professor, Vice-Chair, and Director of Division of Health Services and Psychiatric Epidemiology, University of Washington Medical School, Seattle, Washington

**Antonio Lobo, M.D., Ph.D.**

Professor and Chairman, Department of Medicine and Psychiatry, Universidad de Zaragoza; and Chief, Psychosomatics and Consultation-Liaison Psychiatry Service, Hospital Clínico Universitario, Zaragoza, Spain

**Constantine G. Lyketsos, M.D., M.H.S.**

Professor of Psychiatry and Behavioral Sciences and Director, Division of Geriatric Psychiatry and Neuropsychiatry, The Johns Hopkins Hospital, Baltimore, Maryland

**Luis Ruiz-Flores, M.D.**

Professor and Head of Psychiatry, National University of Mexico, Mexico City; President, Mexican Psychiatric Association, 1998–1999

**Teresa A. Rummans, M.D.**

Professor of Psychiatry, Department of Psychiatry and Psychology, Mayo Clinic College of Medicine, Rochester, Minnesota

**Peter A. Shapiro, M.D.**

Associate Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Associate Director, Consultation-Liaison Psychiatry Service; Director, Transplantation Psychiatry Service, Columbia University Medical Center, New York–Presbyterian Hospital, New York, New York

**Michael C. Sharpe, M.A., M.D., F.R.C.P., M.R.C.Psych.**

Professor of Psychological Medicine and Symptoms Research, School of Molecular and Clinical Medicine, University of Edinburgh, Edinburgh, United Kingdom

**Graeme C. Smith, M.D.**

Professor of Psychological Medicine, Monash University, Clayton, Australia

**Theodore A. Stern, M.D.**

Chief, The Avery D. Weisman, M.D., Psychiatry Consultation Service, Massachusetts General Hospital; Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts

**Donna E. Stewart, M.D., F.R.C.P.C.**

Professor and Chair of Women's Health, University of Toronto, University Health Network Women's Health Program, Toronto, Ontario, Canada

**Paula T. Trzepacz, M.D.**

Medical Director, U.S. Neurosciences, Lilly Research Laboratories; Clinical Professor of Psychiatry, University of Mississippi Medical School, Jackson, Mississippi; Adjunct Professor of Psychiatry, Tufts University School of Medicine, Boston, Massachusetts

**Thomas N. Wise, M.D.**

Chairman, Department of Psychiatry, Inova Fairfax Hospital, Falls Church, Virginia; Professor and Vice Chair, Department of Psychiatry, Georgetown University, Washington, D.C.

**The American Psychiatric Publishing**

James L. Levenson, M.D.

Chair, Consultation-Liaison Psychiatry, and Vice-Chair, Psychiatry  
Professor of Psychiatry, Medicine, and Surgery  
Virginia Commonwealth University  
Richmond, Virginia

American  
**Psychiatric**  
Publishing, Inc.

Washington, DC  
London, England

**Note:** The authors have worked to ensure that all information in this book is accurate at the time of publication and consistent with general psychiatric and medical standards, and that information concerning drug dosages, schedules, and routes of administration is accurate at the time of publication and consistent with standards set by the U.S. Food and Drug Administration and the general medical community. As medical research and practice continue to advance, however, therapeutic standards may change. Moreover, specific situations may require a specific therapeutic response not included in this book. For these reasons and because human and mechanical errors sometimes occur, we recommend that readers follow the advice of physicians directly involved in their care or the care of a member of their family.

Books published by American Psychiatric Publishing, Inc., represent the views and opinions of the individual authors and do not necessarily represent the policies and opinions of APPI or the American Psychiatric Association.

**Alan Stoudemire, M.D.**

Professor of Psychiatry and Behavioral Sciences  
Director of Medical Student Education in Psychiatry  
Emory University School of Medicine

*This book is dedicated to the memory of Alan Stoudemire (1951–2000), a brilliant clinician, true scholar, prolific writer, and dedicated teacher and mentor. His contributions profoundly transformed our field. He was and remains an inspiration to others, in and outside our profession, for he lived life fully with passion and principle. He transcended his own illnesses with rare strength of spirit, deepening his compassion for and commitment to the medically ill, even while his own life was tragically abbreviated. Those of us who knew him well will forever miss his warmth, wit, and heartfelt friendship.<sup>1</sup>*

# Foreword

---

Stephen C. Scheiber, M.D.

**JIM LEVENSON HAS** done superb work in organizing and editing this excellent textbook, which presents the current knowledge base of Psychosomatic Medicine for physicians in all specialties. Dr. Levenson has brought together a superb editorial board, including members from the United States, Canada, United Kingdom, Australia, Spain, Italy, and Mexico. The authors' contributions reflect the breadth and depth of this psychiatric subspecialty, which gained official recognition by the American Board of Psychiatry and Neurology in 2003 through the American Board of Medical Specialties.

The text is neatly divided into sections, including general principles, symptoms and disorders, and different organ systems, which are reflected in the specialties and subspecialties of medicine. It concludes with a detailed discussion of the different treatments and management approaches.

At the interface between psychiatry and other medical specialties, Psychosomatic Medicine is the newest psychiatric subspecialty recognized by the American Board of Medical Specialties. The American Board of Psychiatry and Neurology is developing the competencies and certification examination for this field, with the first examination to be held in June 2005. The Accreditation Council of Graduate Medical Education and the Psychiatry Residency Review Committee have begun the process of accrediting fellowship programs in Psychosomatic Medicine.

While research, clinical treatment, and teaching in Psychosomatic Medicine have been growing rapidly in the past decade, this field has evolved and matured over many years, with contributions from many great psychiatrists and other physicians such as Flanders Dunbar, Felix Deutsch, Franz Alexander, Harold Wolff, and Roy Grinker in the development of Psychosomatic Medicine in the first half of the twentieth century. In the 1930s, the American Psychosomatic Society was founded, and the first issue of the journal *Psychosomatic Medicine* was published, followed in the 1950s by the founding of the

Academy of Psychosomatic Medicine and the first issue of *Psychosomatics*.

Another growth spurt of Psychosomatic Medicine occurred in the 1970s, with the appearance of a plethora of major texts, including those by Oscar Hill; Allister Munro; Wittkower and Warnes; Herbert Weiner; Lipowski, Lipsitt, and Whybrow; and a number of others. George Engel, an internist and psychoanalyst, brought psychiatry and medicine closer together and refocused the conceptual basis of the field through the biopsychosocial model. In the 1970s and 1980s, consultation-liaison psychiatry blossomed as the clinical application of psychosomatic principles over many years, with leaders such as Bish Lipowski, John Schwab, Tom Hackett, Jim Strain, Bob Pasnau, and Jimmie Holland.

Today, Psychosomatic Medicine is a vibrant clinical field informed by a rapidly expanding research base, growing not only in North America and Europe but also in Japan, Australia, New Zealand, and many other nations. This fine work demonstrates the acceleration of advances in the field of Psychosomatic Medicine. The increasing complexity and subspecialization in the rest of medicine requires that the expert in Psychosomatic Medicine keep abreast of the latest advances in diagnosis and treatment in the other medical specialties. The contributors to this latest and most advanced textbook of Psychosomatic Medicine are widely recognized experts who comprehensively cover all of the major psychiatric symptoms and disorders in the medically ill. For each major psychiatric disorder and each major medical disorder, they review epidemiology and risk factors; the effects of the psychiatric disorder on medical disorders and, conversely, the effects of medical diseases on the psyche; clinical features; diagnosis and assessment; differential diagnosis; management; and treatment. This textbook is very up-to-date, scholarly, and encyclopedic but also reflects an understanding that one must approach each patient as a unique, suffering individual.

# Introduction

---

James L. Levenson, M.D.

**WHAT IS PSYCHOSOMATIC** Medicine? In the past, Psychosomatic Medicine has had ambiguous connotations, alternatively “psychogenic” or “holistic,” but it is the latter meaning that has characterized its emergence as a contemporary scientific and clinical discipline (Lipowski 1984). In this book, it refers to a specialized area of psychiatry whose practitioners have particular expertise in the diagnosis and treatment of psychiatric disorders and difficulties in complex medically ill patients (Gitlin et al. 2004).

We treat and study three general groups of patients: those with comorbid psychiatric and general medical illnesses complicating each other’s management, those with somatoform and functional disorders, and those with psychiatric disorders that are the direct consequence of a primary medical condition or its treatment. Psychosomatic Medicine practitioners work as hospital-based consultation-liaison psychiatrists (Kornfeld 1996), on medical-psychiatric inpatient units (Kathol and Stoudemire 2002), and in settings in which mental health services are integrated into primary care (Unutzer et al. 2002). Thus the field’s name reflects the fact that it exists at the interface of psychiatry and medicine.

Psychosomatic Medicine is the newest psychiatric subspecialty formally approved by the American Board of Medical Specialties. There have been many other names for this specialized field, including consultation-liaison psychiatry, medical-surgical psychiatry, psychological medicine, and psychiatric care of the complex medically ill,

among others. In 2001, the Academy of Psychosomatic Medicine applied to the American Board of Psychiatry and Neurology (ABPN) for the recognition of “Psychosomatic Medicine” as a subspecialty field of psychiatry, choosing to return to the name for the field embedded in our history, our journals, and our national organizations (for a detailed account of the field, see Lyketsos et al. 2001). Subsequent formal approval was received from the American Psychiatric Association, ABPN, the Residency Review Committee (RRC) of the Accreditation Council for Graduate Medical Education (ACGME), and the American Board of Medical Specialties (ABMS). The first certifying examination is scheduled for June 2005.

Psychosomatic Medicine has a rich history. The term *psychosomatic* was introduced by Johann Heinroth in 1818, and Felix Deutsch introduced the term *psychosomatic medicine* around 1922 (Lipsitt 2001). Psychoanalysts and psychophysicists pioneered the study of mind-body interactions from very different vantage points, each contributing to the growth of Psychosomatic Medicine as a clinical and scholarly field. The modern history of the field (see Table 1) perhaps starts with the Rockefeller Foundation’s funding of psychosomatic medicine units in several U.S. teaching hospitals in 1935. The National Institute of Mental Health made it a priority to foster the growth of consultation-liaison psychiatry, through training grants (circa 1975) and a research development program (circa 1985).

**Table 2: Selected classic texts in psychosomatic medicine**

1935	<i>Emotions and Body Change</i> (Dunbar)
1943	<i>Psychosomatic Medicine</i> (Weiss and English)
1950	<i>Psychosomatic Medicine</i> (Alexander)
1968	<i>Handbook of Psychiatric Consultation</i> (Schwab)
1978	<i>Organic Psychiatry</i> (Lishman)
1978	<i>Massachusetts General Hospital Handbook of General Hospital Psychiatry</i> (Hackett and Cassem)
1993	<i>Psychiatric Care of the Medical Patient</i> (Stoudemire and Fogel)

Psychosomatic Medicine is a scholarly discipline, with classic influential texts (Table 2), many devoted journals (Table 3), and both national (Table 4) and international (Table 5) professional/scientific societies. The Academy of Psychosomatic Medicine is the only U.S. national organization primarily dedicated to Psychosomatic Medicine as a psychiatric subspecialty. The American Psychosomatic Society, an older cousin, is primarily devoted to psychosomatic research, and its members come from many disciplines (Wise 1995). While consultation-liaison psychiatry and psychosomatic medicine flourished first in the United States, exciting work now comes from around the world. This is reflected in the membership of the Editorial Board and the contributors to this text, who include psychiatrists from the United States, Canada, United Kingdom, Australia, Spain, Italy, and Mexico.

This book is organized into four sections. The first five chapters cover general principles in evaluation and management. Chapters 6–18 are devoted to psychiatric symptoms and disorders in the medically ill. Chapters 19–36 address issues within each of the medical specialties and subspecialties. The final four chapters are summaries of psychiatric treatment in the medically ill. This book has attempted to capture the diversity of our field, whose practitioners do not place equal emphasis on the syllables of “bio-psycho-social.” There is not unanimity among us on some questions, and diverse opinions will be found in this book. Psychosomatic Medicine has evolved, since its start, from a field based on clinical experience, conjecture, and theorizing into a discipline grounded in empirical research that is growing and spreading its findings into many areas of medical care (Levenson 1997).

## Acknowledgments

This book has benefited from those who have gone before in creating comprehensive textbooks for our field, especially Stoudemire, Fogel, and Greenberg’s *Psychiatric Care of the Medical Patient* (2000) and Wise and Rundell’s *The American Psychiatric Publishing Textbook of Consultation-Liaison Psychiatry* (2002).

I owe an enormous debt of gratitude to the many people who made this book possible. First, to Bob Hales, Editor-in-Chief, and Tom Wise, Chair of the Editorial Board at American Psychiatric Publishing, Inc. (APPI), whose faith in me and encouragement were inspirational. This book would not have been conceived if Psychosomatic Medicine had not become an official subspecialty of American psychiatry, and for that we all owe a great deal to Kostas Lyketsos, leader and comrade-in-arms in the long campaign, along with many others from the Academy of Psychosomatic Medicine who worked to make it a reality, including Dan Winstead, whose wise counsel has been invaluable. The value of this text comes from the untiring labors of the contributors, who were patient under repeated onslaughts of red ink from me. An assertive Editorial Board pushed us all toward the highest standards.

Every chapter in this book has been critically reviewed by at least one member of the Editorial Board, and most have been externally reviewed as well. Chapters 19–36 have also been reviewed by one or more nonpsychiatric physician experts of the relevant specialty or subspecialty. I am particularly grateful to my nonpsychiatric colleagues at Virginia Commonwealth University (VCU) who generously gave their time to critique chapters in their respective disciplines, including David Gardner, Mike Edmond, Laurie Lyckholm, Lex Tartaglia, Paul Fairman, Lenore Buckley, Sara Monroe, Brian Kaplan, Michael King, Bob Perry, Ken Ellenbogen, and Marjolein de Wit. Psychiatric colleagues at VCU, including Susan Kornstein, Alison Lynch, Anand Pandurangi, Jim Wade, and Neil Sonenklar, did the same in their areas of expertise. UCLA child psychiatrists Brenda Bursch and Margaret Stuber (authors of Chapter 34) provided expert reviews of several other chapters' coverage of topics involving children and adolescents.

Tina Coltri-Marshall provided invaluable service, keeping everyone organized and on schedule. APPI's John McDuffie and Bob Pursell gave expert advice and encouragement from start to finish, and I am grateful to all of the

APPI staff, including Robin Simpson, Pam Harley, Greg Kuny, Katie Duffy, Abdul Kargbo, Julia Bozzolo, Rebecca Richters, and Judy Castagna.

Finally, this book would not have been possible without the most enthusiastic support from my chair, Joel Silverman; the help of my secretary, Pam Copeland; and the patience and tolerance of my family.

# Psychiatric Assessment and Consultation

---

Felicia A. Smith, M.D.

John Querques, M.D.

James L. Levenson, M.D.

Theodore A. Stern, M.D.

**PSYCHOSOMATIC MEDICINE IS** clinically rooted in consultation-liaison psychiatry, expanding from its beginnings on a few general medical wards of large hospitals in the 1930s to specialized medical units throughout various parts of the health care delivery system. Practitioners in this discipline assist with the care of a variety of patients, especially those with complex illnesses such as cancer, organ transplantation, and HIV infection (Gitlin et al. 2004; Hackett et al. 2004). In the medical setting, prompt recognition and evaluation of psychiatric problems are essential because psychiatric comorbidity often exacerbates the course of medical illness, causes significant distress in the patient, prolongs hospital length of stay, and increases costs of care. Psychiatrists in medical settings may be asked to evaluate a wide variety of conditions. These can include dementia, delirium, agitation, psychosis, substance abuse or withdrawal, somatoform disorders, personality disorders, and mood and anxiety disorders, as well as suicidal ideation, noncompliance, and aggressive and other behavioral problems. In addition, ethical and legal considerations are often critical elements of the psychiatric consultation.

In this introductory chapter, we present a detailed approach to psychiatric assessment and consultation in a medical setting. Flexibility is essential for psychiatric consultants to be successful in the evaluation of affective, behavioral, and cognitive disturbances in medically ill patients. In the final section of the chapter, we briefly outline the benefits of psychiatric consultation for patients as well as for the greater hospital and medical communities.

## Psychiatric Consultation in the General Hospital

---

Psychiatrists who work in medical settings are charged with providing expert consultation to medical and surgical patients. In many respects, psychiatric care of such patients is no different from the treatment of patients in a psychiatric clinic or in a private office. However, the constraints of the modern hospital environment demand a high degree of adaptability. Comfort, quiet, and privacy are scarce commodities in medical and surgical units. Interruptions by medical or nursing staff, visitors, and roommates erode the privacy that the psychiatrist usually expects. Patients who are sick, preoccupied with their physical condition, and in pain are ill-disposed to engage in the exploratory interviews that often typify psychiatric evaluations in other settings. Monitoring devices replace the plants, pictures, and other accoutrements of a typical office. Nightstands and tray tables are littered with medical paraphernalia commingled with personal effects.

The consultant must be adept at gathering the requisite diagnostic information efficiently from the data permitted by the patient's clinical condition and must be able to tolerate the sights, sounds, and smells of the sickroom. Additional visits for more history are often inevitable. In the end, the diagnosis will likely fall into one (or more) of the categories outlined in Lipowski's (1967) classification, which is still relevant today (Table 1-1).

**TABLE 1-1. Categories of psychiatric differential diagnoses in the general hospital**

- Psychiatric presentations of medical conditions
- Psychiatric complications of medical conditions or treatments
- Psychological reactions to medical conditions or treatments
- Medical presentations of psychiatric conditions
- Medical complications of psychiatric conditions or treatments
- Comorbid medical and psychiatric conditions

*Source.* Adapted from Lipowski 1967.

Although the consultant is summoned by the patient's physician, in most cases the visit is unannounced and is not requested by the patient, from whom cooperation is expected. Explicitly acknowledging this reality and apologizing if the patient was not informed are often sufficient to gain the patient's cooperation. Cooperation is enhanced if the psychiatrist sits down and operates at eye level with the patient. By offering to help the patient get comfortable (e.g., by adjusting the head of the bed, bringing the patient a drink or a blanket, or adjusting the television) before and after the encounter, the consultant can increase the chances of being welcomed then and for follow-up evaluations.

When psychiatrists are consulted for unexplained physical symptoms or for pain management, it is useful to empathize with the distress that the patient is experiencing. This avoids conveying any judgment on the etiology of the pain except that the suffering is real. After introductions, if the patient is in pain, the consultant's first questions should address this issue. Failing to do so conveys a lack of appreciation for the patient's suffering and may be taken by the patient as disbelief in his or her symptoms. Starting with empathic questions about the patient's suffering establishes rapport and also guides the psychiatrist in setting the proper pace of the interview. Finally, because a psychiatric consultation will cause many patients to fear that their physician thinks they are "crazy," the psychiatrist may first need to address this fear.

## The Process of the Consultation

Although it is rarely as straightforward as the following primer suggests, the process of psychiatric consultation should, in the end, include all the components explained below and summarized in Table 1-2.

### Speak Directly With the Referring Clinician

Requests for psychiatric consultation are notorious for being vague and imprecise (e.g., "rule out depression" or

**TABLE 1-2. Procedural approach to psychiatric consultation**

- Speak directly with the referring clinician.
- Review the current records and pertinent past records.
- Review the patient's medications.
- Gather collateral data.
- Interview and examine the patient.
- Formulate diagnostic and therapeutic strategies.
- Write a note.
- Speak directly with the referring clinician.
- Provide periodic follow-up.

"patient with schizophrenia"). They sometimes signify only that the team recognizes that a problem exists; such problems may range from an untreated psychiatric disorder to the experience of countertransference feelings. In speaking with a member of the team that has requested the consultation, the consultant employs some of the same techniques that will be used later in examining the patient; that is, he or she listens to the implicit as well as the explicit messages from the other physician (Murray 2004). Is the physician angry with the patient? Is the patient not doing what the team wants him or her to do? Is the fact that the patient is young and dying leading to the team's overidentification with him or her? Is the team frustrated by an elusive diagnosis? All of these situations generate emotions that are difficult to reduce to a few words conveyed in a consultation request; moreover, the feelings often remain out of the team's conscious awareness. This brief interaction may give the consultant invaluable information about how the consultation may be useful to the team and to the patient.

### Review the Current Records and Pertinent Past Records

When it is done with the unfailing curiosity of a detective hot on the trail of hidden clues, reading a chart can be an exciting and self-affirming part of the consultation process. Although it does not supplant the consultant's independent history taking or examination, the chart review provides a general orientation to the case. Moreover, the consultant is in a unique position to focus on details that may have been previously overlooked. For example, nurses often document salient neurobehavioral data (e.g., the level of awareness and the presence of confusion or agitation); physical and occupational therapists estimate functional abilities crucial to the diagnosis of cognitive disorders and to the choice of an appropriate level of care (e.g., nursing home or assisted-living facility); and speech pathologists note alterations in articulation, swallowing, and lan-

guage, all of which may indicate an organic brain disease. All of them may have written progress notes about adherence to treatment regimens, unusual behavior, interpersonal difficulties, or family issues encountered in their care of the patient. These notes may also provide unique clues to the presence of problems such as domestic violence, factitious illness, or personality disorders. In hospitals or clinics where nurses' notes are kept separate from the physician's progress notes, it is essential for the consultant to review those sections.

## Review the Patient's Medications

Construction of a medication list at various time points (e.g., at home, on admission, on transfer within the hospital, and at present) is always good, if not essential, practice. Special attention should be paid to medications with psychoactive effects and to those associated with withdrawal syndromes (both obvious ones like benzodiazepines and opiates, and less obvious ones like antidepressants, anticonvulsants, and beta-blockers). Review of order sheets or computerized order entries is not always sufficient, because—for a variety of reasons—patients may not always receive prescribed medications; therefore, medication administration records should also be reviewed. Such records are particularly important for determining the frequency of administration of medicines ordered on an as-needed basis. For example, an order for lorazepam 1–2 mg every 4–6 hours as needed may result in a patient receiving anywhere from 0 mg to 12 mg in a day, which can be critical in cases of withdrawal or oversedation.

## Gather Collateral Data

Histories from hospitalized medically ill patients may be especially spotty and unreliable, if not nonexistent (e.g., with a patient who is somnolent, delirious, or comatose). Data from collateral sources (e.g., family members; friends; current and outpatient health care providers; case managers; and, in some cases, police and probation officers) may be of critical importance. However, psychiatric consultants must guard against prizing any single party's version of historical events over another's; family members and others may lack objectivity, be in denial, be overinvolved, or have a personal agenda to advance. For example, family members tend to minimize early signs of dementia and to overreport depression in patients with dementia. Confidentiality must be valued when obtaining collateral information. Ideally, one obtains the patient's consent first; however, this may not be possible if the patient lacks capacity or if a dire emergency is in progress (see Chapter 3, "Le-

gal Issues," and Chapter 4, "Ethical Issues"). Moreover, in certain situations there may be contraindications to contacting some sources of information (e.g., an employer of a patient with substance abuse or the partner of a woman who is experiencing abuse). Like any astute physician, the psychiatrist collates and synthesizes all available data and weighs each bit of information according to the reliability of its source.

## Interview and Examine the Patient

Armed with information gleaned and elicited from other sources, the psychiatric consultant now makes independent observations of the patient and collects information that may be the most reliable of all because it comes from direct observations. For non-English-speaking patients, a translator is often needed. Although using family members may be expedient, their presence often compromises the questions asked and the translations offered because of embarrassment or other factors. It is therefore important to utilize hospital translators or, for less common languages, services via telephone. This can be difficult, but it may be necessary in obtaining a full and accurate history.

### *Mental Status Examination*

A thorough mental status examination is central to the psychiatric evaluation of the medically ill patient. Because the examination is hierarchical in nature, care must be taken to complete it in a systematic fashion (Hyman and Tesar 1994). The astute consultant will glean invaluable diagnostic clues from a combination of observation and questioning.

**Level of consciousness.** Level of consciousness depends on normal cerebral arousal by the reticular activating system. A patient whose level of consciousness is impaired will inevitably perform poorly on cognitive testing. The finding of *disorientation* implies cognitive failure in one or several domains, and it is helpful to test orientation near the start of the mental status examination.

**Attention.** The form of attention most relevant to the clinical mental status examination is the sustained attention that allows one to concentrate on cognitive tasks. Disruption of attention—often by factors that diffusely disturb brain function, such as drugs, infection, or organ failure—is a hallmark of delirium. Sustained attention is best tested with moderately demanding, nonautomatic tasks such as reciting the months backward or, as in the Mini-Mental State Examination (MMSE; Folstein et al. 1975), spelling *world* backward or subtracting 7 serially from 100. Serial subtraction is intended to be a test of at-

tention, not arithmetic ability, so the task should be adjusted to the patient's native ability and educational level (serial 3s from 50, serial 1s from 20). An inattentive patient's performance on other parts of the mental status examination may be affected on any task requiring sustained focus.

**Memory.** *Working memory* is tested by asking the patient to *register* some information (e.g., three words) and to *recall* that information after an interval of at least 3 minutes during which other testing prevents rehearsal. This task can also be considered a test of *recent memory*. Semantic memory is tapped by asking general-knowledge questions (e.g., "Who is the President?") and by naming and visual recognition tasks. The patient's ability to remember aspects of his or her history serves as an elegant test of *episodic memory* (as well as of *remote memory*). Because semantic and episodic memories can be articulated, they constitute *declarative memory*. In contrast, *procedural memory* is implicit in learned action (e.g., riding a bicycle) and cannot be described in words. Deficits in procedural memory can be observed in a patient's behavior during the clinical evaluation.

**Executive function.** *Executive function* refers to the abilities that allow one to plan, initiate, organize, and monitor thought and behavior. These abilities, which localize broadly to the frontal lobes, are essential for normal social and professional performance but are difficult to test. Frontal lobe disorders often make themselves apparent in social interaction with a patient and are suspected when one observes disinhibition, impulsivity, disorganization, abulia, or amotivation. Tasks that can be used to gain some insight into frontal lobe function include verbal fluency, such as listing as many animals as possible in 1 minute; motor sequencing, such as asking the patient to replicate a sequence of three hand positions; the go/no-go task, which requires the patient to tap the desk once if the examiner taps once, but not to tap if the examiner taps twice; and tests of abstraction, including questions like "What do a tree and a fly have in common?"

**Language.** *Language disorders* result from lesions of the dominant hemisphere. In assessing language, one should first note characteristics of the patient's speech (e.g., non-fluency or paraphasic errors) and then assess comprehension. Naming is impaired in both major varieties of aphasia, and anomia can be a clue to mild dysphasia. Reading and writing should also be assessed. Expressive (Broca's or motor) aphasia is characterized by effortful, nonfluent speech with use of phonemic paraphasias (incorrect words that approximate the correct ones in sound), reduced use

of function words (e.g., prepositions and articles), and well-preserved comprehension. Receptive (Wernicke's or sensory) aphasia is characterized by fluent speech with both phonemic and semantic paraphasias (incorrect words that approximate the correct ones in meaning) and poor comprehension. The stream of incoherent speech and the lack of insight in patients with Wernicke's aphasia sometimes lead to misdiagnosis of a primary thought disorder and psychiatric referral; the clue to the diagnosis of a language disorder is the severity of the comprehension deficit. Global dysphasia combines features of Broca's and Wernicke's aphasias. Selective impairment of repetition characterizes conduction aphasia. The nondominant hemisphere plays a part in the appreciation and production of the emotional overtones of language.

**Praxis.** *Apraxia* refers to an inability to perform skilled actions (e.g., using a screwdriver, brushing one's teeth) despite intact basic motor and sensory abilities. These abilities can be tested by asking a patient to mime such actions or by asking the patient to copy unfamiliar hand positions. *Constructional apraxia* is usually tested with the Clock Drawing Test. *Gait apraxia* involves difficulty in initiating and maintaining gait despite intact basic motor function in the legs. *Dressing apraxia* is difficulty in dressing caused by an inability to coordinate the spatial arrangement of clothes with the body.

**Mood and affect.** Mood and affect both refer to the patient's emotional state, mood being the patient's perception and affect being the interviewer's perception. The interviewer must interpret both carefully, taking into account the patient's medical illness. Normal but intense expressions of emotion (e.g., grief, fear, or irritation) are common in patients with serious medical illness but may be misperceived by nonpsychiatric physicians as evidence of psychiatric disturbance. Disturbances in mood and affect may also be the result of brain dysfunction or injury. Irritability may be the first sign of many illnesses, ranging from alcohol withdrawal to rabies. Blunted affective expression may be a sign of Parkinson's disease. Intense affective lability (e.g., pathological crying or laughing) with relatively normal mood occurs with some diseases or injuries of the frontal lobes.

**Perception.** Perception in the mental status examination is primarily concerned with hallucinations and illusions. However, before beginning any part of the clinical interview and the mental status examination, the interviewer should establish whether the patient has any impairment in vision or hearing that could interfere with communication. Unrecognized impairments have led to erroneous

impressions that patients were demented, delirious, or psychotic. Although hallucinations in any modality may occur in primary psychotic disorders (e.g., schizophrenia or affective psychosis), prominent visual, olfactory, gustatory, or tactile hallucinations suggest a secondary medical etiology. Olfactory and gustatory hallucinations may be manifestations of seizures, and tactile hallucinations are often seen with substance abuse.

**Judgment and insight.** The traditional question for the assessment of *judgment* (i.e., “What would you do if you found a letter on the sidewalk?”) is much less informative than questions tailored to the problems faced by the patient being evaluated; for example, “If you couldn’t stop a nosebleed, what would you do?” “If you run out of medicine and you can’t reach your doctor, what would you do?” Similarly, questions to assess *insight* should focus on the patient’s understanding of his or her illness, treatment, and life circumstances.

**Further guidance on mental status examination.** An outline of the essential elements of a comprehensive mental status examination is presented in Table 1–3. Particular cognitive mental status testing maneuvers are described in more detail in Table 1–4. More detailed consideration of the mental status examination can be found elsewhere (Strub and Black 2000; Trzepacz and Baker 1993).

### **Physical Examination**

Although the interview and mental status examination as outlined above are generally thought to be the primary diagnostic tools of the psychiatrist, the importance of the physical examination should not be forgotten, especially in the medical setting. Most psychiatrists do not perform physical examinations on their patients. The consultation psychiatrist, however, should be familiar with and comfortable performing neurological examinations and other selected features of the physical examination that may uncover the common comorbidities in psychiatric patients (Granacher 1981; Summers et al. 1981a, 1981b). At an absolute minimum, the consultant should review the physical examinations performed by other physicians. However, the psychiatrist’s examination of the patient, especially of central nervous system functions relevant to the differential diagnosis, is often essential. A fuller physical examination is appropriate on medical-psychiatric units or whenever the psychiatrist has assumed responsibility for the care of a patient’s medical problems. Even with a sedated or comatose patient, simple observation and a few maneuvers that involve a laying on of hands may potentially yield a bounty of findings. Although it is beyond the scope of this chapter to discuss a comprehensive physical examination, Table 1–5

provides a broad outline of selected findings of the physical examination and their relevance to the psychiatric consultation.

### **Formulate Diagnostic and Therapeutic Strategies**

By the time the consultant arrives on the scene, routine chemical and hematological tests and urinalyses are almost

**TABLE 1–4. Detailed assessment of cognitive domains**

<b>Cognitive domain</b>	<b>Assessment</b>
<b>Level of consciousness and arousal</b>	Inspect the patient
<b>Orientation to place and time</b>	Ask direct questions about both of these
<b>Registration (recent memory)</b>	Have the patient repeat three words immediately
<b>Recall (working memory)</b>	Have the patient recall the same three words after performing another task for at least 3 minutes
<b>Remote memory</b>	Ask about the patient's age, date of birth, milestones, or significant life or historical events (e.g., names of presidents, dates of wars)
<b>Attention and concentration</b>	Subtract serial 7s (adapt to the patient's level of education; subtract serial 3s if less educated). Spell <i>world</i> backward (this may be difficult for non-English speakers). Test digit span forward and backward. Have the patient recite the months of the year (or the days of the week) in reverse order.
<b>Language</b>	(Adapt the degree of difficulty to the patient's educational level)
• <i>Comprehension</i>	Inspect the patient while he or she answers questions Ask the patient to point to different objects Ask yes or no questions Ask the patient to write a phrase (paragraph)
• <i>Naming</i>	Show a watch, pen, or less familiar objects, if needed
• <i>Fluency</i>	Assess the patient's speech Have the patient name as many animals as he or she can in 1 minute
• <i>Articulation</i>	Listen to the patient's speech Have the patient repeat a phrase
• <i>Reading</i>	Have the patient read a sentence (or a longer paragraph if needed)
<b>Executive function</b>	Determine if the patient requires constant cueing and prompting
• <i>Commands</i>	Have the patient follow a three-step command
• <i>Construction tasks</i>	Have the patient draw interlocked pentagons Have the patient draw a clock
• <i>Motor programming tasks</i>	Have the patient perform serial hand sequences Have the patient perform reciprocal programs of raising fingers
<b>Judgment and reasoning</b>	Listen to the patient's account of his or her history and reason for hospitalization Assess abstraction (similarities: dog/cat; red/green) Ask about the patient's judgment about simple events or problems: "A construction worker fell to the ground from the seventh floor of the building and broke his two legs; he then ran to the nearby hospital to ask for medical help. Do you have any comment on this?"

**TABLE 1–5. Selected elements of the physical examination and significance of findings**

Elements	Examples of possible diagnoses
<b>General</b>	
General appearance healthier than expected	Somatoform disorder
Fever	Infection or NMS
Blood pressure or pulse abnormalities	Withdrawal, thyroid or cardiovascular disease
Body habitus	Eating disorders, polycystic ovaries, or Cushing syndrome
<b>Skin</b>	
Diaphoresis	Fever, withdrawal, NMS
Dry, flushed	Anticholinergic toxicity, heat stroke
Pallor	Anemia
Changes in hair, nails, skin	Malnutrition, thyroid or adrenal disease
Jaundice	Liver disease
Characteristic stigmata	Syphilis, cirrhosis, or self-mutilation
Bruises	Physical abuse, ataxia, traumatic brain injury
<b>Eyes</b>	
Mydriasis	Opiate withdrawal, anticholinergic toxicity
Miosis	Opiate intoxication, cholinergic toxicity
Kayser-Fleischer pupillary rings	Wilson's disease
<b>Neurological</b>	
Tremors	Delirium, withdrawal syndromes, parkinsonism
Primitive reflexes present (e.g., snout, glabellar, and grasp)	Dementia, frontal lobe dysfunction
Hyperactive deep-tendon reflexes	Withdrawal, hyperthyroidism
Ophthalmoplegia	Wernicke's encephalopathy, brain stem dysfunction, dystonic reaction
Papilledema	Increased intracranial pressure
Hypertonia, rigidity, catatonia, parkinsonism	EPS, NMS
Abnormal movements	Parkinson's disease, Huntington's disease, EPS
Abnormal gait	Normal pressure hydrocephalus, Parkinson's disease, Wernicke's encephalopathy
Loss of position and vibratory sense	Vitamin B <sub>12</sub> deficiency

*Note.* EPS = extrapyramidal side effects; NMS = neuroleptic malignant syndrome.

always available and should be reviewed along with any other laboratory, imaging, and electrophysiological tests. The consultant then considers what additional tests are needed to arrive at a diagnosis. Attempts have been made in the past to correlate biological tests, such as the dexamethasone suppression test, with psychiatric illness; despite extensive research, however, no definitive biological tests are available to identify psychiatric disorders. Before ordering a test, the consultant must consider the likelihood that the test will contribute to making a diagnosis.

There is an extensive list of studies that could be relevant to psychiatric presentations; the most common screening tests in clinical practice are listed in Table 1–6. It was once common practice for the psychiatrist to order routine batteries of tests, especially in cognitively impaired patients, in a stereotypical diagnostic approach to the evaluation of dementia or delirium. In modern practice, tests should be ordered selectively, with consider-

**TABLE 1–6. Common tests in psychiatric consultation**

Complete blood cell count
Serum chemistry panel
Thyroid-stimulating hormone (thyrotropin) concentration
Vitamin B <sub>12</sub> (cyanocobalamin) concentration
Folic acid (folate) concentration
Human chorionic gonadotropin (pregnancy) test
Toxicology
Serum
Urine
Serological tests for syphilis
HIV tests
Urinalysis
Chest X ray
Electrocardiogram

ation paid to sensitivity, specificity, and cost-effectiveness. Perhaps most importantly, careful thought should be given to whether the results of each test will affect the patient's management. Finally, further studies may be beneficial in certain clinical situations as described throughout this book.

### ***Routine Tests***

As far as screening is concerned, a complete blood cell count may reveal anemia that contributes to depression or infection that causes psychosis. Leukocytosis is seen with infection and other acute inflammatory conditions, lithium therapy, and neuroleptic malignant syndrome, whereas leukopenia and agranulocytosis may be caused by certain psychotropic medications. A serum chemistry panel may point to diagnoses as varied as liver disease, eating disorders, renal disease, malnutrition, and hypoglycemia—all of which may have psychiatric manifestations (Alpay and Park 2004). Serum and urine toxicological screens are helpful in cases of altered sensorium and obviously whenever substance abuse, intoxication, or overdose is suspected. Because blood tests for syphilis, thyroid disease, and deficiencies of vitamin B<sub>12</sub> and folic acid (conditions that are curable) are readily available, they warrant a low threshold for their use. In patients with a history of exposures, HIV infection should not be overlooked. Obtaining a pregnancy test is often wise in women of childbearing age to inform diagnostically as well as to guide treatment options. Urinalysis, chest radiography, and electrocardiography are particularly important screening tools in the geriatric population. Although it is not a first-line test, cerebrospinal fluid analysis should be considered in cases of mental status changes associated with fever, leukocytosis, meningismus, or unknown etiology. Increased intracranial pressure should be ruled out before a lumbar puncture is performed, however. More detailed discussion of specific tests is provided in relevant chapters throughout this text.

### ***Neuroimaging***

The psychiatric consultant must also be familiar with neuroimaging studies. Neuroimaging may aid in fleshing out the differential diagnosis of neuropsychiatric conditions, although it rarely establishes the diagnosis by itself (Dougherty and Rauch 2004). In most situations, magnetic resonance imaging (MRI) is preferred over computed tomography (CT). MRI provides greater resolution of subcortical structures (e.g., basal ganglia, amygdala, and other limbic structures) of particular interest to psychiatrists. It is also superior for detection of abnormalities of the brain stem and posterior fossa. Fur-

thermore, MRI is better able to distinguish between gray-matter and white-matter lesions. CT is most useful in cases of suspected acute intracranial hemorrhage (having occurred within the past 72 hours) and when MRI is contraindicated (in patients with metallic implants). Dougherty and Rauch (2004) suggest that the following conditions and situations merit consideration of neuroimaging: new-onset psychosis, new-onset dementia, delirium of unknown cause, prior to an initial course of electroconvulsive therapy, and an acute mental status change with an abnormal neurological examination in a patient with either a history of head trauma or an age of 50 years or older. Regardless of the modality, the consultant should read the radiologist's report, because other physicians tend to dismiss all but acute focal findings or changes and as a result misleadingly record the results of the study as normal in the chart. Psychiatrists recognize, however, that even small abnormalities (e.g., periventricular white-matter changes) or chronic changes (e.g., cortical atrophy) have diagnostic and therapeutic implications (see Chapter 7, "Dementia," Chapter 9, "Depression," and Chapter 32, "Neurology and Neurosurgery").

### ***Electrophysiological Tests***

The electroencephalogram (EEG) is the most widely available test that can assess brain activity. The EEG is most often indicated in patients with paroxysmal or other symptoms suggestive of a seizure disorder, especially complex partial seizures, or pseudoseizures (see Chapter 32, "Neurology and Neurosurgery"). An EEG may also be helpful in distinguishing between neurological and psychiatric etiologies for a mute, uncommunicative patient. An EEG may be helpful in documenting the presence of generalized slowing in a delirious patient, but it rarely indicates a specific etiology of delirium and it is not indicated in every delirious patient. However, when the diagnosis of delirium is uncertain, electroencephalographic evidence of dysrhythmia may prove useful. For example, when the primary treatment team insists that a patient should be transferred to a psychiatric inpatient service because of a mistaken belief that the symptoms of delirium represent schizophrenia or depression, an EEG may provide concrete data to support the correct diagnosis. EEGs may also facilitate the evaluation of rapidly progressive dementia or profound coma; but because findings are neither sensitive nor specific, they are not often helpful in the evaluation of space-occupying lesions, cerebral infarctions, or head injury (Bostwick and Philbrick 2002). Continuous electroencephalographic recordings with video monitoring or ambulatory electroencephalographic monitoring may be necessary in order to document ab-

normal electrical activity in cases of complex partial seizures or when factitious seizures are suspected. As with neuroimaging reports, the psychiatric consultant must read the electroencephalographic report, because non-psychiatrists often misinterpret the absence of dramatic focal abnormalities (e.g., spikes) as indicative of normality, even though psychiatrically significant brain dysfunction may manifest as focal or generalized slowing or as sharp waves. Other electrophysiological tests may be helpful in specific situations; for example, sensory evoked potentials to distinguish multiple sclerosis from conversion disorder, or electromyography with nerve conduction velocities to differentiate neuropathy from malingering.

### *Other Tests*

Other diagnostic tools may also prove useful as adjuncts. Neuropsychological testing may be helpful in diagnosis, prognosis, and treatment planning in patients with neuropsychiatric disorders. Psychological testing can help the consultant better understand a patient's emotional functioning and personality style. For example, elevations on the Hypochondriasis and Hysteria scales of the Minnesota Multiphasic Personality Inventory and a normal or minimally elevated result on the Depression scale constitute the so-called conversion V or psychosomatic V pattern, classically regarded as indicative of a significant psychological contribution to the etiology of somatic symptoms but now recognized as confounded by medical illness. (See Chapter 2, "Neuropsychological and Psychological Evaluation," for a full description of neuropsychological and psychological testing.)

The amobarbital interview has been used as a tool in the diagnosis and treatment of a variety of psychiatric conditions (e.g., conversion disorder, posttraumatic stress disorder, factitious disorder, psychogenic amnesia, neurosis, and catatonia) for the past 70 years (Kavarirajan 1999). The psychiatric literature has been mixed, however, on the utility of the amobarbital interview, and intravenous lorazepam is now generally regarded as a safer alternative. However, the diagnostic validity of amobarbital and lorazepam interviews has not been systematically assessed.

### Write a Note

The consultation note should be clear, concise, and free of jargon and should focus on specific diagnostic and therapeutic recommendations. Although an understanding of the patient's psychodynamics may be helpful, the consultant should usually avoid speculations in the chart regarding unconscious motivations. Consultees fundamentally want to know what is going on with the patient and what they should and can do about it; these themes

should dominate the note. Mental health professionals are trained to construct full developmental and psychosocial formulations, but these do not belong in a consultation note (although they may inform key elements of the assessment and recommendations). Finger-pointing and criticism of the primary team or other providers should be avoided. The consultant should also avoid rigid insistence on a preferred mode of management if there is an equally suitable alternative (Kontos et al. 2003).

The consultation note should include a condensed version of all the elements of a general psychiatric note with a few additions (Querques et al. 2004). The consultant should begin the note with a summary of the patient's medical and psychiatric history, the reason for the current admission, and the reason for the consultation. Next should be a brief summary of the present medical illness with pertinent findings and hospital course; this summary is meant to demonstrate an appreciation for the current medical issues rather than to repeat what has already been documented in the chart. It is often helpful for the consultant to include a description of the patient's typical patterns of response to stress and illness, if known. Physical and neurological examinations, as well as germane laboratory results or imaging studies, should also be summarized. The consultant should then list the differential diagnosis in order of decreasing likelihood, making clear which is the working diagnosis or diagnoses. If the patient's symptoms are not likely to be due to a psychiatric disorder, this should be explicitly stated. Finally, the consultant should make recommendations or clearly describe plans in order of decreasing importance. Recommendations include ways to further elucidate the diagnosis as well as therapeutic suggestions. It is especially important to anticipate and address problems that may appear at a later time (e.g., offering a medication recommendation for treatment of agitation in a delirious patient who is currently calm). For medication recommendations, brief notation of side effects and their management is useful. The inclusion of a statement indicating that the consultant will provide follow-up will reassure the consulting team, and the consultant should include contact information in the event that they have further questions.

### Speak Directly With the Referring Clinician

The consultation ends in the same way that it began—with a conversation with the referring clinician. Personal contact is especially crucial if diagnostic or therapeutic suggestions are time sensitive. Some information or recommendations may be especially sensitive, whether for reasons of confidentiality or risk management, and are better conveyed verbally than fully documented in the chart.

The medical chart is read by a variety of individuals, including the patient at times, and, thus, discretion is warranted.

### Provide Periodic Follow-Up

Many consultations cannot be completed in a single visit. Rather, several encounters may be required before the problems identified by both the consultee and the consultant are resolved. Moreover, new issues commonly arise during the course of the consultative process, and a single consultation request often necessitates frequent visits, disciplined follow-up, and easy accessibility. All follow-up visits should be documented in the chart. Finally, it may be appropriate to sign off of a case when the patient stabilizes or when the consultant's opinion and recommendations are being disregarded (Kontos et al. 2003).

### Role of Other Providers

---

Although the emphasis of this chapter is on the psychiatrist as consultant, the value of members of other professions, working together as a team, should not be overlooked. Psychologists play an essential role in performing neuropsychological and psychological testing and providing psychotherapeutic and behavioral interventions. Psychiatric clinical nurse specialists provide services to the nursing staff that parallel those that the psychiatrist provides to the medical team. They are especially helpful in organizing interdisciplinary care conferences and nursing behavioral treatment plans that include behavioral contracts with patients. Case managers facilitate transfers and set up aftercare. Chaplains address the spiritual needs of patients in distress. Finally, communication with primary care physicians remains of utmost importance, since the primary care physician is well positioned to oversee and coordinate ongoing care after discharge.

### Screening

---

Screening tools may also be helpful in specific situations. Although a comprehensive survey of cognitive function is not required for every patient, even a slim suspicion of the possibility of a cognitive deficit should prompt performance of cognitive screening. Although individualized mental status examinations performed as part of a psychiatrist's clinical interview are much preferred to standardized tests, screening tests have been useful in case finding and research.

Tests such as the MMSE or the Mini-Cog (Borson et al. 2000) are helpful adjuncts in the hands of nonpsychiatrists to quickly identify potential cognitive disorders. The MMSE is a 19-question test that provides an overview of a patient's cognitive function at a moment in time; it includes assessment of orientation, attention, and memory. It is of limited use without modification, however, in patients who are deaf or blind, are intubated, or do not speak English. The MMSE is also particularly insensitive in measuring cognitive decline in very intelligent patients, who may appear less impaired than they really are. The Mini-Cog, on the other hand, combines a portion of the MMSE (3-minute recall) with the Clock Drawing Test, as described by Critchley in 1953 (Scanlan and Borson 2001). In screening for dementia, the MMSE and the Mini-Cog have been shown to have similar sensitivity (76%–79%) and specificity rates (88%–89%) (Borson et al. 2003). However, the Mini-Cog is significantly shorter and enables screening temporoparietal and frontal cortical areas via the Clock Drawing Test—areas that are not fully assessed by the MMSE.

In addition, these tests may be supplemented with others—including Luria maneuvers and cognitive estimations (e.g., How many slices are there in an average loaf of white bread? How long is the human spinal cord?)—that further assess the functioning of frontal-subcortical networks. A formal neuropsychological battery may be useful if these bedside tests produce abnormal results (see Chapter 2, “Neuropsychological and Psychological Evaluation”). In a patient with an altered level of awareness or attention, formal cognitive tests should be deferred until the sensorium clears, because clouding of consciousness will produce uninterpretable results.

Other screening instruments may also prove beneficial, especially in research, for identifying patients in medical settings who could benefit from a comprehensive psychiatric interview. The Primary Care Evaluation of Mental Disorders (PRIME-MD) is a two-stage evaluation tool developed for primary care physicians to screen for five of the most common psychiatric disorders seen in the primary care setting: major depression, substance use disorders, anxiety, somatoform disorders, and eating disorders (Spitzer et al. 1999). The first stage involves a patient questionnaire, and the second stage consists of a clinician-guided evaluation that takes roughly 8 minutes to administer. The PRIME-MD Patient Health Questionnaire (PHQ), an abbreviated form of the PRIME-MD, consists of a shorter three-page questionnaire that can be entirely self-administered by the patient (Spitzer et al. 1999). In addition to the assessment of mood, anxiety, eating, alcohol, and somatoform disorders (as in the original PRIME-MD), the PHQ screens for posttraumatic stress

disorder and common psychosocial stressors and also provides a pregnancy history. Although it has also been shown to be a valid screening tool, the PHQ is more efficient, given that the amount of the physician's time required to administer the tool is diminished. Both the PRIME-MD and the PHQ have improved the diagnosis of psychiatric conditions in primary care settings (Spitzer et al. 1999) and may find a role at the bedside as well.

The General Health Questionnaire is another screening instrument originally developed in the 1970s to help identify the possibility that a medical outpatient has symptoms suggestive of a psychiatric disorder (Goldberg and Blackwell 1970). The original 60-item version has been replaced with well-validated 28- and 12-item versions, and it has been translated into numerous languages worldwide and been cross-culturally validated (Tait et al. 2003). Because of its emphasis on identifying *new* symptoms, the General Health Questionnaire examines state rather than trait conditions (Tait et al. 2003).

The CAGE is a well-known screening device developed by Ewing (1984) to identify alcohol abuse. A total of two or more positive responses on the four-question screen correlates with an 89% chance of alcohol abuse (Mayfield et al. 1974) (see Chapter 18, "Substance-Related Disorders").

## Benefits of Psychiatric Services

The benefits of psychiatric services in health care delivery are significant. A growing body of evidence suggests a link between comorbid psychopathology and increased length of hospital stay and, consequently, increased inpatient costs. Levenson et al. (1990) described a longer median length of hospital stay (a 40% increase) and hospital costs that were 35% higher in a group of medical inpatients with depression, anxiety, cognitive dysfunction, or high levels of pain (independent of severity of medical illness). Cognitively impaired geriatric patients were shown to have an increased length of stay compared with those without cognitive impairment (Fulop et al. 1998), whereas depressed elderly patients in another sample had more hospitalizations and longer hospital stays (Koenig and Kuchibhatla 1998). Although some have suggested that psychiatric consultation might decrease length of stay and inpatient costs (Levitan and Kornfeld 1981; Strain et al. 1991), that is not where its primary value lies. Patients benefit from reductions in mental suffering and improvements in psychological well-being, from more accurate diagnosis, and from more appropriate treatment. Providers of health care profit from the added diagnostic and therapeutic expertise of the psychiatric consultant as well as from a better understand-

ing of health behaviors. The hospital milieu benefits from assistance with disruptive and dangerous patients and is enriched by a safer and more pleasant work environment and better risk management.

## Conclusion

Psychiatric assessment and consultation can be crucial to seriously ill medical patients. The psychosomatic medicine psychiatrist is an expert in the diagnosis and care of psychopathology in the medically ill. Psychiatric consultation affords a unique ability to offer a panoramic view of the patient, the illness, and the relationship between the two. The psychiatric consultant will be called on to help diagnose, understand, and manage a wide array of conditions; when effective, the consultant addresses the needs of both the patient and the medical-surgical team. In this manner, psychiatric consultation is essential to the provision of comprehensive care in the medical setting.

Robert L. Mapou, Ph.D.

Jack Spector, Ph.D.

Gary G. Kay, Ph.D.

**TWO SPECIALIZED AREAS** within the field of psychology specifically address the interrelationships between mental and physical health. These specialties are represented by the divisions of Health Psychology (behavioral medicine) (Division 38, <http://www.healthpsych.org>) and Clinical Neuropsychology (Division 40, <http://www.div40.org>) of the American Psychological Association (<http://www.apa.org>). Although some practitioners specialize in these areas, many general clinical psychologists make them part of their practice as well.

Clinical neuropsychology provides methods for diagnosis, assessment, and intervention of known or suspected brain dysfunction resulting from illness, trauma, or developmental abnormality (Eubanks 1997). Initially, neuropsychological assessment was most often used for diagnosis, but recently developed neuroimaging techniques have proved more efficient for detecting or localizing brain dysfunction (Mapou 1988). Nevertheless, neuropsychological assessment remains valuable in answering questions about the likely etiology in patients with symptoms suggestive of central nervous system (CNS) injury or disease that cannot be resolved by bedside mental status, physical, and neuroradiological examinations. This in-

cludes the legal arena, where neuropsychological assessment can be relied on, for example, to help distinguish between mild traumatic brain injury, posttraumatic stress disorder, and malingering. For individuals with known CNS-related impairments, neuropsychological assessment can inform prognosis and guide treatment and rehabilitation. For example, a patient who presents with significant problems remembering new information may be found to have either a lack of consolidation (i.e., the new information never gets into memory) or difficulty recalling what was learned (i.e., the information was stored in memory but cannot be retrieved efficiently), each of which requires differentiated treatment.

Finally, with repeated testing, neuropsychological evaluations can provide an objective means to monitor a patient's progress (or decline). These contributions appear to be the most significant goals of neuropsychological evaluation at present, with diagnosis more often being a secondary component (Mapou 1995). Although a full neuropsychological evaluation can be costly, use of repeated measures can be accomplished with a more limited, targeted test battery that evaluates the specific areas of interest.

---

The views and opinions expressed herein are the private views of the authors and are not to be considered as official or as reflecting the views of the U.S. Department of Defense. The authors would like to thank Su-Jong Kim for technical assistance in preparation of this chapter.

This chapter is a revision and update of a previous publication (Mapou et al. 2002).

In addition to neuropsychological evaluation, psychological assessment provides a complementary methodology for understanding a patient's emotional functioning and personality style. In some clinical situations, the use of both together is synergistically informative. For example, combined psychological and neuropsychological assessment can better detect patients who intentionally or unintentionally exaggerate their difficulties.

In this chapter, we review neuropsychological and psychological assessments in the medically ill or injured. We review the most often used neuropsychological techniques and discuss their application for differential diagnosis. An overview of psychological assessment techniques follows, with illustrations in both neurological and psychiatric disorders. We close the chapter by discussing special issues in assessment and conclude with some guidelines for selecting a neuropsychologist.

## Neuropsychological Evaluation

---

The neuropsychological evaluation represents an integration of clinical information and empirical findings from neuropsychological testing. Although the different schools of neuropsychology differ somewhat in their approaches to the evaluation of a patient who has or is suspected of having brain dysfunction, all aim to describe cognitive, motor, and affective functioning; contribute to final diagnosis; and summarize how identified difficulties affect everyday functioning.

Each of the approaches to neuropsychological evaluation has advantages and disadvantages (Table 2-1). However, all approaches have been applied to a range of medical-surgical patients (see, for example, Tarter et al. 1988), and each has value for use in the medical setting; the best choice depends on the specific clinical situation and should be individualized.

### Patient-Centered and Process-Oriented Approaches

In patient-centered, process-oriented approaches, neuropsychological assessment is organized around the referral question. Although a consistent core set of measures is typically administered, additional supplementary measures are selectively added. In addition, some of the testing procedures are modified to test the limits of cognitive and behavioral ability, and qualitative data are used to supplement actuarial test scores. The advantage of this approach is that assessment can be limited to the measures that are likely to be most effective for answering the referral question. The disadvantage is that some scores (e.g., IQ, im-

pairment index) cannot be determined with more limited sets of measures, and these scores are sometimes required by the referral source. In addition, although individual measures in patient-centered approaches have established reliability, validity, and sensitivity to brain dysfunction, these characteristics have not been evaluated when all the measures are administered together in combination as a finite battery of tests. Nonetheless, this approach is highly useful when the referring practitioner is primarily interested in understanding limitations in the patient's daily functioning and for considerations of rehabilitation. Additional information on this approach to neuropsychological evaluation can be found elsewhere (Christensen 1979; Jørgensen and Christensen 1995; E. Kaplan 1988, 1990, 1993; Lezak 1983, 1995; Luria 1973, 1980).

### Battery-Based Approaches

In contrast to a more patient-centered approach, battery-based approaches consist of always administering a group of tests that have been standardized and validated together with a well-defined standardization sample. Specific subtests are combined in different fixed batteries, with a primary shared feature among batteries being their empirically established sensitivity to brain dysfunction overall. Interpretation of results from a fixed battery is based on the level and pattern of subtest performance of the individuals in comparison with the group findings from the standardization sample.

Relative to patient-oriented, flexible-battery approaches, battery-based approaches are generally more time-consuming and limited for understanding the unique features of an individual patient. In practice, however, most clinicians use standardized test batteries in a flexible manner. Because most batteries do not provide a comprehensive assessment of cognitive function, additional measures are generally used (Heaton et al. 1991). Clinicians are also likely to use subtests selectively based on observed qualitative aspects of performance, which technically alters the battery's standardized comparison of the individual results with a group. Nonetheless, because practitioners are likely to encounter such batteries, particularly in forensic contexts, we briefly describe the most common of them, noting their strengths and limits.

#### *Halstead-Reitan Neuropsychological Test Battery*

The Halstead-Reitan Neuropsychological Test Battery (HRNTB) (Reitan and Wolfson 1985) is arguably the most frequently used neuropsychological battery in clinical practice. Since its initial development by Halstead in the 1940s, the battery has been refined and has been administered to thousands of patients with different neurologi-

**TABLE 2-1. Advantages and disadvantages of neuropsychological assessment approaches in psychosomatic medicine consultation**

Method	Advantages	Disadvantages
Patient-centered and process-oriented approaches	Comprehensive assessment Can be tailored to answer the referral question	Methods not validated together Can be time-consuming if not applied selectively
Battery-based approaches	Highly standardized and quantified Very sensitive to neurological dysfunction	Require special equipment May not answer specific referral questions Provide limited assessment of certain cognitive realms
Halstead-Reitan Neuropsychological Test Battery (Reitan and Wolfson 1985)	Large body of supporting research	Always time-consuming Difficult for bedside evaluation
Luria-Nebraska Neuropsychological Battery (Golden et al. 1985)	Relatively brief	Criticized for problems with design and validity
Mental status assessment and screening instruments (e.g., Mini-Mental State Examination [Folstein et al. 2001])	Brief, easily learned Can be done anywhere Familiar in medical settings	Not comprehensive Limited sensitivity and specificity

cal and psychiatric disorders, generating extensive normative data. The battery consists of five types of measures: “1) input measures; 2) tests of verbal abilities; 3) measures of spatial, sequential, and manipulatory abilities; 4) tests of abstraction, reasoning, logical analysis, and concept formation; and 5) output measures” (Reitan and Wolfson 1986, p. 136). Strict interpretation emphasizes the pattern and level of performance on individual measures and on computed summary indices, including a measure of overall impairment (see Reitan and Wolfson 1985).

Normative data stratified by age, education, and gender are available (Heaton et al. 1991). When strictly standardized testing procedures are necessary (e.g., in forensic settings), the HRNTB is most often recommended. However, when time is limited (the full battery requires 6–7 hours), as in inpatient medical consultation, or when more in-depth assessment of particular cognitive functions is necessary, the complete HRNTB is less useful. Many clinicians use portions of the HRNTB, to take advantage of its standardization, and supplement the selected measures with other tests and procedures as time permits. However, as indicated, when the battery is not administered in its entirety, it is more comparable to a flexible-battery approach and should be interpreted more cautiously in comparison with the standardization sample for the battery as a whole.

### *Luria-Nebraska Neuropsychological Battery*

The Luria-Nebraska Neuropsychological Battery (LNNB) (Golden et al. 1985) was developed based on procedures described by Christensen (1979), in an effort to standard-

ize the administration and interpretation of procedures associated with Luria’s (1973, 1980) functional systems approach. There are two different forms of the battery (Forms I and II), and a short screening test version has also been published (Golden 1988) to determine whether or not the full battery should be completed. The LNNB has been administered to patients with different neurological and psychiatric disorders, and data from these groups have been compared with those from control subjects (Golden and Maruish 1986). The LNNB is as sensitive to the presence of brain dysfunction as the HRNTB (Kane et al. 1985), but it samples a wider range of cognitive skills and requires considerably less administration time.

A variety of concerns have been raised about the statistical characteristics of the LNNB (Adams 1980, 1984; Stambrook 1983) and the content validity of its clinical scales (Delis and Kaplan 1983; Klein 1993; Spiers 1984). Although the LNNB has utility as an instrument for determining likely cognitive dysfunction, it is limited as an in-depth measure of specific cognitive and motor functions. Because of these difficulties, the LNNB must be used with caution and should always be supplemented with other measures. However, this again changes the standardized nature of the battery as a single entity.

### Bedside Screening and Extended Cognitive Examinations

The mental status examination has a long history in psychiatry and neurology and should always be included in a

standard psychiatric or neurological examination (see also Chapter 1, "Psychiatric Assessment and Consultation"). Physicians perform cognitive screening to determine whether cognitive impairment is present and to develop initial hypotheses about diagnosis. Hodges (1994) outlined an approach to cognitive screening and summarized available measures. Mental status tests run the gamut from informal and idiosyncratic measures of cognitive and motor function, to the brief but standardized Mini-Mental State Examination (MMSE) (Folstein et al. 1975, 2001), to more comprehensive screening tests such as the Dementia Rating Scale (Mattis 1988) and the Neurobehavioral Cognitive Status Examination (Schwamm et al. 1987), now known as COGNISTAT (Northern California Neurobehavioral Group 1995). All such screening measures require little time for administration (5–45 minutes), do not require the use of specialized equipment (although some measures use stimuli presented on printed cards), and are easily administered in the clinic or at the bedside. Therefore, in contrast to more extensive neuropsychological testing, extended cognitive mental status examinations have the advantages of brevity and flexibility of administration.

Most mental status examinations assess the following areas of function: orientation, simple attention, short-term memory, comprehension, repetition, naming, construction, and abstraction skills. Within each area, however, the assessment is necessarily brief. Thus, what is gained in time and flexibility is lost in sensitivity and specificity. Although brief examinations, such as the MMSE, can detect gross changes in cognitive function and provide a baseline for follow-up assessment, they are likely to miss subtle cognitive deficits (Stokes et al. 1991). A. Nelson et al. (1986) reviewed five frequently used bedside screening examinations: the MMSE, Dementia Rating Scale, Cognitive Capacity Screening Examination (Jacobs et al. 1977), Mental Status Questionnaire (Montgomery and Costa 1983), and Short Portable Mental Status Questionnaire (Omer et al. 1983). The researchers found all the tests to be useful in diagnosing dementia and delirium but expressed concern that these measures were likely to miss subtle cognitive deficits.

A new measure, the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) (Randolph 1998), was designed to address shortcomings of past measures but retain brevity of testing time. This measure has 12 subtests that evaluate immediate memory, visuospatial and constructional skills, attention, language, and delayed memory. It takes 30 minutes to administer; has two parallel forms specifically designed to permit repeated testing, with an emphasis on detection of dementia; and has normative data for individuals ages 20–89 years. The RBANS

has shown reasonable sensitivity and specificity for identifying neurological dysfunction and the nature of the dysfunction in different cognitive domains (Randolph 1998).

Bedside screening and extended mental status examinations are often important for initial evaluation but may be inadequate for a full assessment of a complex medical/psychiatric case. An examination that is too brief and too restricted in scope will assess a limited range of functions and is unlikely to be sensitive to subtle deficits. However, a full neuropsychological evaluation that provides more specific data is likely to be lengthy (a problem in the inpatient setting) and more difficult (a problem for patients with limited cognitive or physical abilities). Therefore, the specific purpose of the evaluation should guide the choice of assessment procedures. A careful cognitive screening examination clarifies whether there is a need for more detailed, formal neuropsychological evaluation.

## Applications in Psychosomatic Medicine

In medical settings, neuropsychologists are most frequently consulted to help with differential diagnosis or prognosis of neuropsychiatric disorders and to guide treatment and rehabilitation. Table 2–2 provides examples of typical outcomes that may be gained from neuropsychological evaluation, depending on the referral question. It should be emphasized that no individual neuropsychological test score can be considered pathognomonic for determining or localizing CNS disruption. Nevertheless, individual tests can be informative. For example, a patient with mild hypoactive delirium due to hepatic encephalopathy who completes a basic visuomotor tracking task (e.g., Part A of the Trail Making Test) in the expected amount of time but completes the complex visuomotor tracking task (e.g., Part B of the Trail Making Test) in twice the normal expected time provides objective evidence of slowed processing that is not likely to be solely related to nonspecific illness-related fatigue. In the following sections, case examples are presented to describe some common applications of neuropsychological evaluation.

### *Dementia*

In patients suspected of having dementing conditions, neuropsychological assessment is most valuable in the very earliest stages, during which bedside examination and neuroradiological findings are often equivocal (see also Chapter 7, "Dementia"). Neuropsychological evaluation can also help differentiate degenerative dementias from static and metabolic cognitive disorders, and cortical from subcortical dementias. Cortical dementias, such as Alzheimer's disease, are characterized by memory deficits, language dysfunction or visuospatial impairment, execu-

**TABLE 2-2. Applications of neuropsychological assessment**

- Differential diagnosis of degenerative and static neurological conditions contributing to cognitive and behavioral dysfunction
- Differentiation of symptoms due to neurological conditions versus psychiatric disorders
- Selection of candidates for surgery for intractable epilepsy
- Documentation of sequelae of acute brain insults and application to prognosis and treatment
- Assessment of neurocognitive function in patients with cardiac, pulmonary, hepatic, or renal insufficiency
- Assessment of benefits and adverse effects of new treatments
- Evaluation for a specific learning disability or attention-deficit/hyperactivity disorder
- Assessment of ability of an impaired individual to return to work or school or to perform independent living skills
- Assessment of competence to make medical, legal, or financial decisions
- Longitudinal evaluation to assess level of functioning and treatment responsiveness

tive function deficits, and diminished self-awareness, typically observed in the context of normal psychomotor abilities and near-normal attention (Cummings 1985). In contrast, subcortical dementias, such as those associated with Parkinson's disease, are marked by psychomotor retardation, attentional impairment, and emotional lability, typically in the context of intact language and visuospatial skills and recognition memory (Cummings 1985, 1990) (see Chapter 7, "Dementia"). Repeated neuropsychological evaluation can also be useful for periodic objective assessment of the nature of the deficits and evaluation of competence and response to treatment.

### Case Example 1

Ms. A, a 77-year-old widow of 20 years with a 2-year history of memory problems and depression, was referred by her physician for neuropsychological evaluation to help determine the nature of her memory difficulties. She acknowledged feeling lonely and had experienced some loss of interest in her usual activities, although she continued to play bridge on a monthly basis with old friends. Ms. A lived independently and had experienced a fall the preceding month associated with slippery conditions during her daily walk. She did not seek medical attention, and her adult son initiated contact with her physician after his mother informed him of her fall. Her son reported that she seemed to have some difficulties with short-term memory and frequently repeated things she had already told him. He also reported that she continued to play a very strong game of bridge, which he also enjoyed.

Initial screening conducted by the referring physician revealed an MMSE score of 25, with difficulty reporting the day of the week and the specific date of the month and failure to recall three words. She acknowledged that she was not as sharp as she used to be and that she did not remember things as well. She also had started to let her household finances lapse, forgetting to pay bills on time. A computed tomographic scan of the head showed "mild age-related cortical atrophy." Ms. A's medical history included hypercholesterolemia and hypertension controlled with medication. Her additional medical history was believed to be noncontributory.

Results of the initial evaluation indicated some problems with depression (Geriatric Depression Scale score of 18). The primary care physician prescribed fluoxetine and referred her for neuropsychological assessment. At the time of the evaluation 1 month later, Ms. A felt that her mood had improved, although she still felt lonely. Her Geriatric Depression Scale score at the time of the evaluation was 5. Results from the neuropsychological evaluation indicated that she was a highly intelligent woman with very strong verbally based communication skills. However, test results also showed severe memory encoding and retrieval problems, inability to perform simple mathematical calculations, problems copying a complex figure, impaired simple object naming, and weaknesses in simple auditory attention. On the basis of the findings from the evaluation, Ms. A was given a tentative diagnosis of dementia (probable Alzheimer's disease) and was prescribed donepezil. Follow-up evaluation 1 year later showed continued decline in short-term memory and memory retrieval, but notable improvement in simple auditory attention as well as stability of the remaining affected domains, suggesting that donepezil had been beneficial.

Although it is generally rare, a specific amnesic disorder can occur as a result of several different neuropathological processes (see Chapter 32, "Neurology and Neurosurgery"). Neuropsychological assessment can help differentiate amnesic disorders from degenerative dementias, providing reassurance to patients and families, and informing treatment decisions (e.g., whether to prescribe a cholinesterase inhibitor for the patient). Amnesic difficulties following neurosurgery (e.g., for intractable epilepsy) have been lessened substantially through preoperative neuropsychological assessment (Kapur and Pravett 2003). In other instances, neuropsychological testing can contribute to decision making regarding whether invasive preoperative assessment procedures would be useful in relation to the risks and benefits expected for surgical intervention (M.D. Holmes et al. 2003).

### *Cerebrovascular Accident*

Neuropsychological evaluation has been described as an essential component of the treatment planning process for many survivors of cerebrovascular accident (CVA)

(Tupper 1991) (see also Chapter 32, “Neurology and Neurosurgery”). Patients with severe dominant-hemisphere lesions will often be served best through consultation with speech pathologists, particularly during the initial phases of recovery. When language is not severely disrupted (or after improvement in language-impaired patients), a comprehensive neuropsychological evaluation can identify subtle deficits in memory, attention, or judgment (Brown et al. 1996; Lishman 1998). Disruption of any of these cognitive domains has implications for continued functional recovery and for rehabilitation. This may be particularly relevant when the patient also has psychiatric sequelae, such as depression or personality change. Patients with right parietal or frontal lobe CVA may not acknowledge their deficits or even notice obvious motor or sensory disabilities (neglect and denial syndromes) (McGlynn and Schacter 1989). They often want to drive or return to work, unaware of potential risk to themselves or others. Neuropsychological assessment can objectively document such deficits, and the results of such an assessment can aid interventions by primary clinicians and families (e.g., taking away driving privileges).

Like most acute neurological disorders, CVA syndromes can change rapidly in the weeks immediately following occurrence (Meier and Strauman 1991). Therefore, during acute recovery, a relatively brief cognitive evaluation should be administered periodically to annotate changes associated with resolution of nonspecific inflammation and injury effects (DeGraba 1998). Residual difficulties, including neuropsychiatric sequelae, are more likely to become apparent after the patient is medically stabilized. At this point, referral for neuropsychological evaluation may be useful to help differentiate psychological reactions to the stroke from more CNS-based causes of cognitive, behavioral, and affective symptoms.

### Case Example 2

Ms. B—a 45-year-old previously successful independent Web site designer—experienced a subarachnoid hemorrhage due to rupture of an anterior communicating artery aneurysm. She was referred for a neuropsychological evaluation 6 months after hospital discharge because of her husband’s concerns regarding her changed personality and problems with memory. Specifically, since her CVA she was doggedly insistent on rehashing problems with members of her extended family that the couple had resolved years earlier. When her husband returned from work each night, she would begin talking to him as soon as the door opened with complaints of past family interferences and emphatic vehemence that none of their family members were going to be allowed to visit over the summer. She also became despondent nightly, worrying that she would have a second aneurysm and not survive.

The purpose of neuropsychological evaluation was to better characterize Ms. B’s deficits and abilities and to shed light on the cause of her difficulties (brain injury vs. emotional adjustment vs. preexisting limitations). Results of the evaluation indicated that she was at least of average general intellectual ability, based on a composite measure from the Wechsler Adult Intelligence Scale—3rd Edition (WAIS-III; Wechsler 1997). However, marked variability among the subtest scores included below-average retrieval of old knowledge, well-above-average vocabulary, above-average abstract reasoning, and low-average ability on some of the visual tasks. Additional findings on tests of memory included impaired encoding for learning unstructured (word list) material and deficient retrieval in a more highly structured task (paragraph memory). Ms. B also “remembered” incorrect information on the paragraph recall task that never was a part of the initial information (confabulation). On other tasks, Ms. B demonstrated marked repetition of responses, whether the response was correct or incorrect (perseveration). The results of the evaluation indicated that she was experiencing cognitive dysfunction attributable to the subarachnoid hemorrhage. She and her husband were informed of the findings and the relation to the behaviors she was exhibiting at home. Although she did not freely recall this explanation on a daily basis, when reminded by her husband of the results from the evaluation, she was able to remember the gist of the feedback and could then alter her behavior, redirecting her attention to less aggravating topics.

### *Traumatic Brain Injury*

Neuropsychological evaluation is generally of limited use in moderate to severe traumatic brain injury (TBI) during the acute postinjury period because most patients are still experiencing acute posttraumatic confusion and altered consciousness (see also Chapter 35, “Physical Medicine and Rehabilitation”). The duration of impaired consciousness and the rate of improvement in cognitive functions are both predictive of cognitive function outcome after rehabilitation (Zafonte et al. 1997). The Galveston Orientation and Amnesia Test (Levin et al. 1979) is a 100-point, 16-item questionnaire that evaluates orientation and memory for events occurring before and after moderate to severe injuries. This brief measure is particularly useful because it can be administered in a very short time and can be given repeatedly, even multiple times within the same day if there is a rapid change in the patient’s status. If the patient achieves a stable score of at least 75 of the 100 points, it is appropriate to administer a neuropsychological evaluation to assess the presence, extent, and impact of brain injury-related difficulties. Most moderate to severe closed-head injuries produce deficits in attention, memory, and executive skills (Brooks 1984; Levin et al. 1982, 1987). Judgment and reasoning may also be impaired and can affect willingness to participate in treatment. Although sub-

tle naming and perceptual deficits can be identified, more severe impairment in these areas is rare in the absence of focal damage to the relevant areas.

Preexisting learning disabilities, attention-deficit/hyperactivity disorder (ADHD), substance abuse, and prior head injuries are frequent in TBI; their contributions to the patient's postinjury status must always be carefully considered (Dikmen and Levin 1993), and careful assessment of the patient's emotional status and personality structure before and after injury is essential for evaluation of functional deficit and prediction of outcome (Prigatano 1991; Prigatano et al. 1986) (see also Chapter 35, "Physical Medicine and Rehabilitation").

### Case Example 3

Ms. C, a 20-year-old client at a TBI day treatment program, was referred for neuropsychological evaluation to assist with treatment and college planning. Specifically, the referral requested an evaluation to determine her residual cognitive strengths and weaknesses and the likelihood that she would be able to pursue further education, either with or without accommodations. Ms. C had experienced a severe TBI 1 year earlier, with coma for about 11 weeks. She described some improvement in memory over the 6 months after the injury, but she still had 6-month retrograde amnesia for events preceding the date of injury. Ms. C had been forced to switch from her dominant left to her nondominant right hand because of tremor and ataxia. During testing, she expressed frustration with her rehabilitation, complaining that not enough was being done to help her left hand. She indicated that she preferred to focus on physical rather than on cognitive or functional issues. However, she did report word-finding difficulties, distractibility, and problems with vision when reading.

Ms. C's estimated verbal IQ was in the low-average range, whereas her estimated performance IQ was moderately impaired, judged to be a decline from estimated preinjury functioning in the average range. Impairments were evident in attention, marked by very low processing speed and susceptibility to interference. Difficulties in executive functioning were marked by poor planning and impulsivity, weak organizational skills when learning new information, and deficits in visually based reasoning. Learning and memory were best for organized verbal information and were far poorer for a word list and complex visual design. Naming, timed word retrieval, and visuospatial constructional skills were impaired. Access to school-based knowledge, span for verbal information, and mental manipulation skills were relatively spared, and strength was evident in flexibility of thinking and use of feedback. A comprehensive academic evaluation, accommodations in college, a light class load, and tutoring were recommended. A neuro-ophthalmological evaluation, to determine the cause of her complaints of visual problems that also were revealed by testing, was recommended as well. On the basis of the reported findings, Ms. C was able to obtain accommoda-

tions in school and continue her academic pursuits, albeit at a slower rate. She also continued to improve cognitively and successfully completed classes at the local community college.

### *Depression Versus Dementia*

Knowledgeable older patients who note difficulties with attention, memory, and word finding may worry that they are in the early stages of dementia (see also Chapter 7, "Dementia," and Chapter 9, "Depression"). In addition to early dementia, the differential diagnosis includes normal age-related memory decline, depression, medication side effects, and metabolic derangements.

Major depression is often accompanied by impairment in attention and in the ability to actively encode information, with associated reduction in learning and memory (Burt et al. 1995; Cassens et al. 1990; Sweeney et al. 1989; Veiel 1997). Psychomotor slowing and reductions in performance IQ (nonverbal intelligence) and in visuospatial skills may be observed. In contrast, focal language deficits are unlikely in depressed patients, and difficulties with memory from depression tend to reflect inadequate encoding rather than the forgetting that is more typical of dementia. In fact, despite the frequency of word-finding complaints, formal tests of naming often help differentiate depression from dementia; naming deficits are much less common in depressed individuals (Hill et al. 1992). However, recent studies have demonstrated that it is not uncommon for depression to be the first manifestation of Alzheimer's disease or another dementia. Although some depressed individuals show no cognitive deficits on formal testing, others manifest a neuropsychological pattern similar to that associated with subcortical dementia (Massman et al. 1992). In the latter case, in elderly patients in whom there is no other explanation for subcortical dementia (e.g., Parkinson's disease, acquired immune deficiency syndrome), recent studies have suggested a vascular etiology for both the depressive and the cognitive symptoms, correlated with subcortical lesions that are seen on magnetic resonance imaging (see Chapter 7, "Dementia").

### Case Example 4

Ms. D, a 65-year-old woman, was referred by her psychotherapist because of a 20-year history of forgetfulness. Previous evaluations, including a recent magnetic resonance imaging (MRI) scan, had revealed no evidence of dementia despite the fact that Ms. D believed her problems were worsening. Ms. D had a history of diabetes mellitus, hypothyroidism, migraine, and hypertension (all controlled with medication) and a lifelong history of depression, for which she had received antidepressants and psychotherapy without a lasting remis-

sion. She commented that each time her memory problems worsened, she became more depressed.

Ms. D's skills on neuropsychological testing were largely in the superior range and were consistent with expectations based on her background. Although she had some problems retrieving learned information on measures of learning and memory, she retained information without difficulty over a delay. There was some evidence of weakness in attention and overall cognitive efficiency. Sometimes, when she perceived a task as difficult, she became frustrated and continued to ruminate into the next task, even when her performance was fine. Ms. D later acknowledged that she often "beat up" herself when she had cognitive difficulty. Psychological testing indicated a coping style in which Ms. D appeared more comfortable with a physical explanation for her difficulties. It was concluded that Ms. D did not have dementia. Her depression, and perhaps personality style, appeared to account for her cognitive inefficiency. Her other medical conditions were well controlled and were unlikely to be contributing. Expectations of cognitive failure occupied her thoughts and became a self-fulfilling prophecy. It was believed that if she were able to focus her thoughts on her cognitive successes rather than her failures, it was likely that her everyday skills could improve. Cognitive-behavioral psychotherapy and compensatory strategies designed to improve her attention and memory skills were recommended.

## Psychological Assessment

---

A psychological evaluation represents a comprehensive integration of psychological assessment results (objective and projective test results, behavioral observations, and a patient's self-report) with professional knowledge and expertise for the purpose of identifying a patient's emotional status, personality structure, psychological symptoms, and motivational state. Psychological assessment can supplement the standard clinical interview both because clinicians tend to miss what they do not anticipate and because some states and traits may be hard to confirm through interviewing even when they are suspected (e.g., malingering, occult psychosis). Psychological assessment typically involves combining information obtained through psychological tests, interviews, and other clinical evaluations. A wide range of tests and approaches to testing are available, and most instruments have established standardization, reliability, and validity (Anastasi and Urbina 1997).

In medical settings, psychological evaluation can help clarify differential diagnosis; assess a patient's resistance to specific treatment approaches; evaluate the role of psychological factors in a patient's medical condition; determine the need for psychosocial interventions (e.g., stress management in anxious individuals before a medical pro-

cedure); and predict outcomes of surgical, medical, or psychiatric treatments. In addition, psychological assessment is a requisite portion of any neuropsychological evaluation.

## Objective Personality Measures

In this section, we discuss the most frequently used clinical instruments having well-established reliability and validity. These personality instruments are self-report measures, in which the patient responds to a series of statements or questions relating to attitudes, beliefs, symptoms, and experiences and for which the scoring of the individual's response is based solely on an objective format in which all raters would agree (e.g., Likert scale items in which a response of "1" has the same meaning to all raters). On some tests, patients simply agree or disagree with target statements; on other tests, they report a degree of endorsement on a scale. Typically, the patient's responses are aggregated, scaled, and compared with data from normative groups.

There are some general cautions when using self-report instruments with medically ill patients. Instruments that are reliable and valid for identification of psychopathology in psychiatric patients may be inappropriate for use with medical patients, among other reasons because somatic items on these instruments will be endorsed by medical patients on the basis of symptoms of their illness. Because psychological evaluation represents an integration of multiple sources of information, idiographic features of the individual patient also must be considered in relation to standardized psychological assessment results. In the following sections, we discuss the use of specific psychological assessment instruments in medical settings, with the caveat that specific features of the individual patient may alter the interpretation of even these well-standardized and highly reliable measures.

### *Minnesota Multiphasic Personality Inventory*

The Minnesota Multiphasic Personality Inventory (MMPI), developed by Hathaway and McKinley (1967) in the early 1940s, is the most widely used and researched objective personality measure. It has demonstrated sensitivity to many psychiatric disorders. The MMPI was restandardized (MMPI-2) (Butcher et al. 1989), and debate continues regarding the comparability of the two forms (see Helmes and Reddon 1993). The MMPI-2 consists of 567 true-false items. It yields scores on 3 major validity indices and 10 major clinical scales. In addition to these scales, many specific content scales are sensitive to health concerns, neurological disorders, affective symptoms,

thought disturbance, and ego strength, among other factors. Other scales also permit assessment of response bias and potential symptom embellishment. Test results are interpreted relative to census-based normative data. Additional information is learned by reviewing a patient's responses to critical items. A vast body of literature exists on the interpretation of MMPI results in mental health settings, and a similar research literature is developing for the updated MMPI-2. For the purposes of this chapter, unless specifically indicated, we use MMPI to refer to the general test, without differentiating the original form of the test from the more recent update.

Despite the significant empirical basis of the MMPI, it may be inappropriate to apply these interpretations to general medical patients, given the sensitivity of the MMPI to the "normal" experiences and symptoms of patients with well-defined medical conditions (Cripe 1989). Pincus and Callahan (1993), for example, studied the MMPI in patients with rheumatoid arthritis. The researchers asked rheumatologists to identify the test items that were expected to differ between patients with rheumatoid arthritis and matched individuals without arthritis, based on rheumatoid arthritis symptoms and not psychological state. The researchers also compared MMPI results from rheumatoid arthritis patients with those from control subjects without medical or psychiatric illness. Using these criteria, the authors identified five items from the original MMPI that were clearly related to rheumatoid arthritis. These items appeared to account for the higher scores of rheumatoid arthritis patients on scales 1 (Hypochondriasis), 2 (Depression), and 3 (Hysteria).

Other MMPI items are frequently endorsed by patients with neuropsychiatric disorders. Specifically, patients with seizure disorders, TBI, and CVA often have clinically elevated scores on scales that were primarily designed to measure somatic preoccupation (scale 1, Hypochondriasis), conversion (scale 3, Hysteria), depression (scale 2, Depression), and thought disorder (scale 8, Schizophrenia, Sc) (Alfano et al. 1992; Bornstein and Kozora 1990; Gass and Russell 1986; Wooten 1983). For this reason, Alfano and colleagues (1992) and Gass and Russell (1986) recommended computing "neurocorrected" scores on these scales by eliminating specific items when determining the total scale score, to separate the effects of neurological disorder. The resulting MMPI profile would then presumably reflect only the "pure" psychiatric symptoms experienced by the patient. A competing view, however, is that a neuropsychiatric patient's report of atypical experiences is due to the actual cognitive deficits, affective reactions, and personality changes associated with these disorders. Therefore, increased scores on scales that assess these symptoms may accurately reflect a patient's experience of his or her

disorder, but results for patients with neuropsychiatric disorders still should be interpreted differently from results from psychiatric patients (Mack 1979).

In general, because somatic items are prevalent in MMPI scales used to identify depression, conversion, somatization, and somatoform disorders, scores on these scales often may be increased among medically ill patients. For example, Mayo Clinic data on the MMPI for general medical outpatients showed that 32.4% of females and 24.5% of males had significantly increased scores on scale 1 (Hypochondriasis) and scale 3 (Hysteria) compared with the original MMPI normative data (Osborne et al. 1983). In a parallel study, new MMPI normative data were collected. These data were considered more comparable to MMPI-2 normative data than the original MMPI data (Colligan et al. 1983). Investigators who used these normative data found that 37.8% of females and 30.6% of males in a general medical outpatient sample had elevated scores on the same two scales (Osborne et al. 1983). Some of these elevations may be explained by the increased prevalence of psychiatric disorders in medical inpatients and outpatients, but it is clear that caution is still warranted when interpreting MMPI scores of medical patients on these somatically loaded scales.

Finally, an elevation in scores on scales 1 (Hypochondriasis) and 3 (Hysteria), with a significantly lower score on scale 2 (Depression), is often referred to as the classic "conversion V" configuration. In psychiatric patients, this pattern is interpreted as showing that the "client is using somatic symptoms to avoid thinking about or dealing with psychological problems...[and is] converting personally distressing troubles into more rational or socially acceptable problems" (Greene 1991, p. 148). Patients with this profile are described as lacking insight, being very resistant to psychological interpretations of their problems, and presenting bizarre somatic complaints. However, these interpretations may not apply to medical patients, whose scores on these scales may be elevated to a level approximately equivalent to that among patients with conversion disorders (Fricke 1956; Lair and Trapp 1962). As noted, studies have shown significant overlap between symptoms of physical diseases (e.g., multiple sclerosis, pulmonary disease) and MMPI items that lead to clinically significant increases in scale scores (Labott et al. 1996; Meyerink et al. 1988; Mueller and Girace 1988). Even in the absence of a medical explanation for the symptoms, the presence of a conversion V does not itself prove diagnosis of a somatoform disorder. Furthermore, in some patients "unexplained" somatic complaints cannot be clearly attributed to medical or psychiatric causes and are best regarded as functional disorders. Thus, the presence of a conversion V in patients with physical symp-

toms in medical settings should not be interpreted as indicating a conversion disorder without careful consideration of and integration with the patient's history, physical examination, review of specific MMPI items endorsed, and any other diagnostic tests.

In summary, the MMPI-2 and its predecessor are powerful tools, but they must be interpreted in light of the patient's medical condition and other information, particularly if positive test results occur in the absence of other findings of psychiatric illness. When included as one component of a comprehensive psychological assessment, MMPI results can help the clinician understand medical patients' experience of their disorder. In the past the MMPI was used to help predict outcome and identify treatment modalities for some specific medical conditions (e.g., headache [Kudrow and Sutkers 1979] and impotence [Beutler et al. 1975]) and for some surgical procedures (e.g., candidates for cardiac surgery [Henrichs and Waters 1972] or laminectomy [Long 1981] and patients with intractable seizures who are candidates for surgery [Dodrill et al. 1986]). However, because of the frequent misuse of MMPI results in patients with medical conditions, others have cautioned about use of the MMPI in evaluation of medical patients when psychiatric disorder is not present (Green 1982).

### ***Millon Clinical Multiaxial Inventory***

The Millon Clinical Multiaxial Inventory–II (MCMI-II) (Goncalves and Woodward 1994; Groth-Marnat 1997; Millon 1987) addresses psychopathology according to DSM-III-R diagnostic categories (American Psychiatric Association 1987). The MCMI-III (Davis et al. 1999; Groth-Marnat 1997; Millon 1994) is an updated version using DSM-IV categories (American Psychiatric Association 1994, 2000). The MCMI-III consists of 175 true–false questions about basic personality patterns, severe personality disorders, and clinical syndromes. The test is scored by computer; specific normative data, such as the distribution of scores on specific scales, are treated as proprietary and generally are not available to the user. Thus, it is difficult to evaluate individual differences in factors associated with a specific patient that might contribute to elevations for reasons other than the test's expressed purpose.

The MCMI-III generates a narrative report and a score profile. The test is designed for use in mental health settings and assumes that the examinee is seeking assistance. The explicit purpose of the MCMI-III is to determine personality and characterological contributions to behavioral difficulties in individuals with confirmed Axis I psychopathology. As of January 7, 2004, 14 studies of any MCMI were identified through a MEDLINE search as

having direct reference to medical populations. However, for most of these studies, the profiles of the target medical samples were established on the basis of the existing MCMI standardization sample rather than by comparing performance of the research study samples with that of a nonpsychiatric sample. Therefore, published findings of studies evaluating MCMI/MCMI-II/MCMI-III profiles and score elevations in medical and surgical populations must be interpreted with caution.

### ***Personality Assessment Inventory***

The Personality Assessment Inventory (PAI) (Morey 1991) is an instrument with psychometric properties that is intended to be an advance over the MMPI. The PAI consists of 344 items, yielding standard scores on 4 validity scales, 11 clinical scales, 5 treatment scales, and 2 interpersonal scales. The test can be completed by persons who are able to read at the fourth-grade level, requires approximately 45 minutes to complete, and is easily scored by hand or by computer. The patient's responses are plotted and compared with data from a large, census-based, psychiatrically healthy population and from a large, community-based sample of psychiatric patients. In addition to measures of type and severity of psychopathology, the test yields measures of suicidality, aggression, perception of social support, level of recent stress, and resistance to psychological treatment.

As with the MMPI tests, one must be careful interpreting PAI findings obtained from medically ill patients. Medical symptoms elevate scores on clinical scales, leading to a risk of overdiagnosis of conversion or other somatoform disorders. Therefore, the same caveats mentioned regarding the MMPI and MCMI tests must also be considered when the PAI is used in clinical settings.

### ***Millon Behavioral Health Inventory***

The Millon Behavioral Health Inventory (MBHI) (Millon et al. 1982) was designed specifically to assess personality traits, interpersonal style, impact of stress, motivation for change, and compliance with care in medical settings. The test provides specific predictions for patients with cardiac, gastrointestinal, genitourinary, or orthopedic disease, as well as predictions about compliance with treatment. Our experience with the test, however, suggests that it is somewhat lacking in terms of assessment of personality traits and that its content is too obvious to many patients.

### ***Millon Behavioral Medicine Diagnostic***

The Millon Behavioral Medicine Diagnostic (MBMD) (Millon et al. 2001) was developed to provide a self-report

measure of psychosocial factors that can affect health outcome in the medically ill. Standardized on a wider-based sample of the medically ill than the MBHI, the MBMD provides summary information on seven scales (Response Patterns, Negative Health Habits, Psychiatric Indicators, Coping Styles, Stress Moderators, Treatment Prognostics, and Management Guide) based on patient responses to 165 true–false questions. Although this more recent assessment tool has improved some of the weaknesses associated with the MBHI, because of its recency there has been little empirical research demonstrating its application effectiveness. Thus, the utility of the MBMD in the context of psychosomatic medicine has not yet been established.

### Projective Personality Measures

Among the best-known and least-understood psychological tests are the projective measures (e.g., Rorschach inkblot test, Thematic Apperception Test). These tests employ less structure with more ambiguous stimuli and have greater task demands in comparison with the aforementioned objective personality measures. In addition, a primary goal of projective assessment is to elicit responses rich enough to permit psychodiagnostic inference and detect disorders of reality testing and thought processes (Anastasi and Urbina 1997). Although many clinicians rely on qualitative analysis of patient responses, quantitative summaries from some of these measures are as reliable, valid, and objective as results from the personality inventories described earlier in this chapter. However, data on medically ill populations are available for few of the projective test measures, and caution must be exercised when using these instruments with cognitively impaired patients. Deficits in attention, executive function, language, and visuospatial skills can render a patient's responses on these instruments unsuitable for measuring psychopathology.

When applied appropriately, projective tests such as the Rorschach inkblot test (Exner 1993; Rorschach 1921) may provide extensive information on how the individual's medical condition affects his or her perceptual processing and may be useful for treatment planning. However, it is even more important for the referring physician to be aware of and recognize the potential misuse of the results from such tests, so that medical conditions that may produce perceptual distortion are not inaccurately characterized as psychiatric disorders. Because these tests are less frequently used or are less appropriate for medical-illness samples, specific information or discussion of the various projective measures is not included in this chapter.

### Self-Rating Scales

In addition to the objective and projective personality measures, which are most commonly administered and interpreted by qualified professionals, there are a variety of self-rating scales that have been developed to measure anxiety, depression, life-event stress, and other behavioral and affective symptoms. Newer instruments have been designed to measure health-related quality of life and well-being in medical patients, with less emphasis placed on diagnosing psychiatric disorders. Self-rating scales have the advantage of permitting a relatively brief assessment of current emotional functioning and are sensitive to factors that can affect neuropsychological functioning. Because their purpose is usually obvious, however, patients are prone to underreport or overreport difficulties. Furthermore, by definition of their targeted focus on current state, these measures provide little information about personality structure or typical coping style. If more extensive information is needed, more-detailed, objective measures should be used. For self-rating instruments that include somatic items but that have not been validated in the medically ill, results should be interpreted with caution in patients with medical illness.

Because of the ease of use, brevity of administration, and wealth of information that can be obtained from self-report instruments, the number of tests that have been developed is almost innumerable. Common examples of self-report measures with well-established reliability, validity, and standardization are described in the following subsections. A more complete description of currently available self-report measures is contained in the *Handbook of Psychiatric Measures* (American Psychiatric Association 2002).

#### *Depression Scales*

Among the best-known scales for measuring depression are the Beck Depression Inventory (BDI) (Beck and Steer 1987) and its revision, the BDI-II (Beck et al. 1996), a 21-item scale on which a patient rates the severity of current affective and somatic symptoms (see Chapter 9, "Depression"). Although the BDI is sensitive to depressive symptoms, its use among patients with medical illness has been criticized because of the scale's somatic content (Cavanaugh et al. 1983; Emmons et al. 1987; Schulberg et al. 1985). For this reason, Cavanaugh and colleagues (1983) recommended using only affective items on the BDI when evaluating general medical patients. Similarly, Pincus and Callahan (1993), in the study described earlier in the subsection "Minnesota Multiphasic Personality Inventory," found that six BDI items were likely to be endorsed by rheumatoid arthritis patients. Thus, clinicians using

the BDI or the newer BDI-II (Beck et al. 1996) with medical and surgical patients should examine the pattern and level of item endorsement before interpreting a total score that is in the clinical range.

The Zung Self-Rating Depression Scale (Zung 1965), also known as the Zung Depression Scale, is frequently used in medical settings. It is a 20-item scale that measures severity of affective and physiological symptoms of depression. The Zung Depression Scale is less highly standardized than the BDI (Green 1982). As with the BDI, the total score must be interpreted judiciously in patients with medical illness. Another popular depression inventory is the Geriatric Depression Scale (Gallagher 1986; Yesavage et al. 1983), but the validity of this scale in patients with dementia is questionable (Feher et al. 1992).

In general, self-report measures of depression are less sensitive to changes due to treatment compared with assessment scales requiring professional expertise (e.g., the Hamilton Rating Scale for Depression [Hamilton 1960]). In general, specific symptom items included in these scales are less sensitive to change in response to treatment in comparison with overall summary scores (Lambert and Lambert 1999).

The Chicago Multiscale Depression Inventory (CMDI) (Nyenhuis et al. 1998) was developed for differentiating self-report symptoms of depression associated with mood, negative evaluation, and vegetative features. The CMDI is a one-page, 50-item self-report measure in which target items are presented as either a single word or a simple phrase and patients rate the relevance of each item to themselves with a Likert rating scale, ranging from 1 to 5. The CMDI has been used in patients with multiple sclerosis, and separating the participants with multiple sclerosis into groups based on the subscale scores was found to be useful in differentiating cognitive changes associated with mood state rather than medical illness symptoms (Nyenhuis et al. 1995). Similarly, depression rates in patients with myasthenia gravis were elevated only for the Vegetative Features scale of the CMDI, validating the importance of separating depression symptoms into distinct components when evaluating patients with medical disorders (Paul et al. 2000). Thus, the CMDI may be useful for differentiating the types of symptoms endorsed by various medically ill samples and for separating symptoms of depression from illness-related symptoms.

### *Anxiety Scales*

The best-known anxiety scale is the State-Trait Anxiety Inventory (STAI) (Spielberger et al. 1983) (see also Chapter 12, "Anxiety Disorders"). It consists of two sections: 20 items that assess the patient's anxiety at the time of evaluation (state) and 20 items that evaluate the pa-

tient's long-standing, characteristic level of anxiety (trait). Unfortunately, if patients do not read the instructions for each section carefully, the distinction between state and trait measures can be minimal. The STAI was designed as a research instrument, and normative data are limited (Spielberger et al. 1983). However, this instrument has been successfully applied in repeated assessments of patient anxiety in research involving medically ill samples (e.g., patients undergoing coronary artery bypass surgery [Phillips et al. 2003]). In addition, the STAI successfully discriminated medical care factors that could affect patients' experienced anxiety after receiving adverse health information from test findings (e.g., Bekkers et al. 2002). Thus, the STAI may have utility for evaluating and assessing changes in experienced anxiety. Of particular relevance, several studies show that heightened anxiety is predictive of reduced treatment compliance across different medical conditions (e.g., cardiac rehabilitation [Whitmarsh et al. 2003]; medication regimen adherence in HIV infection [Escobar et al. 2003]; and cancer assessment follow-up [Yassin et al. 2002]).

The Beck Anxiety Inventory (Beck 1993) is an alternative to the STAI and is reportedly more effective in differentiating individuals with anxiety from those with depression. However, the extensive overlap between these two disorders complicates differential diagnosis, and reliance should not be placed solely on summary scores of self-report measures (Wilson et al. 1999).

### *General Distress and Life-Event Scales*

A more general instrument that surveys psychiatric and medical symptoms as well as general level of distress is the Hopkins Symptom Checklist-90—Revised (SCL-90-R) (Derogatis 1994); the abbreviated version of this measure is the Brief Symptom Inventory (Derogatis 1993). The SCL-90-R includes 90 items, which patients are asked to rate in terms of severity, and provides results on several psychiatric symptom scales. Its utility for both psychiatric and medical populations has been criticized (Green 1982), but it has been used extensively in research with diverse medical and psychiatric patients. When this type of self-report measure is included as part of a comprehensive assessment, it can provide useful information about specific symptoms experienced by the patient (Anastasi and Urbina 1997).

The General Health Questionnaire (GHQ) (Goldberg and Blackwell 1970; Goldberg and Williams 1988) is another widely used and multidimensional scale that assesses self-reported symptoms. Available in the original 60-item version as well as several shortened versions (e.g., GHQ-12), this measure evaluates patients' reports of mental health concerns associated with somatic, affective,

and social functioning and disturbances. Shortened versions have also been validated as mental health screening measures across diverse cultures in a World Health Organization study (Goldberg et al. 1997). Another popular measure relevant to psychosomatic medicine is the Profile of Mood States (McNair et al. 1981). Patients rate a series of words that are specific to affective state, and results are reported on several different scales. Because this measure includes few somatic items, it can be used for the assessment of medically ill patients. For measurement of life-event stress, the Schedule of Recent Experience (Casey et al. 1967) and the Social Readjustment Rating Scale (T.H. Holmes and Rahe 1967) are particularly well established.

### *Health-Related Quality-of-Life and Well-Being Scales*

Self-report questionnaires addressing quality of life have been developed with medical patients in mind. These scales evaluate well-being, distress, and life events that can affect coping and psychological response to medical conditions. They either target behavioral characteristics and complaints associated with an illness or survey multiple attributes that are prevalent features of an illness. Well-being and quality of life are subjective individual characteristics that are measured best by self-report. Effective treatment of symptoms (psychological or medical) does not always result in improved subjective satisfaction or perceived quality of life. Conversely, quality of life can sometimes be improved with treatment without a corresponding change in medical symptoms (Frisch 1999). The importance of measuring quality of life through patient self-report, rather than through physician observation, has been emphasized (Gill and Feinstein 1994). Some have even argued that behavioral outcomes are even more important measures of health outcomes than are indices of symptoms (R.M. Kaplan 1990). Consequently, these measures can be useful supplements to more traditional measures of psychiatric (and medical) symptoms.

The Quality of Life Inventory (Frisch 1994) is a brief self-report measure that assesses satisfaction and perceived importance of basic life pursuits in 16 domains (e.g., personal health, relationship status). The measure's psychometric properties have been well established and have contributed to its frequent description as one of the best of the available measures of health-related quality of life (Frisch 1999). Another well-known measure was developed by the RAND Corporation for the Medical Outcomes Study (Tarlov et al. 1989). This instrument has also been used frequently in research, particularly an abbreviated version (36-item short form, or SF-36) (Hays

1998; Ware and Sherbourne 1992) and its updated version (SF-36v2) (Ware and Kosinski 1996). The SF-36 has been widely used as a measure of health-related quality-of-life outcome across the eight domains that are the most significantly affected by medical illness and also provides summary outcome scores for physical, mental, and overall health (Ware 1999). The Functional Assessment of Cancer Therapy Scale (Cella et al. 1993) was designed to measure quality of life in cancer patients. The scale contains questions for all cancer patients, and additional scales have been designed to measure symptoms of specific cancers and of HIV infection (Cella 1994). All these measures of patients' subjective status can provide useful indications of the need for psychological intervention or the effectiveness of a medical treatment regimen, independent of changes in primary symptoms. With any of these measures, however, the selection of the appropriate normative comparison group is still critical in making a diagnosis and planning treatment for medically ill patients with psychiatric symptoms (Derogatis et al. 1995).

The Stress Profile (Nowack 1999) is a 123-item, Likert-type self-report measure of seven major categories of individual functioning and coping (Stress Domains, Health Habits, Social Support Network, Type A Behavior, Cognitive Hardiness, Coping Style, and Psychological Well-Being) that are reported in terms of 15 subscales found to moderate the impact of perceived and experienced stress on health and well-being. The questionnaire also includes two measures of response validity (response bias and response inconsistency) and yields standard scores represented as Health Risk Alerts and Health Protection Resources. The questionnaire was standardized on a nonclinical sample. Administration of this measure typically requires 20–25 minutes. Results from this comprehensive health risk appraisal provide targeted information on lifestyle and health behaviors that contribute to illness, and it has been shown to have adequate psychometric characteristics. The Stress Profile has been found to effectively categorize stress effects on health outcomes, work absenteeism, and job burn-out in both retrospective and prospective analysis studies (Nowack 1999).

### Summary of Psychological Assessment and Self-Report Instruments

Advantages and disadvantages of the different types of psychological assessment measures are listed in Table 2–3. As noted, caution must always be exercised when interpreting scores of patients with medical illness because normative data established for normal samples or psychiatric patients are not directly applicable. This is especially true when using computer-generated interpretations of

**TABLE 2-3. Advantages and disadvantages of psychological assessment methods**

Method	Advantages	Disadvantages
Objective personality measures	Standardized, reliable, and valid for psychiatric diagnosis Large body of supporting data Quantitative indices of distress, coping, and personality style	Time-consuming (30–45 minutes) Results must be interpreted with caution in patients with medical illness Can be difficult for patients with cognitive deficits to complete
Projective personality measures	Qualitative information on personality structure Sensitive to thought disorder Rich psychodiagnostic information Less vulnerable to self-report bias	Time-consuming (45–60 minutes) Few data on profiles of medical patients Results are difficult to interpret when cognitive dysfunction is present
Self-rating symptom scales	Standardized, reliable, and valid for psychiatric diagnosis Brief (5–15 minutes) Easily administered at bedside	Results must be interpreted with caution in patients with medical illness Prone to underreporting or overreporting of symptoms Do not provide comprehensive assessment of psychopathology
Health-related quality-of-life scales	Standardized, reliable, and valid Brief (5–15 minutes) Easily administered at bedside Supplement traditional measures of psychopathology Evaluate issues important to recovery from illness	Must be selected with reference to a specific medical condition Prone to underreporting or overreporting of symptoms Do not assess psychopathology

measures such as the MMPI, which do not take any individual factors into account. In addition, cognitive disorders can make it difficult for a patient to complete a measure and can render results invalid. However, when results from these instruments are interpreted in the context of the patient's history, clinical interview, and other diagnostic information, they can provide information on current coping style, emotional state, reactions to illness, quality of life, and general well-being. For a classic review regarding factors that must be considered when administering psychological tests to general medical patients, the reader is referred to Green 1982.

## Applications to Psychosomatic Medicine

Psychological evaluation and self-report measures can be useful in a variety of circumstances in psychosomatic medicine. In the following subsections, we provide several examples of relevant applications.

### Emotional Factors and Physical Symptoms

Psychological tests can help to determine how emotional factors contribute to a patient's physical symptoms. A patient's current and chronic levels of stress can be evaluated with instruments such as the PAI, STAI, and specific Ror-

schach indices. These instruments assess tendencies toward repression and denial, coping resources, and personal reaction to illness, among other factors. These factors affect the development, maintenance, and progression of a disorder, as well as success or failure of treatment programs. The MMPI and PAI provide measures of guardedness, willingness to address psychological conflicts, and ability to admit directly to experiencing distress.

### Case Example 5

E, an adolescent male, was admitted to a neurology unit for evaluation of atypical dystonia and intermittent seizures. While hospitalized, he experienced prolonged periods of tonic-clonic movements, marked by head thrashing, pelvic thrusting, and bilateral cycling motions with his legs. These events almost always occurred during clinician visits and were unaccompanied by incontinence, postevent confusion, or baseline cognitive deficit. Electroencephalographic recordings during the patient's spells were normal. E's approach to the MMPI-2 was guarded and defensive. He denied common shortcomings and presented himself in an unusually positive light. He expressed no psychological concerns. The clinical scale profile revealed a tendency to emphasize physical symptoms as a defense against emotional discomfort. Similar patients are described as naive, immature, and demanding and are prone to employ repression and denial as defenses against psychological stress or conflict. The psychiatric consultant was able to alternately provoke and terminate the patient's attacks dur-

ing an amobarbital interview. Eventually, suggestion-based intervention resulted in remission of the events, and the dystonic posturing resolved. However, the patient's spells returned shortly after he was discharged to his home. At that point, hypnotic suggestion-based intervention with the patient was combined with family therapy and parent training to minimize the contingencies that appeared to be maintaining the patient's symptoms.

Although findings of psychological contributions to physical symptoms can often be made in the absence of psychological test data, the addition of such data can provide important support for a diagnosis of a somatoform disorder (as in Case Example 5 above), which should not be made solely on the basis of a normal medical evaluation. Psychological test data that strongly support a diagnosis of conversion disorder can help avoid multiple unnecessary neurological diagnostic tests. Psychological assessment may be especially helpful when the questionable symptoms appear in a patient with a known neurological disorder (L. D. Nelson et al. 2003).

### Adjustment to Medical Illness

Interpersonal style, psychosocial competencies, and character structure can interact with physical illness and can determine a patient's ability to cope with illness, deal with health care providers, and respond to intervention. Psychological and personality testing can be valuable components of the psychiatric assessment of patients whose physical conditions force them into intense regressed relationships with their care providers. In some patients, severe character pathology may manifest as unusual physical symptoms or as pathological interactions with the treatment team. Careful assessment of personality variables can protect both patient and provider from maladaptive or destructive interactions.

#### Case Example 6

Ms. F, a 35-year-old licensed practical nurse, was referred for testing by a defense law firm; she presented with severe cognitive and emotional difficulties after a very mild head injury sustained in a fall from a chair. Clinical interview, projective testing, and responses on personality inventories revealed chronic impairment in emotionality, judgment, impulse control, and interpersonal relationships. Her interpersonal boundaries were weak, with marked evidence of chronic overidealization and undervaluation of those close to her. Symptom inventories and a review of records revealed impulsive behaviors, including buying sprees, bingeing-purging, sexual improprieties, and substance abuse. Her relationships were typically intense and short-lived. On self-report checklists and on structured interviews, Ms. F re-

ported many inconsistent and incompatible symptoms and could be led to endorse vague, unusual, and nonphysiological complaints. A review of the patient's record revealed marked inconsistencies and outright fabrications in her medical and psychosocial history. Evidence suggested that she may have misrepresented her symptoms in the past, which caused her to undergo a number of painful and invasive diagnostic and operative procedures. Projective and personality testing supported the diagnosis of borderline personality disorder and a probable factitious disorder with physical symptoms. It was later discovered that the patient had been pursuing treatment elsewhere, having attended nearly 140 diagnostic and treatment appointments in the 90 days before her psychological evaluation.

### Emotional Sequelae of Neurological Disorders

A number of neurological and medical disorders are associated with cognitive and emotional sequelae. At times, CNS manifestations of a patient's disorder are difficult to discriminate from emotional reactions to the disorder. Psychological testing can help to determine how the psychomotor retardation, agitation, cognitive inefficiency, or emotional lability of patients with brain disease is related to illness.

### Competence and Other Medical-Legal Issues

Neuropsychological and psychological testing can provide objective data on cognitive or emotional factors that affect patients' ability to appreciate their circumstances and the consequences of their decisions and to respond to environmental demands in an appropriate manner. Such evaluations can be very helpful in complex competency determinations, especially when competency is being contested (see Chapter 3, "Legal Issues"), as well as in determining the extent of injuries (especially brain injuries) in personal injury and workers' compensation litigation.

#### Case Example 7

Mr. H, a 67-year-old resident of a senior citizen apartment complex, sustained a left middle cerebral artery infarction, which initially left him globally aphasic, emotionally labile, and right hemiparetic. Immediately after the CVA, he was not believed to be competent to make decisions on his own behalf, and plans were made to have him transferred from the hospital to a nursing home near his eldest daughter, hundreds of miles from his home and friends. Mr. H grew increasingly alert, oriented, and engaged as he recovered from his CVA and was markedly upset by the decision to move him to a nursing

facility so far away from his home. Neuropsychological testing revealed that Mr. H had relatively intact intellectual resources. Despite language difficulties, his nonverbal processing skills, memory, and reasoning abilities were nearly normal for his age and education. He became facile at using gesture and other forms of nonverbal communication to overcome his expressive language deficits and was able to communicate an understanding of most of what he heard. Mr. H expressed his desire to remain in his home and to receive outpatient rehabilitation services and home health care. He formulated a plan to receive these services and demonstrated the skills necessary to manage the social and financial resources needed to remain in his home. The family's initial reticence was overcome as Mr. H demonstrated his competencies.

## Malingering

---

A patient may intentionally misrepresent or exaggerate his or her symptoms. Even the most experienced clinicians may be less capable than they suspect of determining when patients are feigning psychological or cognitive deficits (Bernard 1990; Faust et al. 1988; Heaton et al. 1978). Psychological testing can help clinicians detect feigning of symptoms. The MMPI and PAI both contain scales sensitive to intentional efforts to misrepresent symptoms (Bagby et al. 2002; Rothke et al. 2000). The Structured Interview of Reported Symptoms (Rogers et al. 1992) is a "rare symptom" inventory that is sensitive to inconsistent or unusual complaints not associated with known clinical entities. Careful analysis of neuropsychological test performance also helps to identify patients whose complaints are highly inconsistent with or disproportionate to their objective deficits (Ruff et al. 1993; Trueblood and Schmidt 1993).

*Symptom validity testing* refers to the process of repeatedly administering a simple binary forced-choice task to assess possible malingering (Bianchini et al. 2001; Pankrantz 1979, 1983). Trials with longer interresponse intervals and more complex interresponse tasks are described to the patient as "harder," and a large number of such trials are used. Malingering patients frequently deviate from the standard normal distribution, perform significantly worse than chance (a patient responding randomly is expected to respond correctly 50% of the time), and often perform far worse than patients with genuine brain injuries (Binder 1993). One can generate statistical probabilities that a patient's performance on this deceptively easy procedure reflects a conscious effort to perform poorly. The Portland Digit Recognition Test (PDRT) (Binder 1993; Binder and Willis 1991) is a frequently used version of this procedure. Computerized versions of the PDRT

and other forced-choice procedures have been developed and are seeing increased clinical use (Bianchini et al. 2001; Gutierrez and Gur 1998).

## Case Example 8

Mr. I is a 32-year-old right-handed cab driver who was referred for an independent medical examination about 20 months after he sustained blunt chest trauma, a fractured ankle, and an apparent mild head injury in a motor vehicle accident. Mr. I's reports of coma and posttraumatic amnesia expanded over time, such that by the time of his neuropsychological evaluation he reported that he had lost consciousness for several days and reported nearly 1 year's retrograde memory loss and nearly 6 months' postconcussive amnesia. In the ensuing months Mr. I complained of changes in personality and behavior and reported severe difficulties in memory and concentration affecting all elements of personal and vocational functioning. He consistently misrepresented his pre-morbid abilities and accident-related disabilities.

Neuropsychological evaluation found Mr. I to be of borderline impaired intelligence with markedly impaired spatial, psychomotor, and attention-related intellectual abilities. These latter IQ scores were below levels expected from Mr. I's past academic attainment and vocational functioning and seemed to have been suppressed by an apparent motivation to perform poorly during testing. Performance on the remainder of this evaluation revealed uniformly severe cognitive impairment, in most cases much worse than is typically observed in more obviously severely injured patients. The pattern, extent, and progress of deficits were judged to be inconsistent with what is seen after much more severe, objectively demonstrable CNS insults. Mr. I performed below chance levels on procedures demonstrated to be sensitive to the effects of embellished or feigned deficit. His performance on objective indicators of dissimulation and pattern of performance on other standardized procedures very strongly suggested that Mr. I was intentionally spoiling his test performance. The ongoing litigation, the discrepancy between his subjective report and objective findings, his lack of normal effort during assessment, his complaints of remote memory loss, his exaggeration and fabrication of elements of personal history, and the improbable mechanism of injury relative to the nature and extent of his deficits were all consistent with the conclusion that the patient was malingering.

## Computerized Testing

---

Several familiar neuropsychological measures have been adapted for computerized administration, and new computerized neuropsychological tests have also been developed.

Computerized cognitive screening tests represent some of the recent innovations in computerized testing. Computers offer a way to administer brief cognitive func-

tion tests; laptop computers enable bedside administration. Two batteries have been available for several years. CogScreen (Kay 1995), a group of 11 tests, requires approximately 30 minutes for administration. CogScreen was designed to detect subtle cognitive deficits that could affect aviation performance and is sensitive to mild neurocognitive disorder in general. MicroCog (Powell et al. 1996) was designed to assess mild cognitive decline in physicians, but it has been applied to cognitive screening of a wide range of patients, particularly older adults. The Cambridge Neuropsychological Test Automated Battery (Sahakian and Owen 1992) includes computerized versions of several common neuropsychological tasks accompanied by novel measures of reaction time and executive problem solving; it has been used extensively in research. Although to date these computerized batteries have not seen widespread clinical use, it is likely they and others will become more prevalent.

Computerized continuous performance tests (CPTs) have been increasingly used as part of a more comprehensive neuropsychological battery. These measures of sustained attention require a client to respond to a specific but infrequent stimulus (e.g., the number 1 presented among many 2s, an X presented among many different letters) for a lengthy period (Rosvold et al. 1956). Examples of these instruments include the Test of Variables of Attention (Lark et al. 1996), Integrated Auditory and Visual Continuous Performance Test (Sandford and Turner 1999), and Conners Continuous Performance Test (Conners 1994). The most common application of these measures has been in diagnosing ADHD. Unfortunately, because of their ease of administration, they have been used in isolation, with some professionals making a diagnosis of ADHD solely on the basis of an abnormal CPT result. This is inappropriate because it has been well established that there is no single cognitive test, the CPT included, that is sufficiently sensitive to and specific for diagnosing ADHD (Barkley 1998).

## Selecting a Neuropsychologist

Clinical neuropsychology is a specialized area of practice within clinical psychology. It is unfortunate that no formal regulations exist regarding use of the title of neuropsychologist. Although guidelines for training and continu-

ing education in neuropsychology have been published (Bornstein 1988; Hannay et al. 1998; Reports of the INS–Division 40 Task Force 1987), adherence to these guidelines is not yet required. Neuropsychology has now been recognized as a specialty by the American Psychological Association, which is responsible for credentialing psychological training programs in the United States, but it will be several years before graduates begin emerging from accredited programs. One indicator of competence is board certification in Clinical Neuropsychology by either the American Board of Professional Neuropsychology or the American Board of Professional Psychology, recognized as the “clearest evidence of competence as a Clinical Neuropsychologist” by the Clinical Neuropsychology Division of the American Psychological Association (“Definition of a Clinical Neuropsychologist” 1989, p. 22).<sup>1</sup> However, there are no legal requirements for certification, and some excellent neuropsychologists are not board certified.

# 3 Legal Issues

Robert I. Simon, M.D.

Barbara A. Schindler, M.D.

James L. Levenson, M.D.

**PSYCHIATRISTS WORKING IN** medical settings regularly encounter a number of difficult ethical and legal issues. Although these issues are not unique, there are special challenges in caring for patients with multiple comorbid medical and psychiatric illnesses in settings in which multiple disciplines are involved. In this chapter, we discuss confidentiality, the Health Insurance Portability and Accountability Act (HIPAA), informed consent, competency, guardianship, substituted judgment, end-of-life decisions, advance directives, voluntary and involuntary treatment, discharges against medical advice (AMA), the use of physical restraints, the Emergency Medical Treatment and Active Labor Act (EMTALA), collaborative care, managed care, and risk management. Although there can be clinically significant overlap, this chapter focuses primarily on legal issues; corresponding ethical issues are covered in Chapter 4, “Ethical Issues.” It should be noted that this chapter refers to the laws of the United States. Similar principles are applicable to other nations whose jurisprudence has English origins.

## Confidentiality and Testimonial Privilege

### Confidentiality

*Confidentiality* refers to the right of a patient to have confidential communications withheld from outside parties without implied or expressed authorization. Once the doctor–patient relationship is created, the physician assumes an automatic duty to safeguard a patient’s disclosures. This duty is not absolute, and in some circumstances breaching confidentiality is both ethical and legal (Table 3–1) (American Psychiatric Association 1987).

**TABLE 3–1. Common statutory exceptions to confidentiality between physician and patient**

Child abuse
Competency proceedings
Court-ordered examination
Posing a danger to self or others
Patient–litigant exception
Intent to commit a crime or harmful act
Civil commitment proceedings
Communication with other treatment providers

Consultation psychiatrists are faced with a unique challenge of balancing patient confidentiality with the need to provide adequate information to the medical staff requesting the consultation. Sensitive clinical information flows between the patient and consulting psychiatrist, the patient’s nonpsychiatric physicians, and the team of health care providers, as well as to family members and other personnel and agencies outside the acute health care setting (e.g., nursing home, boarding home, or rehabilitation center). Documentation in the medical record and verbal communication to the staff providing patient care require careful consideration of what to communicate and what to keep confidential. The medical record is widely available to all who provide care to the patient as well as a very large number of nonclinical personnel inside and outside the hospital (Siegler 1982). To further complicate the issue of confidentiality, the involvement of the consulting psychiatrist is most often initiated at the request of the attending physician, not the patient. The psychiatrist’s working relationship with the attending physician is as key to the consultative process as the rela-

tionship with the patient. In addition, in complicated clinical situations a large number of health care providers and family members must be involved, increasing the burden of maintaining confidentiality. In most circumstances the consulting psychiatrist should obtain the competent patient's verbal permission before speaking to the patient's family or other third parties and if possible should have the patient confirm what sensitive data may be shared in the medical record and with the attending physician. Most patients are either agreeable to sharing pertinent data or quite specific about what data cannot be disclosed. There is less need for consent when seeking information from family members than when sharing information obtained from the patient.

In general, psychiatrists should not assume that they possess *carte blanche* authorization when speaking to hospital staff members about all matters revealed by the patient. Information should be provided that would enable the staff to function effectively in caring for the patient. It is often unnecessary to disclose intimate details of the patient's history or current mental life.

Recent federal legislation addresses confidentiality issues in the health care environment. The Health Insurance Portability and Accountability Act (HIPAA) of 1996 established standards for the protection of patient privacy that were implemented in 2003. The U.S. Department of Health and Human Services has developed regulations for maintaining the confidentiality and transmission of personal health information. Health care organizations, providers, and insurers are mandated to comply with both the "Transactions" and "Privacy" rules of the HIPAA legislation. The two HIPAA guidelines that are most relevant to consulting psychiatrists are that 1) treating health care providers are explicitly exempted from requiring patient consent for sharing information with each other, and 2) psychotherapy notes receive extra confidentiality protection when they are kept separate from the rest of the medical record. The psychiatric consultant's note on the medical chart would not be considered a psychotherapy note even if it documented psychotherapy (American Psychiatric Association 1987; Appelbaum 2002).

## Testimonial Privilege

Testimonial privilege is the privilege to withhold information that applies only to the judicial setting. The patient, not the psychiatrist, holds the testimonial privilege that controls the release of confidential information. In other words, if a competent patient waives the right to confidentiality about his or her treatment, a psychiatrist cannot claim doctor–patient privilege and must testify. Privilege statutes represent the most common recogni-

tion by the state of the importance of protecting information provided by a patient to a psychotherapist. This recognition moves away from the essential purpose of the American system of justice (e.g., "truth finding") by insulating certain information from disclosure in court. The rationale for this protection is that the special need for privacy in the doctor–patient relationship outweighs the unbridled quest for an accurate outcome in court.

There are specific exceptions to testimonial privilege. Although exceptions vary, the most common include child abuse reporting, civil commitment proceedings, court-ordered evaluations, criminal proceedings, and cases in which a patient's mental state is part of the litigation. This last exception, known as the *patient–litigant exception*, commonly occurs in will contests, workers' compensation cases, child custody disputes, personal injury actions, and malpractice actions. The extent of testimonial privilege and its exceptions varies among jurisdictions.

## Informed Consent and the Right to Refuse Treatment

---

Mr. J, a 73-year-old retired mechanic with known peripheral vascular disease and chronic atrial fibrillation, is brought to the emergency room with severe acute right leg pain. His peripheral pulses are absent, and he is diagnosed with an embolus to the right femoral artery. He refuses embolectomy, a potentially limb-saving and life-saving procedure. A psychiatric consultation is called to evaluate competency. His decisional capacity is judged to be sufficiently intact to refuse treatment.

Although the process of informed consent is highly integrated in modern health care settings, many legal issues remain regarding informed consent in seriously medically compromised patients, especially those with neuropsychiatric impairment. Medical staff members routinely overestimate patients' capacity to fully understand the informed consent forms they are signing, basing their views on a gestalt impression rather than explicit assessment. It is most often when patients refuse treatment that their understanding of the consent process is called into question, resulting in a psychiatric consultation to evaluate competency. Consultations are rarely called to evaluate patients who willingly sign a consent form (Lipfert and Stewart 1988).

The right to refuse treatment is intimately connected with the doctrine of informed consent (Simon 1989). By withholding consent, patients such as Mr. J express their right to refuse treatment except under certain circumstances. The right to refuse treatment also reflects the ex-

ercise of basic constitutional rights. As Stone (1981) pointed out, the right to refuse psychiatric medication is not an isolated issue. Protection of individual autonomy includes the right to refuse emergency life-saving treatment, the right to establish advance directives, and the so-called right to die.

## Informed Consent

Informed consent provides patients with a legal cause of action if they are not adequately informed about the nature and consequences of a particular medical treatment or procedure. The legal theory of informed consent is based on two distinct principles. First, every patient has the right to determine what is or is not done to his or her body (also referred to as the right of self-determination) (*Schloendorff v. Society of New York Hospital* 1914). The second principle emanates from the fiduciary nature of the doctor–patient relationship (Simon 1987). Inherent in a physician’s fiduciary duty is the responsibility to disclose honestly and in good faith all requisite facts about a patient’s condition. The primary purpose of the doctrine of informed consent is to promote individual autonomy; a secondary purpose is to facilitate rational decision making (Appelbaum et al. 1987).

Informed consent has three essential ingredients:

1. *Competency.* Clinicians provide the first level of screening to establish patient competency and to determine whether to accept a patient’s treatment decision. The risk–benefit ratio in any given medical intervention should influence the amount of scrutiny that physicians apply to the patient’s decisional capacity, as discussed later in this chapter.
2. *Information.* The patient or a bona fide representative must be given adequate information.
3. *Voluntariness.* The patient must voluntarily consent to or refuse the proposed treatment or procedure.

## Exceptions and Liability

Table 3–2 shows the four basic exceptions to the requirement for obtaining informed consent. When emergency treatment is necessary to save a life or prevent imminent serious harm, and it is impossible to obtain either the patient’s consent or that of someone authorized to provide consent for the patient, the law will typically “presume” that consent is granted. Inability to obtain the patient’s consent may be related to clear lack of decisional capacity, to indeterminate capacity, to inability to communicate (e.g., intubation), or, in extreme emergencies, to insufficient time to evaluate capacity. Two qualifications are

**TABLE 3–2. Basic exceptions to obtaining informed consent**

Emergencies
Incompetence
Therapeutic privilege
Waiver

necessary to apply this exception. First, the emergency must be serious and imminent, and second, the patient’s condition, and not other circumstances (e.g., availability of the surgeon), must determine that an emergency exists. This exception does not apply if the patient is competent and is refusing treatment, even if the intervention is life-saving (e.g., transfusion in a Jehovah’s Witness). Such emergency interventions should be guided by patients’ advance directives, if they are clearly known. This was not the case with Mr. J.

The second exception to informed consent exists when a patient lacks sufficient mental capacity to give consent (e.g., a patient with delirium) or is legally incompetent. Someone who is incompetent is incapable of giving informed consent. Under these circumstances, consent is obtained from a substitute decision maker.

The third exception, therapeutic privilege, is the most difficult to apply. Informed consent may not be required if a psychiatrist determines that a complete disclosure of possible risks and alternatives might have a deleterious effect on the patient’s health and welfare. Jurisdictions vary in their application of this exception. When specific case law or statutes outlining the factors relevant to such a decision are absent, a doctor must substantiate a patient’s inability to psychologically withstand being informed of the proposed treatment. Some courts have held that therapeutic privilege may be invoked only if informing the patient will worsen his or her condition or will so frighten the patient that rational decision making is precluded (*Canterbury v. Spence* 1972; *Natanson v. Kline* 1960). Therapeutic privilege is not a means of circumventing the legal requirement for obtaining informed consent from the patient before initiating treatment. It should be very rarely necessary to invoke therapeutic privilege in the medical setting, because a skilled clinician should be able to explain the diagnosis and proposed treatment in language the patient can cognitively and emotionally handle, aided by the consulting psychiatrist.

Finally, a physician need not disclose risks of treatment when the patient has competently, knowingly, and voluntarily waived his or her right for information (e.g., when the patient refuses information on drug side effects). However, the physician should then consider whether the

patient's lack of information could adversely affect treatment outcome, in which case it may be more appropriate not to proceed with treatment.

Aside from these four exceptions, a physician who treats a patient without obtaining informed consent is subject to legal liability. In some jurisdictions, however, case law or statutes specify that informed consent is unnecessary if a reasonable person under the given circumstances would have consented to treatment. As a rule, treatment without any consent or against a patient's wishes may constitute battery (intentional tort), whereas treatment commenced with inadequate consent is treated as an act of medical negligence. On rare (usually emergent) occasions, the physician may decide to treat a patient without fully disclosing the risks, benefits, and alternatives, understanding that it is better to be at risk for battery than for medical negligence.

Infrequently, courts have authorized treatment against the wishes of a competent patient. Generally, these cases involve situations in which the life of a fetus is at risk, a patient is encumbered with or is responsible for the care of dependent children and can be restored to full health through the intervention in question (e.g., blood transfusions), or a patient has attempted suicide.

## Patient Competency in Health Care Decision Making

---

Ms. L—a 73-year-old single, retired librarian with diabetes mellitus and multiple complications, including retinopathy and poorly healing leg ulcers—is admitted to the hospital for the third time in 6 months in a state of ketoacidosis. She lives alone in the house in which she was born, has minimal family support, and has consistently refused home health aides or nursing home placement. She insists that she can care for herself and that she wants to die in the house she was born in. A psychiatric consultation is requested to evaluate the patient's competency to care for herself at home and to make medical treatment decisions.

Consulting psychiatrists are frequently asked to assess a patient's competency. The case of Ms. L is a common example of a complex clinical situation that precipitates such a consultation.

Competency can be defined as "having sufficient capacity, ability... (or) possessing the requisite physical, mental, natural, or legal qualifications" (Black 1990, p. 284). This definition is deliberately vague and ambiguous because the term *competency* is a broad concept encompassing many different legal issues and contexts. As a result, its definition, requirements, and application can

vary widely depending on the circumstances (e.g., making health care decisions, executing a will, or confessing to a crime).

In general, *competency* refers to some minimal mental, cognitive, or behavioral ability, trait, or capability that is required for a person to perform a particular legally recognized act or to assume a legal role. The determination of impaired competency requires a judicial decision. Although the term *competency* is widely used in the clinical setting, health care providers cannot declare an individual incompetent. In this regard, it is clinically useful to distinguish the terms *incompetence* and *lack of decisional capacity*. *Incompetence* refers to a court decision, whereas *lack of decisional capacity* refers to a determination made by a clinician (Mishkin 1989). Legally, only competent persons may give informed consent. An adult patient is considered legally competent unless he or she has been adjudicated incompetent or temporarily incapacitated because of a medical condition. Incapacity does not prevent treatment. It merely means that the clinician must obtain substitute consent, usually from a designated family member. Legal competence is very narrowly defined in terms of cognitive capacity. This definition derives largely from the laws governing transactions. Important clinical concepts such as incompetence due to a psychiatric illness may not be recognized by the law unless the disorder significantly diminishes cognitive capacity. Psychiatric treatment may be refused by severely depressed patients because of hopelessness, by manic patients because of grandiosity, and by schizophrenic patients because of paranoia. The challenge becomes more complex in the medical setting, where serious mental illness causes a patient to reject needed medical as well as psychiatric treatment. Denial of illness often interferes with insight and the ability to appreciate the significance of information provided to the patient. In the case *In the Guardianship of John Roe* (1992), the Massachusetts Supreme Judicial Court recognized that denial of illness can render a patient incompetent to make treatment decisions.

Under the Anglo-American system of law, an individual is presumed to be competent unless adjudicated incompetent. Thus, incompetence is a legal determination made by a judge based on evidence from health care providers and others that the individual's functional mental capacity is significantly impaired. The Uniform Guardianship and Protective Proceedings Act (UGPPA) or the Uniform Probate Code (UPC) is used as a basis for laws governing competency in many states (Mishkin 1989). The Uniform Acts were drafted by legal scholars and practicing attorneys to achieve uniformity among states by enactment of model laws (Uniform Guardianship and Protective Proceedings Act, sec. 5-101).

Competency is not a scientifically determinable state; it is situation specific. Although there are no hard-and-fast rules, germane to determining competency is the patient's ability to 1) understand the particular treatment choice being proposed, 2) make a treatment choice, and 3) be able to verbally or nonverbally communicate that choice. The above standard, however, obtains only a simple consent from the patient rather than an informed consent because alternative treatment choices are not provided.

A review of case law and scholarly literature reveals four standards for determining mental incapacity in decision making (Appelbaum et al. 1987; Appelbaum and Grisso 1997). In the order of levels of mental capacity required, these standards include 1) communication of choice, 2) understanding of information provided, 3) appreciation of options available, and 4) rational decision making. Cognitive disorders can reduce all four of these capacities, while noncognitive psychiatric disorders primarily affect the third and fourth capacities.

Psychiatrists are generally most comfortable with a rational decision-making standard in determining mental incapacity. Most courts, however, prefer the first two standards. A truly informed consent that considers the patient's autonomy, personal needs, and values occurs when rational decision making is applied by the patient to the risks and benefits of appropriate treatment options provided by the clinician. Grisso and Applebaum (1995; Grisso et al. 1997) found that the choice of standards determining competence affected the type and proportion of patients classified as impaired. When compound standards were used, the proportion of patients identified as impaired increased. They advise that clinicians should be aware of the applicable standards in their jurisdictions.

Assessing the risk–benefit ratio of each medical intervention should dictate the level of understanding required of each patient in the decision-making process. While a lumbar puncture is a low-risk, highly beneficial procedure in a patient with a high fever and stiff neck, heart transplantation is a high-risk, potentially highly beneficial procedure in the patient with end-stage cardiac disease. While both may be life-saving procedures, a different level of understanding of the risks and benefits is usually expected from each patient. Table 3–3 provides a useful

tool in conceptualizing the level of scrutiny needed in different risk–benefit ratios.

Scrutiny of capacity should always be high for high-benefit, high-risk interventions. Scrutiny should be high for patients who refuse high-benefit, low-risk interventions. On the other hand, less scrutiny is warranted for patients *refusing* low-benefit, high-risk treatment. Careful attention should be directed at patients who readily agree to such treatment. Finally, it is less important to scrutinize capacity when both the benefits and risks of treatment are low, for there is little at stake for the patient.

States vary with regard to the extent of their reliance on psychiatric assessments. Nonmedical personnel, such as social workers, psychologists, family members, friends, colleagues, and even the individual who is the subject of the proceeding, may testify.

Because severely mentally disordered patients frequently lack adequate understanding of or deny their illness, they may communicate a choice and appear to understand the information provided but lack the insight or ability to truly appreciate the information. Rational decision making is impaired as well. For example, a schizophrenic patient with end-stage renal disease may understand that his kidneys are not working and may clearly communicate whether he will agree to dialysis without fully understanding the dialysis process, its complications, or the long-term commitment to treatment. Furthermore, his decision may be driven by irrational thoughts (e.g., “the machine will control me”).

A valid consent is either expressed (orally or in writing) or implied from the patient's actions. The issue of competency, whether in a civil or criminal context, is commonly raised in two situations: when the person is a minor and when he or she is mentally disabled and lacks the requisite cognitive capacity for health care decision making. In many situations, minors are not considered legally competent; therefore the consent of a parent or designated guardian is required. However, there are exceptions to this general rule, such as minors who are considered emancipated (Smith 1986) or mature (*Gulf S I R Co. v. Sullivan* 1928), or in some cases of medical need, such as abortion (*Planned Parenthood v. Danforth* 1976) or mental health counseling (*Jehovah's Witnesses v. King County Hospital* 1968).

**TABLE 3–3. Level of scrutiny needed in different risk–benefit ratios**

	<b>High benefit</b>	<b>Low benefit</b>
<b>High risk</b>	Scrutinize capacity closely (e.g., cardiac transplantation)	Scrutinize accepters > refusers (e.g., chemotherapy for metastatic large-cell lung cancer)
<b>Low risk</b>	Scrutinize refusers > accepters (e.g., intravenous penicillin for endocarditis)	Close scrutiny not necessary (e.g., cholinesterase inhibitors in dementia)

Mentally disabled patients, including mentally impaired psychiatric patients and psychiatrically impaired medically ill patients, present a slightly different problem in evaluating competency. Lack of capacity or competency *cannot* be presumed from either treatment for mental illness (*Wilson v. Leberman* 1964) or institutionalization (*Rennie v. Klein* 1978). Mental disability or illness does *not* in itself render a person incompetent in all areas of functioning. Instead, the patient must be examined to determine whether specific functional incapacities render a person incapable of making a particular kind of decision or performing a particular type of task. Generally, the law will recognize only those decisions or choices that are made by a competent individual. The law seeks to protect incompetent individuals from the harmful consequences of their acts. Persons older than 18 years (U.S. Department of Health and Human Services 1981) are presumed to be competent (*Meek v. City of Loveland* 1929). This presumption, however, is rebuttable by evidence of an individual's incapacity (*Scaria v. St. Paul Fire and Marine Ins Co* 1975). Perception, short- and long-term memory, judgment, language comprehension, verbal fluency, and reality orientation are mental functions that a court will scrutinize regarding mental capacity and competency.

Medically ill patients who are found to lack the requisite functional mental capacity to make a treatment decision, except in cases of an emergency (*Frasier v. Department of Health and Human Resources* 1986), must have a surrogate (usually next of kin) or appointed guardian to make health care decisions on their behalf (*Aponte v. United States* 1984). Several consent options are available for patients who lack the mental capacity for health care decisions, depending on the jurisdiction. In most states, proxy consent for the evaluation and treatment of a medical condition is available for the patient lacking health care decision-making capacity, without the need to involve the courts. However, in many states, proxy consent in the patient lacking health care decision-making capacity is prohibited for specific types of treatment (e.g., psychiatric treatment, abortion, sterilization, psychosurgery).

## Guardianship

---

Historically, the state or sovereign possessed the power and authority to safeguard the estate of incompetent persons (Regan 1972). In modern times, guardianship is a method of substitute decision making for individuals who are judicially determined to be unable to act for themselves (Parry 1985). In some states, there are separate provisions

for the appointment of a "guardian of one's person" (e.g., health care decision making) and for a "guardian of one's estate" (e.g., authority to make contracts to sell one's property) (Sales et al. 1982, p. 461). The latter guardian is frequently referred to as a *conservator*, although this designation is not uniformly used throughout the United States. Two further distinctions—*general (plenary)* and *specific* guardianship—are made in some jurisdictions (Sales et al. 1982). As the name implies, a specific guardian is restricted to making decisions about a particular subject area. For instance, the specific guardian is authorized to make decisions about major or emergency medical procedures, and the disabled person retains the freedom to make decisions about all other medical matters. The general guardian, by contrast, has total control over the disabled individual's person, estate, or both (Sales et al. 1982).

Guardianship arrangements are increasingly used with patients who have dementia, particularly AIDS-related dementia and Alzheimer's disease (Overman and Stoudemire 1988). Under the Anglo-American system of law, an individual is presumed to be competent unless adjudicated incompetent. Thus, incompetence is a legal determination made by a court of law based on evidence from health care providers and others that the individual's functional mental capacity is significantly impaired. In many states either the UGPPA (sec. 5-101) or the UPC is used as a basis for laws governing competency (Mishkin 1989). The Uniform Acts were drafted by legal scholars and practicing attorneys to achieve uniformity among states by enactment of model laws.

*General incompetency* is defined in the UGPPA as meaning impaired by reason of mental illness, mental deficiency, physical illness or disability, advanced age, chronic use of drugs, chronic intoxication, or other cause (except minority) to the extent of lacking sufficient understanding or capacity to make or communicate reasonable decisions (Uniform Guardianship and Protective Proceedings Act, sec. 1-101[7]; see also Uniform Probate Code, sec. 5-101).

A significant number of patients with severe medical or psychiatric disorders meet the above definition. Generally, the appointment of a guardian is limited to situations in which the individual's decision-making capacity is so impaired that he or she is unable to care for personal safety or provide necessities such as food, shelter, clothing, and medical care (*In re Boyer* 1981).

The standard of proof required for a judicial determination of incompetency is clear and convincing evidence. Although the law does not assign percentages to proof, Simon (1992) has suggested that clear and convincing evidence should be in the range of 75% certainty.

## Substituted Judgment

Psychiatrists often find that the process required to obtain an adjudication of incompetence is unduly burdensome, is costly, and frequently interferes with the provision of quality treatment. Moreover, families may be reluctant to face the formal court proceedings necessary to declare their family member incompetent, particularly when sensitive family matters are disclosed. Common consent options for patients lacking health care decision-making capacity are listed in Table 3–4.

Clear advantages are associated with having the family serve as decision makers (Perr 1984). First, the use of responsible family members as surrogate decision makers maintains the integrity of the family unit and relies on the sources who are most likely to know the patient's wishes. Second, it is more efficient and less costly. The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (1982) recommended that the relatives of incompetent patients be selected as proxy decision makers for the following reasons:

1. The family is generally most concerned about the good of the patient.
2. The family is usually most knowledgeable about the patient's goals, preferences, and values.
3. The family deserves recognition as an important social unit to be treated, within limits, as a single decision maker in matters that intimately affect its members.

There are some disadvantages, however. Proxy decision making requires synthesizing the diverse values, beliefs, practices, and prior statements of the patient for a specific circumstance (Emanuel and Emanuel 1992). As one judge characterized the problem, any proxy decision made in the absence of specific directions is at best only an optimistic approximation (*In re Jobes* 1987). Ambivalent feelings, conflicts within the family and with the patient, and conflicting economic interests may make certain family members suspect as guardians (Gutheil and Appelbaum 1980). Some family members are more impaired than the patient for whom proxy consent is being sought. In addition, relatives may not be available or may not want to get involved.

Some states permit proxy decision making by statute, mainly through their informed consent statute (Solnick 1985). Some state statutes specify that another person (e.g., specific relatives) may authorize consent on behalf of the incompetent patient. As noted earlier in this chap-

**TABLE 3–4. Common consent options for patients who lack the mental capacity for health care decisions**

Proxy consent of next of kin
Adjudication of incompetence; appointment of a guardian
Institutional administrators or committees
Treatment review panels
Substituted consent of the court
Advance directives (living will, durable power of attorney, health care proxy)
Statutory surrogates (spouse or court-appointed guardian) <sup>a</sup>

<sup>a</sup>Medical statutory surrogate laws (when treatment wishes of the patient are unstated).

ter, a number of states permit proxy consent by next of kin only for patients with medical conditions. Proxy consent is not available in many states for individuals with psychiatric conditions (Simon 2001).

As noted above, in most jurisdictions, a durable power of attorney or health care proxy permits the next of kin to consent (Solnick 1985). When proxy consent by a relative is not provided by statute or by case law authority within the state, physicians should be cautious about relying on the good-faith consent by next of kin in treating a patient believed to be incompetent (Macbeth 1994). The legally conservative procedure is to seek judicial recognition of the family member as the substitute decision maker. This approach can be impractical medically because of unacceptable delays in treatment and can be impractical legally because courts are not capable of handling the potential volume of such cases.

Some patients recover competency within a few days (e.g., those with delirium). As soon as the patient recovers sufficient mental capacity, consent for further treatment should be obtained directly from the patient. For the patient who continues to lack mental capacity for health care decisions, an increasing number of states have statutes that permit involuntary treatment of incompetent medically ill patients who refuse treatment, even if the patient does not meet current standards for involuntary civil commitment (Hassenfeld and Grumet 1984; Zito et al. 1984).

## End-of-Life Decisions

Psychiatric consultations are often requested regarding the termination of medical treatment, especially in terminally ill patients with chronic, progressively debilitating illnesses (Cohen 2000). Although many of these consultations are called ostensibly to assess the patient's compe-

tency, a covert reason for the consultation may be the physician's and staff's anxiety or conflict surrounding end-of-life decisions (Umapathy et al. 1999). Withholding or withdrawing life support may trigger an emotional response from the health care team that can cloud established legal mandates. In addition to the overt request to evaluate competency, the consulting psychiatrist needs to carefully evaluate any contributing factors to the patient's and the health care team's decision. Both untreated depression and inadequate pain management can contribute significantly to a premature decision to terminate treatment (Leeman 1999; Leeman et al. 2001). Full evaluation and provision of adequate treatment make it rarely necessary for the courts to become involved. In addition, a clear understanding of family and team support of the decision to terminate treatment and the family dynamics is a necessary part of the consultative process, especially when there is a disagreement between the patient and the family. For example, with a uremic patient who is refusing dialysis, if the family is having difficulty letting go of their loved one, they might wait until the patient becomes delirious and then insist on beginning dialysis.

## Right to Die

Legal decisions addressing the issue of a patient's right to die involve one of two categories of patients: 1) patients who are incompetent (i.e., removal of life-support systems) (*In re Conroy* 1985; *In re Quinlan* 1976) or 2) patients who are competent.

### *Incompetent Patients*

On the very difficult and personal question of patient autonomy, the United States Supreme Court ruled in *Cruzan v. Director, Missouri Department of Health* (1990) that the state of Missouri could prohibit the removal of a feeding tube surgically implanted in the stomach of Nancy Cruzan without clear and convincing evidence of her wishes. The patient had been in a persistent vegetative state for 7 years. Without clear and convincing evidence of a patient's decision to have life-sustaining measures withheld in a particular circumstance, the state has an interest in maintaining that individual's life, even to the exclusion of the family's wishes.

The importance of the *Cruzan* decision for physicians treating severely or terminally impaired patients is that they must seek clear and competent instructions from the patient regarding foreseeable treatment decisions. For example, physicians treating patients with progressive degenerative brain diseases should attempt to obtain the patient's wishes regarding the use of life-sustaining measures while that patient can still competently articulate

those wishes. This information is best provided in the form of a living will, durable power of attorney agreement, or health care proxy. However, any written document that clearly and convincingly sets forth the patient's wishes—including contemporaneous documentation by the physician in the patient's chart—could serve the same purpose. Most states have enacted legislation since *Cruzan* that allows surrogate decision makers to make critical end-of-life decisions in the absence of written evidence of the patient's wishes.

Although physicians fear civil or criminal liability for stopping life-sustaining treatment, liability may in theory also arise from overtreatment critically or terminally ill patients (Weir and Gostin 1990), although such suits are rare. Legal liability may occur for providing unwanted treatment to a competent patient or treatment that is against the best interests of an incompetent patient.

### *Competent Patients*

A small but growing body of cases has emerged involving competent patients who usually have excruciating pain, severe chronic debilitating illness, and terminal diseases and seek to stop further medical treatment (e.g., dialysis). The single most significant influence in the development of this body of law is the doctrine of *informed consent*. Beginning with the fundamental tenet that "no right is held more sacred...than the right of every individual to the possession and control of his own person" (*Schloendorff v. Society of New York Hospital* 1914, pp. 92–93; see also *Union Pacific Ry Co v. Botsford* 1891, pp. 250–251), courts have fashioned the present-day informed consent doctrine and have applied it to right-to-die cases.

Notwithstanding these principles, the right to decline life-sustaining medical intervention, even for a competent person, is not absolute. As noted in *In re Conroy* (1985), four countervailing interests may limit the exercise of that right: 1) preservation of life, 2) prevention of suicide, 3) safeguarding the integrity of the medical profession, and 4) protection of innocent third parties. In each of these situations, and depending on the surrounding circumstances, the trend is to support a competent patient's right to have artificial life-support systems discontinued (*Bartling v. Superior Court* 1984; *Bouvia v. Superior Court* 1986; *In re Farrell* 1987; *In re Jobes* 1987; *In re Peter* 1987; *Tune v. Walter Reed Army Medical Hosp* 1985).

As a result of the *Cruzan* decision, courts will focus primarily on the reliability of the evidence presented to establish the patient's competence—specifically, the clarity and certainty with which a decision to withhold medical treatment was made. Assuming that a terminally ill patient chose to forgo any further medical intervention *and* the patient was competent at the time of the decision,

courts are unlikely to overrule or subvert the patient's right to privacy and autonomy

## Do-Not-Resuscitate Orders

Cardiopulmonary resuscitation (CPR) is a medical life-saving intervention. Immediate initiation of CPR at the time of cardiac arrest leaves no time to think about the consequences of reviving a patient. Most patients requiring CPR have not thought about or expressed a preference for or against its use. Physicians and their patients can have significant anxiety discussing do-not-resuscitate (DNR) orders despite clear clinical indications and established hospital policies grounded in legal guidelines. Failure of adequate and appropriate doctor-patient communication can result in significant misunderstanding of the purpose of DNR orders. Patients can feel overwhelmed and paralyzed by the decision or railroaded by their physician into making a decision that might not reflect their true intentions. The consulting psychiatrist can help facilitate this difficult conversation between the patient and his or her primary physician.

The ethical principle of patient autonomy justifies the position that the patient or substitute decision maker should make the decision about the use of CPR. A seriously ill, competent patient's request not to be resuscitated should be respected, and a DNR order should be documented in the clinical record.

Schwartz (1987) noted that two key principles have emerged concerning DNR decisions:

1. DNR decisions are reached consensually by the attending physician and the patient or substitute decision maker.
2. DNR orders, including date and time, are written on the doctor's order sheet, and the reasons for the DNR order are documented in the chart.

The laws regarding DNR orders may vary among states, and hospital policies may vary as well (Luce 1990). In some jurisdictions a physician may enter a DNR order, even without the consent of the patient or family, when CPR is judged utterly futile (e.g., sepsis with advanced multi-organ failure). Ethical and legal guidance for CPR and emergency cardiac care is available (Council on Ethical and Judicial Affairs 1991).

## Physician-Assisted Suicide

With the increasing legal recognition of physician-assisted suicide, psychiatrists are likely to be called on to become gatekeepers as part of their practice in medical

settings (see also Chapter 10, "Suicidality," and Chapter 40, "Palliative Care"). Such a role would be a radical departure from the physician's code of ethics, which prohibits participation by an ethical doctor in any intervention that hastens death. Previously, the Supreme Court ruled in *Cruzan* that terminally ill persons could refuse life-sustaining medical treatment. Courts and legislatures will determine whether hastening death is an unwarranted extension of the right to refuse treatment. Almost every proposal for physician-assisted suicide requires a psychiatric screening or consultation to determine the terminally ill person's competence to terminate his or her life, although the state of Oregon does not require it. The presence of psychiatric disorders associated with suicide, particularly depression, will have to be ruled out as the driving factor behind physician-assisted suicide. Much controversy rages over the ethics of this gatekeeping function (Council on Ethical and Judicial Affairs 1994). Currently, the only jurisdictions that legally sanction physician-assisted suicide are Oregon in the United States and the Netherlands in Europe (Batlle 2003; Hedberg et al. 2003).

## Advance Directives

Advance directives such as a living will, health care proxy, or durable medical power of attorney are recommended so that a patient's preferences can guide the health care team and family and to avoid ethical and legal complications, particularly in withholding or withdrawing life-sustaining treatment (Simon 1992; Solnick 1985). The Patient Self-Determination Act (Omnibus Budget Reconciliation Act of 1990), which became effective on December 1, 1991, requires all hospitals, nursing homes, hospices, managed care organizations, and home health care agencies to advise patients or family members of their right to accept or refuse medical care in the form of an advance directive and to inquire if the patient has made an advance directive (LaPuma et al. 1991). If possible, copies of an advance directive should be included as part of the patient's medical record.

Federal law does not specify the right to formulate advance directives; therefore, state law applies. State legislators have recognized that individuals may want to stipulate who should make important health care decisions if they become incapacitated and unable to act in their own behalf. All 50 states and the District of Columbia permit individuals to create a durable power of attorney (i.e., one that endures even if the competence of the creator does not) (*Cruzan v. Director, Missouri Department of Health* 1990). Several states and the District of Columbia have durable power of attorney statutes that expressly authorize the ap-

pointment of proxies for making health care decisions (see, e.g., *Cruzan v. Director, Missouri Department of Health* 1990).

Generally, durable power of attorney is construed to empower an agent to make health care decisions. Such a document is much broader and more flexible than a living will, which covers just the period of a diagnosed terminal illness and usually specifies only that no “extraordinary treatments” be used to prolong the act of dying (Mishkin 1985). To clarify the uncertain status of the durable power of attorney for health care decisions, several states have passed health care proxy laws. The health care proxy is a legal instrument akin to the durable power of attorney but is specifically created for the delegation of health care decisions. It provides a mechanism for a patient to designate a decision maker other than next of kin (e.g., an unmarried partner instead of a parent).

In a durable power of attorney or health care proxy, general or specific directions can be set forth about how future decisions are to be made in the event that one becomes unable to make these decisions. The determination of a patient’s competence, however, is not specified in most durable power of attorney and health care proxy statutes. When this becomes a clinical issue, an examination by two physicians to determine the patient’s ability to understand the nature and consequences of the proposed treatment or procedure, ability to make a choice, and ability to communicate that choice usually is sufficient. This information, like all significant medical observations, should be clearly documented in the patient’s chart. If the determination is disputed, an independent examination by another physician should be obtained.

Despite the growing use of advance directives, increasing evidence suggests that physician values rather than patient values are more decisive in end-of-life decisions (Orentlicher 1992).

The application of advance directives to patients with serious psychiatric illness may present difficulties. For example, a patient with an intermittent thought disorder may draw up an advance directive during a period of mental stability and then disavow it when psychotic. Because durable power of attorney agreements or health care proxies are easily revoked, the treating clinician or institution may have to honor the patient’s refusal, even if there is reasonable evidence that the patient lacks decisional capacity. If this situation occurs, legal consultation should be considered. When the patient is grossly confused and is an immediate danger to self and others, the physician or hospital is on firmer ground, both medically and legally, to consult with the previously disregarded proxy and to temporarily override the patient’s treatment refusal. Otherwise, it is generally better to

seek a court order for treatment. Typically, unless there are compelling medical reasons to do otherwise, courts will generally honor the patient’s original treatment directions.

## Maternal Competency

---

Ms. N, a 32-year-old woman with a 5-year history of almost daily crack cocaine abuse, is admitted to the maternity service at 36 weeks’ gestation in active labor with premature rupture of the membranes. The newborn male infant is small for gestational age and has a positive toxicology screen for cocaine but is otherwise healthy. A psychiatric consultation is called to determine Ms. N’s maternal competency to care for the newborn infant, as well for her other three children (all under age 10), at home.

Psychiatric consultations are increasingly being requested for evaluations of maternal (or, more rarely, paternal) competency (i.e., capacity to care for a child) when it is thought that a vulnerable infant or child in the pediatric ward, clinic, or newborn nursery will be at risk if the parent is allowed to take the child home (Nair and Morrison 2000). This most commonly occurs in situations of maternal substance abuse, maternal psychiatric illness, or child abuse or neglect or when there is question of Munchausen syndrome by proxy. Child protective services frequently become involved. Courts can be asked to temporarily or even permanently terminate parental rights given the clinical situation. The determination to sever parental rights even temporarily is extremely stressful and painful for all involved in the decision. This is not a competency evaluation in the legal sense described above; rather, it is an assessment of maternal capacity to care for the child and of potential threats to the child’s safety. The consulting psychiatrist will require significant input from a variety of sources—including family members, pediatricians, social workers, and nursing staff—to determine maternal capacity to care for the child. Those individuals may have very polarized opinions about what is needed to protect the child, and in the case of maternal substance abuse, strong negative countertransference may be involved. Awareness of local laws pertaining to parental rights, physician reporting of suspected abuse and neglect, and guardianship is necessary.

Whether maternal substance abuse during pregnancy should be legally considered child abuse is controversial in both the medical and legal fields. Two relevant recent legal cases in South Carolina, both of which threatened the doctor–patient relationship and confidentiality, have received national attention. In *Ferguson v. City of Charles-*

ton (2001), medical personnel in a Charleston hospital reported to police positive urine toxicology screenings from pregnant women and postpartum mothers that were obtained without a warrant or consent. These women were arrested in the hospital without appropriate medical or psychiatric referral and treatment for their addictions. In 2001, the United States Supreme Court ruled that the hospital's policy of searching for evidence of substance abuse violated the Fourth Amendment's prohibition of unlawful searches. More recently, in *McKnight v. South Carolina* (2003), a woman who used cocaine during pregnancy and delivered a stillborn child was convicted of homicide by child abuse and is serving a 12-year prison sentence. The conviction was upheld after one mistrial by the South Carolina Supreme Court. This case is being appealed to the United States Supreme Court.

## Voluntary and Involuntary Psychiatric Treatment in the Medical Setting

---

Psychiatrists frequently become involved when medical inpatients with psychiatric disorders refuse treatment or a psychiatric disorder interferes significantly in the medical decision-making process or compliance with treatment. The needs of these patients are often inadequately evaluated and undertreated (Lamdan et al. 1997). In addition, confusion exists about the legal power of temporary psychiatric detention and psychiatric commitment. Involuntary psychiatric detention or commitments specifically allow only acute psychiatric evaluation, not other involuntary medical evaluations or treatments (Wise 1987). Psychiatric treatment may occur only when further judicial authorization is obtained or a second psychiatric opinion is documented, depending on the jurisdiction. The mental health laws of each state determine the criteria for involuntary psychiatric treatment, typically based on dangerousness to self or others in the presence of a psychiatric illness. The laws that specifically allow nonpsychiatric medical treatment without patient consent are based on competency criteria. In other words, judicial authorization for involuntary medical treatment depends on demonstrating that the patient does not have sufficient capacity to refuse treatment; it does not require that the patient's medical condition be life- or limb-threatening.

When a medical patient is so psychiatrically ill as to require court-ordered treatment, there is often pressure from nonpsychiatric physicians, nurses, hospital administrators, and even the legal process to transfer the patient to a psychiatric unit. Decisions on whether or not to do so

should be based primarily on what is in the patient's best interest and the need to protect other patients' welfare. It is the consulting psychiatrist's responsibility to independently assess whether the patient is sufficiently medically stable for transfer and to advocate for the patient. When available, medical-psychiatric units may be an ideal solution for some patients. Other patients can be best managed on secure medical units with one-to-one nursing supervision until they are stable enough for transfer. Concomitant psychiatric treatment should be provided while the patient is being medically treated.

Although an expressed or implied contract may be lacking, it is well established legally that a doctor is not obligated to accept a patient who simply seeks medical or psychiatric treatment (*Salas v. Gamboa* 1988). In some situations, however, an implied contractual arrangement does exist, even between a physician and a patient who have had no contact. The most common situation is a hospital's emergency room, where it is expected that emergency medical services will be provided to all who need them. This principle may extend to include physicians and psychiatrists who are on call for patient admissions or who consult with the emergency room staff (*Dillon v. Silver* 1987). Once a patient is admitted to a hospital, whether through voluntary or involuntary admission, the hospital is responsible to provide reasonable care.

Depending on the circumstances, liability associated with patient admission may arise involving the psychiatrist's failure to comply with civil commitment requirements, giving rise to a lawsuit based on the theories of false imprisonment (*Gonzalez v. New York* 1983), malicious prosecution, or assault (*St. Vincent's Medical Center v. Oakley* 1979).

Medical-surgical patients who are transferred to a psychiatric unit may want to leave. Because these patients were originally admitted for a medical or surgical problem, transfer to a psychiatric unit can be a bewildering, frightening experience. On encountering disturbed, noisy, or threatening patients, the medical-surgical patient may become terrified and demand immediate release. Grounds for a lawsuit may exist when a voluntary patient seeks to leave a hospital and is then coerced to remain in the hospital by threat of civil commitment. A patient should not be told that he or she will be involuntarily hospitalized unless that is the psychiatrist's actual intention (*Marcus v. Liebman* 1978).

In addition, a lawsuit can result when actual commitment proceedings are initiated without appropriate evidence for such an action (*Plumadore v. State* 1980). Liability may also arise if a patient represents a foreseeable risk of danger to self or others and the hospital does not hospitalize such a patient (*Clark v. State* 1985).

To protect a patient's civil rights, the consultant should inform the patient about the types of voluntary admission. Pure or informal voluntary admission permits the patient to leave the hospital at any time. Only persuasion is available to encourage the patient to stay. Conditional or formal voluntary admissions contain provisions that may require the patient to stay for a period of time after giving written notice of intention to leave. The latter provision is used when the patient is judged to be a danger to self or others. In reality, the distinction between voluntary and involuntary admissions is not always clear. Patients are often induced or pressured into accepting voluntary admissions. If voluntary admission were maintained as truly voluntary, involuntary admissions would likely increase. In addition to voluntary admissions procedures, an increasing number of states permit nonjudicial hospitalization of nonprotesting persons. For example, the District of Columbia statute provides a simple, nontraumatic admission process for individuals who either do not recognize their need for hospitalization or are unwilling to seek admission but nevertheless sign a "no objection" statement when others initiate the admission process (DC CODE ANN 1981/1984).

## Discharges Against Medical Advice

Voluntary patients may demand to leave the hospital against medical advice (AMA). This commonly occurs with patients who have experienced failures in physician–patient communication, who have external family or other pressures to leave the hospital, or who have an addictive disorder that has not been adequately diagnosed or treated in the hospital (e.g., heroin or nicotine withdrawal) (Schindler et al. 1988). The consulting psychiatrist must determine if the patient is a danger to self or others and if the patient has decisional capacity. In addition, the psychiatrist plays a key role in determining the reason the patient wants to leave the hospital AMA and in offering appropriate interventions. Regardless of whether the patient signs an AMA form, clear and complete documentation should be made in the medical record detailing the recommendations made to the patient about the need for further treatment as well as the possible risks of premature discharge (Gerbası and Simon 2003). Voluntary patients who lack decisional capacity but are not dangerous or gravely disabled can be kept in the hospital against their will if they have been adjudicated incompetent and a guardian gives consent for continued hospitalization. This authority also exists for individuals vested with durable power of attorney for health care decisions. For other cases, an emergency judicial order should be sought to restrain the incompetent patient who wishes to leave

AMA. In contrast to involuntary hospitalization for psychiatric treatment, a judicial order to permit continued treatment of an objecting incompetent medical patient does not require demonstration of dangerousness. From a clinical perspective, family or other responsible parties should be involved if possible to prevent a premature discharge.

Although competent patients can leave the hospital AMA, the consulting psychiatrist can provide significant input and intervention in preventing such a discharge (Schindler et al. 1988).

Mr. T, a 36-year-old male intravenous heroin user admitted with bacterial endocarditis, demanded to leave the hospital AMA after only 3 days of intravenous antibiotics. He refused to stay until home treatment could be arranged. He was able to describe his illness, his need for treatment, and the consequences of terminating treatment. He appeared restless and uncomfortable. His decisional capacity was determined to be intact. On further investigation, it was discovered that the medical staff had decided to give him clonidine instead of methadone to manage his withdrawal symptoms, that the patient in the next bed had had cardiac arrest during the previous night and died, and that the patient's wife was to be discharged from the psychiatric unit that day after a suicide attempt.

This case illustrates some of the areas in which psychiatric consultation can play a key role in preventing potentially life-threatening AMA discharges. First, the consultant should develop a differential diagnosis of the patient's reasons to leave AMA and should attempt to address one or all of them with the patient, family, and medical staff. In the case of Mr. T, an initial priority is better control of withdrawal symptoms by the addition of methadone. For other patients, analogous interventions include nicotine patches and adequate pain control. A second priority in the case of Mr. T is to address his anxiety about his roommate's death and his fear of his wife being home alone. A combination of supportive psychotherapy, anxiolytics, and environmental changes (e.g., having his wife spend the rest of the day and night in the patient's hospital room) may result in a marked decrease in the patient's anxiety and an increase in his trust in the health care team. Discussions with staff about the patient's current emotional state and the determinants of his wish to leave AMA helped decrease the staff's countertransference, resulting in more supportive patient–staff interactions and improved staff–patient communication.

When such efforts fail, anger directed at the patient by any member of the health care team is not clinically constructive and may contribute to legal liability. Such angry responses are understandable when physicians and

nurses have worked hard to help the patient. The consulting psychiatrist can help the team members modulate their feelings. The patient should be told that he is welcome to return to the hospital if he changes his mind or his symptoms get worse. The key goals in such interventions are to ensure the patient is making an informed, competent decision to leave and to encourage the patient to return if further care is needed. All too often, a power struggle ensues and the physicians or nurses become fixated on getting the patient to sign the AMA form, a step that is neither necessary nor sufficient for proper documentation.

## Involuntary Hospitalization

The consulting psychiatrist must often consider involuntary hospitalization for patients on medical units who have made suicide attempts requiring acute medical care or who have complex comorbid medical and acute psychiatric symptoms. The criteria are identical to those governing all psychiatric commitments (Simon 1998a, 2001; Tardiff 1996). The individual must be 1) mentally ill, 2) dangerous to self or others, and/or 3) unable to provide for basic needs. Generally, each state determines which criteria are required and defines each criterion. Because terms such as mentally ill are often loosely described, the proper definition relies on the clinician's judgment and a clear understanding of the local commitment laws.

Clinicians cannot themselves legally commit patients. This process is solely under the court's jurisdiction. Psychiatrists who use reasonable professional judgment and act in good faith when requesting involuntary hospitalization are granted immunity from liability in many states. It is helpful to keep this in mind, especially when the non-psychiatric health care professional may not understand and even oppose psychiatric commitment and transfer of patients (e.g., a superficially rational patient with anorexia nervosa and a dangerously low weight) (Appelbaum and Rumpf 1998).

Commitment statutes do not mandate involuntary hospitalization (Appelbaum et al. 1987). The statutes are permissive and enable mental health professionals and others to seek involuntary hospitalization for persons who meet certain criteria. On the other hand, the duty to seek involuntary hospitalization is a standard-of-care issue. That is, patients who are mentally ill and pose an imminent, serious threat to themselves or others may require involuntary hospitalization as a primary psychiatric intervention. This is equally true of the patient who starts out as a medical-surgical patient.

## Physical Restraints

The psychiatric-legal issues surrounding physical restraints are complex (Tardiff 1984). What the general psychiatrist may regard as contraindications to the use of restraints on psychiatric units are often viewed as indications by consulting psychiatrists on medical units. Physical restraint may be required in confused, medically unstable patients, especially when chemical restraint is ineffective or contraindicated. If restraints are not used in some delirious patients or patients with dementia, the patients may pull out their intravenous lines, endotracheal tubes, arterial lines, or other vital lines or tubes. Furthermore, confused medically ill patients often climb over bed rails, risking falls, which may result in fractures and subdural hematomas. Physical restraint is sometimes the most humane alternative.

Stringent legal regulation of physical restraints has increased during the past decade, as have legal challenges to their use. Generally, courts hold that restraints and seclusion are appropriate only when a patient presents a risk of harm to self or others and a less restrictive alternative is not available. Some health care professionals have overused restraints, whereas others are uncomfortable with their use, viewing it as an assault on the patient. Psychiatrists can help explore the various options for managing the patient and address the discomfort of the staff while keeping in mind that there are clinical and legal risks both in using and in forgoing restraints.

## Emergency Medical Treatment and Active Labor Act

---

The Emergency Medical Treatment and Active Labor Act (EMTALA), a United States federal law enacted in 1986, obligates emergency departments of all hospitals that participate in Medicare to examine patients who seek emergency care and to either stabilize them before discharge or transfer to another facility or admit them if medically indicated (Quinn et al. 2002). In this situation, health care providers cannot discriminate against patients because of their inability to pay for medical care. The law has been interpreted by the courts to require nondiscrimination in medical care rather than the establishment of standard-of-care quality (Rosenbaum 2003). In the infamous Baby K case (*In re Baby K* 1993), the United States Supreme Court went further and ruled that EMTALA requires the provision of "stabilizing treatment" even if such treatment is outside the prevailing standard of care and is considered clinically and ethically inappropriate. Difficult EMTALA problems may arise with patients pre-

sending to emergency rooms with unstable medical and psychiatric illness who may be uncooperative with treatment.

Conflicts between hospitals and between physicians occur when the patient appears too psychiatrically unstable to be treated in a medical facility and too medically unstable to transfer to a psychiatric facility. The potential penalties for violations of the law are so severe that it has led to “EMTALA-phobic” behaviors in which emergency physicians have admitted patients against the advice of psychiatric consultants, or psychiatrists have admitted patients they regard as clinically inappropriate. EMTALA does not apply to discharges from medical or psychiatric inpatient units of previously stabilized patients, although this is a commonly expressed fear. New rules (issued in September 2003) clarified that the EMTALA obligation ends once a patient has been admitted. Issues regarding the transfer of psychiatric patients were not addressed in the new rules.

## Legal Issues in Collaborative Care in the Medical Hospital

---

Psychiatrists in the medical setting work in a complex environment with a variety of health care and administrative professionals, requiring a sound understanding of the boundaries of their role in the health care setting and in the care of each patient (Appelbaum 1991; Kleinman 1991). In the medical inpatient setting, the psychiatric consultant is called to the bedside by the primary physician to evaluate and at times co-manage the patient with psychiatric symptoms. The consulting psychiatrist is not the patient’s primary physician. The consultant’s relationship is with the physician who called for the consultation, not the patient. The primary physician is free to accept or reject the findings and recommendations of the psychiatric consultant. Although psychiatrists are not likely to be found ultimately liable for adverse outcomes when their suggestions are not acted on, ironically they may be sued along with the primary physician. Whereas primary responsibility for the patient remains with the consultee, who normally relies on the consultant’s recommendations and writes the orders in the chart, both parties can be held liable for negative patient outcomes (Beran 1997; Garrick and Weinstock 1994). For example, both the nonpsychiatric physician and the consulting psychiatrist may be sued when a patient given haloperidol on the psychiatrist’s advice develops neuroleptic malignant syndrome, even when there is no negligence. In addition, psychiatrists need to be aware of their supervisory role and re-

sponsibilities with psychiatric nurse practitioners, social workers, and trainees in the hospital setting (see American Psychiatric Association 1980)

A number of nonclinical roles that psychiatrists may play in the medical setting can raise both legal and ethical concerns. Frequent interactions with the medical health care team around patient care issues lead to involvement on hospital committees (e.g., impaired physician, ethics, pharmacy and therapeutics) and often to leadership roles in the hospital system. Psychiatrists in the medical setting are also sought out for curbside consultations and referrals for staff members and their families. The consultant may also be privy to information about other health care providers (attending physicians, house staff, medical students, nurses, and other staff)—ranging from minor complaints to allegations of impairment, incompetence, or unprofessional behavior—and may become aware of health professionals who are struggling with mental health or addiction problems. Patients, families, or staff may ventilate to the psychiatrist about quality-of-care concerns. Psychiatrists should maintain awareness of the conflicts of interest that may arise and at the same time assess the likely accuracy and validity of the information. They then must balance competing legal as well as ethical obligations (e.g., the information may have been obtained confidentially from a patient, but there may be a legal mandate requiring reporting of impaired health care professionals). When in doubt, psychiatrists should seek consultation with legal services or the chief of staff of the hospital.

## Managed Care: Impact on Psychiatric Care in the Medical Setting

---

A number of managed care issues have been particularly problematic in providing psychiatric care in the medical setting. These include conflicts over responsibility for payment for psychiatric consultations, limited formularies, and restrictive determinations by insurance companies of availability and sites for posthospital psychiatric treatment (Alter et al. 1997). There may be limited or no provisions for psychiatric consultation and treatment during medical hospitalization, which has fallen between the cracks of the medical insurer and the psychiatric “carve out.” Regardless of insurance coverage, psychiatrists should strive to ensure that the medical patient receives any urgently needed psychiatric intervention. If another staff psychiatrist is a part of the patient’s insurer’s panel, he or she should provide the service. If not, then the psychiatrist should provide the clinical service and is

normally entitled to bill the insurer full charges. Psychiatrists' primary responsibility is always to the patient first; they must use their best clinical judgment in providing competent care to patients regardless of what the managed care company states it will allow (Simon 1998b). Psychiatrists must not suspend their judgment in making competent dispositions and referrals for patients, because they are more likely to be held responsible for making a negligent choice than the insurer.

## Risk Management and Risk Reduction

Dr. P, a 73-year-old recently retired physician, is admitted to the orthopedic service with a right hip fracture. On his fifth postoperative day, he is noted to be missing from his room, only to be found 30 minutes later in the hospital stairwell with new pelvic and ulnar fractures. A psychiatric consultation is called 2 days later when the patient becomes agitated and repeatedly removes his intravenous line. Review of the medical record by the consultant reveals several physician and nursing notes documenting the patient's confusion and irritability on initial admission to the hospital and worsening on subsequent hospital days. The patient's daughter confirms that the patient had retired because of cognitive impairment and had occasionally wandered away from home since his wife's death 6 months ago. Soon after Dr. P's discharge to a nursing home, the family files a malpractice suit against the hospital.

Psychiatrists and other mental health professionals contribute to risk reduction in the hospital through their assistance with patients who are angry, suicidal, disruptive, confused, noncompliant, or otherwise difficult and in decisions about restraint, level of observation, AMA discharges, and determination of decisional capacity. In the case of Dr. P described above, earlier psychiatric consultation could have recognized the likely preexisting dementia and the high risk of postoperative delirium and could have facilitated appropriate precautions and management.

It is widely believed that poor doctor-patient communication is a frequent underlying stimulus for avoidable malpractice suits, and there are data to support this belief (Moore et al. 2000). Psychosomatic medicine specialists have considerable expertise on the doctor-patient relationship and can assist other physicians and other health care professionals in preventing breakdown of the relationship, improving communications, and repairing damaged relationships. Primary prevention of malpractice suits through physician continuing medical education about the psychodynamics of the doctor-patient relationship has been considered helpful (Virshup et al. 1999).

# 4 Ethical Issues

---

Donald L. Rosenstein, M.D.

Franklin G. Miller, Ph.D.

**ETHICAL ISSUES PERMEATE** the practice of psychosomatic medicine. Psychiatrists who work in medical and surgical settings routinely perform clinical evaluations and make treatment recommendations with deep moral significance. For example, psychiatrists render opinions about the decision-making capacity of medically ill patients, whether they pose a danger to themselves or others, or if they are appropriate candidates for organ transplantation. These clinical assessments bear directly on patients' autonomy and the medical care they receive. Similarly, psychiatrists who provide end-of-life care frequently confront the possibility that medical interventions provided to their patients delay death rather than prolong life. The fact that there are no clear lines of demarcation between these types of clinical considerations and their ethical ramifications makes the practice of clinical ethics in psychosomatic medicine both compelling and challenging. All consulting psychiatrists should be adept at identifying ethical issues relating to the practice of psychosomatic medicine and need to be familiar with ethical rules, principles, and standards that should guide solving moral problems in patient care.

Historically, practitioners of psychosomatic medicine and consultation-liaison psychiatry have been active and influential participants in the ethical life of hospitals, hospice settings, and nursing homes. Many serve as members or chairs of ethics committees, institutional review boards, and ethics consultation services. Even for clinical or research psychiatrists who do not participate in these formal ethics activities, the practice of psychosomatic medicine requires familiarity with the principles of biomedical ethics.

The routine care of medically ill patients usually requires neither psychiatric consultation nor explicit ethical deliberation. However, when difficulties arise in the provi-

sion of clinical care, ethical and psychiatric concerns are often packaged together in partially formulated and emotionally charged requests for help (Lederberg 1997). In some cases, a psychiatric disorder may be inaccurately perceived as an ethical problem. For example, a patient's missed dialysis appointments might be interpreted as refusal of treatment when the patient's absences are actually due to panic attacks. In this case, the proper psychiatric diagnosis and clinical intervention may obviate misplaced ethical concerns. Conversely, a legitimate ethical dilemma (i.e., an impasse in the clinical care of a patient due to conflicting moral values) can prompt a misguided request for a psychiatric evaluation (e.g., disagreement between family members and the medical team about the value of continued aggressive medical interventions for a severely ill and clearly incapacitated patient). This second example requires careful moral deliberation among the relevant decision makers rather than a specialist's assessment of the patient's decision-making capacity. Such cases often require the help of an ethics consultant or committee. Nonetheless, the successful resolution of the ethical issues may not be possible until the presence of psychopathology in the patient, or a systems problem involving the health care team, has been identified and addressed by the psychiatric consultant.

Psychiatrists and ethicists are frequently consulted on the same complicated patients at the same urgent moment. Just as the psychiatrist has been trained to enter carefully into a dynamic system, gather information, and formulate the proper questions in the proper sequence, so too must the ethicist. Either consultant may call for a multidisciplinary team meeting to get the critical decision makers talking with each other in the same room rather than through notes in the patient's chart.

Despite the fact that many of the core skills needed for effective psychiatric intervention are also required for

the resolution of ethical dilemmas that arise in the care of medically ill patients, there are important distinctions between the tasks and methods of these two consultative activities. Psychiatric consultation follows the medical model of providing expert advice on diagnosis and therapy. Physicians who ask for psychiatric consultations want specific answers to specific questions. They want to be told precisely how to manage a certain aspect of their patient's care. Health care professionals often desire the same type of direction from an ethics consultant. However, within the bioethics community the traditional medical model is one of the least favored approaches to ethics consultation. Instead, most ethics committees and consultation services seek to facilitate discussion and conflict resolution between the stakeholders in the case. The purpose of this process-oriented approach is to identify the range of ethically permissible options rather than to provide the "right answer" or stipulate a specific course of action. The consulting psychiatrist should be able to identify ethical issues that fall outside the scope of psychiatric expertise and encourage wider moral deliberation. Similarly, the ethics consultant who can identify unaddressed clinical questions (e.g., Is the patient depressed, anxious, or confused?) can help resolve an apparent ethical problem by bringing the prior clinical questions to the attention of the medical team or psychiatrist.

The purpose of this chapter is to provide a framework for integrating ethical considerations into the practice of psychosomatic medicine. The chapter is organized into two sections. The first section provides a brief overview of the discipline of ethics and the rules governing the behavior of physicians. The second section presents a case vignette to illustrate the complex interplay between several key clinical and ethical issues encountered in psychosomatic medicine and the process of moral problem solving. The case is interrupted at critical junctures in order to facilitate a discussion of specific ethical issues as they might unfold in actual practice (e.g., decision-making capacity and treatment refusal; involuntary medication; withdrawal of care). Although the primary focus of the case is on ethical issues related to the provision of clinical care, we also discuss the relevant differences between the ethics of clinical medicine and the ethics of clinical research.

This chapter does not cover all ethical issues in psychosomatic medicine. Relevant legal considerations are discussed in Chapter 3 ("Legal Issues"). Specific ethical topics covered elsewhere in this book include physician-assisted suicide in Chapter 10 ("Suicidality"), terminal weaning in Chapter 20 ("Lung Disease"), dialysis decisions in Chapter 22 ("Renal Disease"), transplant candi-

date and donor issues in Chapter 31 ("Organ Transplantation"), sterilization in Chapter 33 ("Obstetrics and Gynecology"), placebos in Chapter 36 ("Pain"), and palliative care in Chapter 40 ("Palliative Care"). Readers are referred to other sources for ethics topics not covered, including confidentiality (Kimball and Silverman 1979), truth-telling (Horikawa et al. 1999, 2000), and the scope of the psychiatric consultant's role in medical settings (Agich 1985).

## Overview of the Discipline of Ethics

---

The discipline of ethics consists of systematic investigation and analysis of moral issues, including judgments concerning deliberation and conduct in specific situations, the identification and application of appropriate moral rules or principles, methods of justifying actions and practices, and the development of moral character. In the field of medical ethics, the focus of inquiry is often morally problematic cases involving complex interactions between health care professionals and patients (or research subjects) in which competing moral considerations are relevant.

Ethical inquiry aimed at resolving a problem in patient care or clinical research proceeds in accordance with a series of connected steps (Fins et al. 1997). First, the factual contours of the case, including pertinent medical facts, patient needs and preferences, institutional contexts, and attitudes and actions of involved professionals, should be investigated. Second, the moral considerations relevant to the case are identified and assessed. This calls for discerning the bearing of specific moral rules and principles on the case and their relative weight in determining what to do when such moral considerations conflict. Third, a decision is made on a plan of action to resolve the moral problem. Finally, the plan is implemented and its results are evaluated. Typically, all these stages of ethical inquiry take place within a process of discussion among the individuals with a stake in the outcome of the case, which may also include ethics consultation with an ethicist or ethics committee in especially difficult situations.

The most general moral considerations guiding ethical inquiry in medical contexts are the principles of biomedical ethics. The leading conception identifies four such principles (Beauchamp and Childress 2001). *Respect for patient autonomy* requires that professionals recognize the right of competent adult individuals to make their own decisions about health care or participation in research. This includes the obligation to obtain informed consent and the right of competent patients to refuse rec-

ommended diagnostic interventions or therapy or to decline an invitation to enroll in research. In the therapeutic context, *beneficence* directs professionals to promote the health and well-being of particular patients by offering and providing competent medical care; in research it directs investigators to produce valuable knowledge with the aim of improving medical care for future patients. *Nonmaleficence* enjoins professionals to avoid harming patients or research subjects. Taken together, beneficence and nonmaleficence underlie the obligation of clinicians to assess the risk–benefit ratios of patient care and research interventions. The principle of *justice* requires that medical care and research be performed in a way that is fair and equitable.

Complex moral problems in medicine are rarely resolved by simple application of one of these principles. The specific relevance and weight of principles and subsidiary moral considerations are assessed in the deliberative process of ethical inquiry. An extensive and instructive account of the meaning and application of these principles is presented in *Principles of Biomedical Ethics* by Beauchamp and Childress (2001).

Ethical considerations relevant to the ethical practice of medicine and research are incorporated in various medical oaths (Hippocratic Oath) and codes (Nuremberg Code, American Medical Association Code of Ethics); declarations (Helsinki Declaration) (World Medical Association Declaration of Helsinki 2000); and reports, guidelines, policies, and laws regarding the behavior of physicians. Some of these documents conflict with each other, and some are even internally inconsistent with respect to permissible activities (Miller and Shorr 2002). Indeed, many physicians find their own beliefs at odds with existing laws and policies concerning specific medical practices (e.g., abortion, physician-assisted suicide, use of medical marijuana).

There is no specific code of ethics for psychosomatic medicine. The most relevant professional documents are the Principles of Medical Ethics of the American Medical Association (2001) and the annotation of this code by the American Psychiatric Association (2001). The American Psychiatric Association's annotation goes into substantial detail regarding specific behaviors (e.g., sexual boundary violations, breaches of confidentiality, fee splitting, abandonment of patients) and is directly relevant to all psychiatric practice, including subspecialties. However, certain aspects of the practice of psychosomatic medicine pose ethical challenges that are not specifically addressed by these codes. The case presented through the remainder of the chapter illustrates several of these difficult issues and suggests a clinically oriented approach to their resolution.

## Assessment of Decision-Making Capacity

---

Mr. P, a 74-year-old man who was separated from his wife, was hospitalized for a recurrence of prostate cancer. He was first diagnosed with cancer in his early 60s and had been free of disease for 10 years following prostatectomy and hormonal therapy. Other than his prostate cancer, his health was excellent. He had not been taking any medications and reported drinking 2–4 beers per night. On the day before admission, he went to see his primary care physician because of low back pain. Diagnostic imaging revealed multiple lesions in his lumbar spine consistent with metastatic prostate cancer. His physician recommended hospitalization for a course of standard chemotherapy.

The morning after his admission, the patient appeared demoralized and withdrawn but was cooperative with the start of chemotherapy. He received intravenous lorazepam and oral prochlorperazine as part of his chemotherapy regimen. On the fourth day after admission, his nurse attempted to insert a new intravenous catheter for the continued administration of chemotherapy. The patient reacted with irritability and pulled his arm away from the nurse. Repeated attempts by the nurse to persuade Mr. P to allow the intravenous line to be restarted resulted in an escalation of his anger, and he demanded that he be “unhooked from all these tubes” so that he could go home. Psychiatric consultation was requested to determine if the patient was competent to refuse treatment.

Consultation requests concerning a patient's ability to make his or her own medical decisions pose two related questions. The first requires a *clinical judgment*: Does this patient have a medical, neurological, or psychiatric disorder that compromises his or her capacity to understand, appreciate, and reason with respect to the details of a given diagnostic or therapeutic procedure? The second question requires a *moral judgment*: Based on the clinical assessment described above, ought this person be allowed to give or refuse permission for medical care? Capacitated adults are entitled to refuse medical care or demand the withdrawal of life-saving treatments if they so desire. Consequently, the assessment of Mr. P's decision-making capacity (DMC) is a critical task in his hospitalization and exemplifies the importance of addressing the clinical issue before the ethical one.

The domains of legal competence, the capacity to make autonomous decisions, and the ability to provide informed consent are closely related but distinct from each other (Berg and Appelbaum 2001; Faden et al. 1986). In our society, there is a presumption that adults are legally competent to make their own decisions. A judgment that someone is incompetent is made by judicial ruling and is

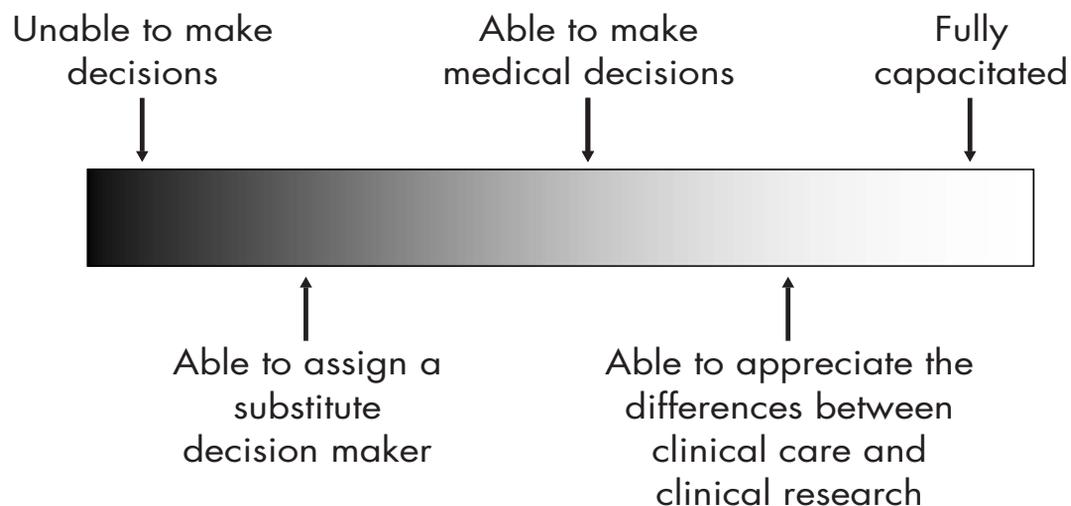

typically based on the ability to make specific decisions (e.g., choices concerning medical care, management of finances, designation of a substitute decision maker, execution of a will) at a given point in time. Standards for determining competence vary by jurisdiction but are based in large part on clinical assessments of an individual's cognitive state and DMC. From a legal perspective, a person is either competent to make decisions for himself or herself or incompetent to do so, in which case someone else makes decisions on his or her behalf (see also discussion of DMC in Chapter 3, "Legal Issues").

In contrast to the dichotomous nature of competency determinations, DMC varies along a continuum from incapacitated to fully capacitated (Figure 4–1). In the medical setting, it is common for patients to manifest diminished DMC in some domains but retain the ability to make decisions in other domains. For example, although a patient may have impaired DMC such that she does not understand the procedures, risks, and benefits of a complicated medical intervention, she may still be quite capable of designating her spouse or other loved one to make medical decisions for her. Furthermore, the nature of comorbid medical and psychiatric illnesses and their treatments is such that DMC often changes over time. Patients with secondary mania, traumatic brain injury, and delirium characteristically manifest fluctuating DMC. Despite the greater prevalence in hospital settings of delirium or comorbid delirium and dementia (Trzepacz et al. 1998) compared with uncomplicated dementia, the vast majority of published literature on clinical and ethical aspects of impaired DMC has focused on individuals with

either stable or progressive cognitive impairment.

The assessment of DMC is particularly challenging in the setting of physical or behavioral communication barriers. Clinical decisions must also be made regarding patients who are either unable to speak (e.g., due to mechanical ventilation) or unwilling to be interviewed (e.g., due to a personality disorder). The use of written notes or communication boards (often of limited utility because of the patient's fatigue or weakness) and behavioral indicators may allow only tentative conclusions about the patient's DMC. These cases require frequent assessment, patience, and clinical creativity. Because medically ill patients rarely undergo formal competency evaluations and judicial proceedings, the clinical assessment of DMC carries an extra burden in health care settings to ensure that medical decisions are made by capacitated patients or appropriate substitute decision makers for those who are incapacitated.

Few human activities are as complex and individually determined as how we make decisions. Basic components of DMC include intellectual ability; memory; attention; concentration; conceptual organization; and aspects of executive function such as the ability to plan, solve problems, and make probability determinations. Most of the psychiatric literature on DMC has focused on these cognitive functions and has employed psychometric approaches to the study of subjects with neuropsychiatric illnesses such as dementia, psychosis, major depression, and bipolar disorder (Chen et al. 2002). In contrast, the contributions of mood, motivation, and other influences on risk assessment and decision making have received less

**FIGURE 4–1.** Continuum of decision-making capacity.

attention but have clear implications for the process and quality of informed consent for both clinical procedures and research participation. The extent to which these factors (and less discrete concepts such as intuition, trust, and ambivalence) affect the decision-making process is not known. Although much work remains to be done to better understand the determinants of decision making, it is clear that focusing exclusively on measures of cognitive impairment is short-sighted.

A frequently observed but unfortunate phenomenon on medical and surgical wards is the differential threshold for concern about DMC depending on the degree to which the patient is compliant with medical care. Patients who refuse a diagnostic or therapeutic procedure are often suspected of having impaired DMC and are referred for psychiatric or neurological evaluation. In contrast, decisionally impaired patients who are passive and agreeable with requests from their nurses and doctors rarely engender these same concerns. The diagnosis of delirium, particularly the hypoactive subtype, is often missed in hospital settings (see Chapter 6, “Delirium”) and can be very distressing to patients, family members, and health care professionals (Breitbart et al. 2002a). One of several reasons to diagnose and aggressively treat delirium (with or without agitation) is that its resolution may restore DMC and thus allow patients to make important medical decisions for themselves (Bostwick and Masterson 1998).

Medically ill patients are at risk for impaired DMC for multiple reasons. The most common causes for concern are related to the patient’s underlying medical problems (e.g., respiratory compromise, hepatic failure, cerebrovascular event, severe pain) or their treatment (e.g., excessive narcotics, high-dose glucocorticoid or cytokine therapy) rather than due to a primary psychiatric disorder. In Mr. P’s case, there are several potential medical causes for his treatment-refusing behavior (e.g., delirium due to alcohol withdrawal, inadequate pain control, akathisia). A judgment that Mr. P is or is not capacitated to refuse treatment would be premature without a careful clinical evaluation of his mental state.

## Physical Restraint and Involuntary Medical Treatment

---

Dr. M, a psychiatrist specializing in psychosomatic medicine, visited Mr. P for a psychiatric examination. She observed that Mr. P was an elderly man who was unshaven and poorly groomed. His temperature was 38.4°C, and his pulse and blood pressure were slightly elevated. When asked if he understood the purpose of the psychiatric evaluation, he replied, “I’m not inter-

ested in talking to you. I’m not crazy. I just want to go home.” The patient was irritable and uncooperative with the interview, and after a few minutes of complaining about his nursing care, he insisted that the psychiatrist leave his room. The nursing report and the description from his daughter revealed that the patient had been increasingly irritable over the past few days and was briefly disoriented the previous evening. His daughter was unsure of the patient’s typical alcohol consumption but suspected that he drank more than he had reported to his physicians.

Suspecting that Mr. P was experiencing delirium, possibly due to alcohol withdrawal, Dr. M recommended treatment with benzodiazepines, a multivitamin, and folate and a workup for other metabolic, infectious, or structural causes of delirium (including blood tests, a lumbar puncture, and a magnetic resonance imaging scan). However, before completion of this workup, the patient struck a nurse and was placed in a harness and wrist restraints.

Physical restraint of patients should be used only when no less restrictive method is available to protect them and the staff from harm. The Centers for Medicare and Medicaid Services (U.S. Department of Health and Human Services 2003) and the Joint Commission on Accreditation of Healthcare Organizations (2003) require that hospitals have policies on physical restraint and seclusion. In cases of extreme agitation and violence, nuanced mental status examinations are unnecessary and often impossible, and most physicians and nurses are comfortable deciding whether and when a patient’s behavior warrants physical restraint. However, when the underlying neuropsychiatric disorder is not well characterized, the consulting psychiatrist can provide critical information regarding the justification for restraint and steps to improve the patient’s condition. The medical team is looking for an expert opinion as to the patient’s degree of self-control and dangerousness. Is there an imminent risk of harm to the patient or staff, and how can that risk be reduced? If the patient is capacitated and not dangerous, then forcible restraint violates his dignity, privacy, and autonomy. On the other hand, if an incapacitated and dangerous patient is not restrained, the rights of staff and other patients, and the patient’s safety, have been compromised.

It appears that Mr. P has temporarily lost DMC, and the principal concern at this point is his safety and that of his caregivers. Occasionally health care providers question whether it is ethically and legally permissible to physically restrain patients under these circumstances (see Chapter 3, “Legal Issues”). There should be no confusion in this regard: standard of care, as well as legal precedent, for acutely agitated and confused patients is to immediately ensure their safety even if it requires physical restraint. Compassionate care requires that the patient be treated

with dignity and respect under such circumstances and that restraint be continued only for as long as necessary. The critical distinction to be made at this juncture is between capacitated, informed refusal of care that warrants respect and refusal behavior due to compromised DMC.

A comprehensive workup for delirium often involves invasive diagnostic procedures and may necessitate the use of force to overcome the patient's resistance. Under what circumstances is it permissible to hold a confused patient down for blood tests (e.g., electrolyte concentrations, serum drug levels, or blood cultures), a bladder catheterization, or a lumbar puncture? The clinical presentations that prompt such diagnostic interventions range from true medical emergencies to subacute and self-limiting syndromes. There is no simple solution to this problem. Such decisions require clinical judgments about the necessity of each diagnostic test, its associated risks, and the degree to which the patient's condition is deemed to threaten life or risk permanent serious injury. For minimally invasive testing that is judged to be of urgent and critical importance, physicians have an obligation to act in the best medical interests of their patients even if this entails the use of force. At the other end of the spectrum, a relatively high-risk, low-yield diagnostic test in a stable but incapacitated patient is substantially more difficult to justify.

## Durable Power of Attorney and Advance Directives for Health Care

---

Mr. P is separated but not legally divorced. He has lived alone for 5 years and has one adult daughter with whom he is very close. Mr. P's daughter thought that her father had a living will but did not know where it was or if his estranged wife was still the holder of a durable power of attorney.

At this point in his hospitalization, attempts should be made by the health care team to identify the most appropriate substitute decision maker for Mr. P. Involving a spouse, close relative, or friend in medical decision making for incapacitated patients demonstrates respect for them. As with competency standards, laws regarding substitute decision makers vary by jurisdiction. The Patient Self-Determination Act of 1991 (Omnibus Budget Reconciliation Act of 1990) was intended to inform patients of their right to direct their own medical care should they become incapacitated or otherwise lose the ability to communicate their preferences. These rights include designating a holder of a durable power of attorney (DPA) for health care decisions. The completion of a living will

or an advance directive for health care allows patients to specify in writing the medical care they wish to receive under different catastrophic medical circumstances (e.g., brain death, persistent vegetative state).

Clinicians and caregivers often make false assumptions about the legal status of family members and significant others when it comes to surrogate decision making. Parents of disabled adults (e.g., patients with mental retardation, autism, or psychotic disorders) may erroneously conclude that they automatically remain the patient's legal guardian even after their child's eighteenth birthday. In most of these cases, the parents are the logical and most appropriate choices as legal guardians or surrogate decision makers. However, not all parents of incapacitated adult patients have the best interests of their children in mind. Similarly, when an unmarried incapacitated patient has more than one adult child, differences of opinion among the children about what is best for that sick or dying parent are common. Consequently, clinicians should clarify the legal status of their patients' substitute decision makers whenever possible to avoid compromised medical care and its legal ramifications.

Research on the use of advance directives and the behavior of substitute decision makers suggests two important conclusions. First, most individuals are reluctant to put in writing the kind of medical care they would like to receive if they should become gravely ill and incapacitated. Several studies found that only 15%–20% of patients fill out an advance directive for health care or research when given an opportunity to do so (Gross 1998; SUPPORT Principal Investigators 1995; Wendler et al. 2002). Second, regardless of the expressed wishes of patients, substitute decision makers tend to make decisions based on what they would want to have happen to themselves or, alternatively, what they consider to be in the best interests of the patient, rather than employing a substituted judgment standard (i.e., what the patient would have wanted) when making decisions for someone else.

## Depression in the Medically Ill

---

The clinician in charge of Mr. P's care obtained verbal permission from the patient's daughter to continue the physical restraints and complete the diagnostic testing. The medical workup suggested delirium secondary to alcohol withdrawal and hypomagnesemia. The patient was treated with intravenous magnesium sulfate, lorazepam, and a low dosage of an antipsychotic to treat his confusion, conceptual disorganization, and agitation.

Two days after initiation of treatment with magnesium, lorazepam, and haloperidol, Mr. P had a markedly improved sensorium. He was considerably less irritable

and was able to complete a detailed psychiatric interview. He was relieved to be able to “think clearly again,” and over the course of several sessions he developed a trusting relationship with Dr. M. However, as his delirium resolved, Mr. P expressed a deepening sadness and sense of hopelessness about his medical condition. He expressed skepticism about the value of more chemotherapy and wished to avoid a painful death.

In Mr. P’s case, the aggressive treatment of his delirium had the value of restoring his decision-making capacity but left him painfully aware of his progressive cancer and feeling depressed as a consequence. The clinicians caring for Mr. P are again faced with a complex clinical problem that raises ethical issues. Mr. P is contemplating stopping chemotherapy but is manifesting symptoms of depression. Is his depression influencing his decision making, and if so, what is the proper response from his health care providers? As discussed earlier, clinical considerations should be explored first in the service of an ethically desirable outcome for Mr. P.

It is important to recognize that major depression in the medically ill usually does not make the patient decisionally incapacitated. To be sure, the presence of depression may well influence patients’ ability to tolerate uncomfortable symptoms, maintain hope, or assess a treatment’s risk–benefit ratio but does not necessarily render them unable to make medical decisions for themselves (Elliott 1997). Untreated depression has been linked to poor compliance with medical care, increased pain and disability (Spiegel et al. 1994), and a greater likelihood of considering euthanasia and physician-assisted suicide (Emanuel et al. 1996). Depression produces more subtle distortions of decision making than delirium or psychosis, but refusal of even life-saving treatment by a depressed patient cannot be assumed to constitute suicidality or lack of capacity (Katz et al. 1995; Sullivan and Youngner 1994). Consequently, depressed patients should be strongly encouraged to accept treatment of depression, but decisions regarding overriding a refusal of medical treatment should be based on whether they lack DMC.

## Differentiating the Ethics of Clinical Research From the Ethics of Medical Care

---

Mr. P was moderately depressed and declined the recommended trial of an antidepressant because he was not interested in “taking any more drugs.” Although he was ambivalent about proceeding with chemotherapy, he agreed to resume the standard chemotherapy regimen and received another full cycle. When, after 4 weeks of

chemotherapy, he complained of new chest pain, it was discovered that he had new metastatic bone lesions in his ribs.

At this point, he told his daughter he wanted to stop treatment and go home to die. He asked his oncologist to discharge him to his home or hospice. His oncologist responded that Mr. P could go home but recommended that he consider enrolling in a Phase I clinical trial of a new chemotherapeutic agent. Mr. P’s daughter also encouraged him to enroll in the clinical trial and to “keep fighting.”

In some respects, the option of enrolling in a clinical trial is a logical consideration following the failure of standard medical treatment. However, this decision point in Mr. P’s clinical course warrants a thoughtful exploration of the differences between the practice of medicine and clinical research. Clinical medicine aims at providing optimal medical care for particular patients. The risks of diagnostic tests and treatments are justified by the prospect of compensating medical benefits for the patient. By contrast, clinical research is devoted to answering scientific questions to produce generalizable knowledge. Physician-investigators conduct clinical trials to evaluate experimental treatments in *groups* of patient-subjects, with the ultimate goal of benefiting future patients by improving medical care. To be sure, the contrast between the group focus of research trials and the individual focus of medical care should not be overstated. Physicians are obligated to practice medicine in the context of a professional standard of care rather than by idiosyncratic judgments about what is best for individual patients. Nonetheless, they are expected to make competent treatment recommendations tailored to the characteristics of their individual patients.

Many patients receive therapeutic benefits from participating in clinical trials, which may even surpass the benefits from standard medical care (Braunholtz et al. 2001). However, the randomized clinical trial differs fundamentally from patient care in its purpose, characteristic methods, and justification of risks. Interventions evaluated in these trials are allocated by chance. Double-blind conditions and often placebo controls are employed. For scientific reasons, protocols governing clinical trials typically restrict flexibility in dosing of study drugs and use of concomitant medications. Trials often include drug wash-outs before randomization to establish a drug-free baseline to assess treatment efficacy. Research interventions such as blood draws, imaging procedures, and biopsies are often administered to measure trial outcomes. These strictly research interventions pose risks to participants that are not compensated by medical benefits to them but are justified by the potential value of the knowledge to be

gained from the trial. Although the differences between research trials and medical care have been frequently noted (Appelbaum et al. 1987; Beecher 1970; Levine 1986; Miller et al. 1998), their ethical significance has not been sufficiently appreciated. Accordingly, clinical trials continue to be conceived from a therapeutic perspective oriented around the physician–patient relationship (Miller and Rosenstein 2003).

Clinical research has changed dramatically in recent years. Two decades ago, the majority of clinical trials were conducted in academic medical centers. Today, they are more likely to be conducted in private practice settings under the direction of clinicians rather than full-time investigators. Increasingly, psychiatrists are being consulted on patients who either are enrolled in or are considering enrolling in a clinical trial. Practitioners of psychosomatic medicine can make several contributions in this context. They may be asked to render an opinion about the psychiatric appropriateness of a patient for a clinical trial. Their patients may ask for advice about enrolling in a study. There may be an opportunity to modify the existing study or design a new one that addresses psychiatric aspects of the medical illness or its treatment.

In each of these activities, the consulting psychiatrist is well served by possessing an understanding of the critical aspects of clinical research and how they differ from those related to standard medical care (Emanuel et al. 2000; Miller and Rosenstein 2003). For example, many patients and physicians do not appreciate that the primary purpose of a Phase I trial (what was offered to Mr. P) is to assess the tolerability and toxicity of a drug rather than to obtain preliminary data on the effectiveness of the drug (Phase II).

Another aspect of research ethics directly relevant to Mr. P's case is the issue of research involving subjects considered "mentally disabled." The regulations governing federally funded human-subjects research were written more than 20 years ago and mandated additional safeguards for research subjects considered "vulnerable to coercion or undue influence" (U.S. Department of Health and Human Services 1991). Included in this category of vulnerable subjects are the mentally disabled. These regulations, known as the Common Rule, were clearly intended to prevent the exploitation of individuals for the sake of scientific progress. Unfortunately, the Common Rule does not include a definition of mental disability, nor does it specify what would constitute either the degree or the likelihood of mood, cognitive, or behavioral impairment that would render someone vulnerable in this respect. In practice, a psychiatric consultation often serves as an important additional safeguard by virtue of eliciting an expert opinion about a prospective research subject's DMC and ability to provide informed consent.

The nature of the research protocol, rather than the disorder being studied, might also place research subjects at risk for impaired DMC. Oncology trials in which subjects receive interleukin-2 or interferon-alpha, cytokines that are associated with central nervous system toxicity, provide examples of protocols that place otherwise capacitated subjects at risk of losing DMC. In these cases, the concern is less about adequate informed consent on the "front end" of the study than it is on subjects losing their ability to provide adequate consent for continuing participation. For such studies, institutional review boards (IRBs) can require subjects to appoint a holder of a DPA as a condition of enrollment. This approach has the advantages of highlighting an important risk of the study (i.e., loss of DMC) and ensuring appropriate initial and ongoing research authorization.

## Research Ethics in Psychosomatic Medicine

---

Guidance on ethical issues raised specifically by research in psychosomatic medicine is needed. For example, obtaining proper authorization for research with individuals who lack DMC is relevant to both research on delirium and research on other conditions in which delirium might develop as a complicating factor. In the case of delirium research, current publication standards for informed consent are highly variable. Investigators have described research authorization from subjects who provided prospective informed consent (Breitbart et al. 1996). Other manuscripts state that informed consent was obtained from the subjects or their surrogates (often without detailing the circumstances of surrogate consent) (Bogardus et al. 2003; Cole et al. 2002; Inouye et al. 1999; Laurila et al. 2002). It has also been argued that prospective IRB review and informed consent are not necessary for studies that involve very little deviation from (standard) clinical practice (Breitbart et al. 2002a, 2002b; Lawlor et al. 2000). We contend that this view confuses research with medical care and is inconsistent with the principle of respect for persons and federal regulations for human-subjects research (Davis and Walsh 2001; U.S. Department of Health and Human Services 1991). Some reports of delirium research are silent on the issue of IRB review (Lawlor et al. 2000). Finally, we have suggested that published reports of medical and psychiatric research should address ethical issues in a more comprehensive fashion (i.e., providing more detail than the standard sentence that the study was approved by a local IRB and informed consent was obtained from subjects) (Miller et al. 1999; Tanaka 1999).

## When Patients Express a Wish to Die

---

After considering the pros and cons of enrolling in the Phase I clinical trial, Mr. P decided to “stop poisoning myself and let this thing run its course.” He told his oncologist that he was ready to go home but that he was very afraid the cancer would spread to more of his bones. When he told his oncologist that he would rather end his life than suffer through a painful death, his oncologist responded that he would not do anything to “bring on” Mr. P’s death and again requested a consult with Dr. M.

On psychiatric examination, Mr. P was judged to be capacitated and not depressed. He confided that he had cared for his father during a “prolonged, excruciating, and undignified” death. He had accepted the inevitability of his own death but wished to avoid the kind of experience his father had endured. Dr. M then facilitated a discussion between the oncologist and Mr. P about available options. Mr. P decided to stop eating and drinking and was discharged to hospice with assurances that he would be kept comfortable while awaiting death. Dr. M was also able to help Mr. P’s daughter understand her father’s decision. Mr. P died from terminal dehydration 12 days after his transfer to hospice.

Few clinical scenarios generate requests for psychiatric consultation more predictably than when a patient expresses a wish to die. The range of possible meanings underlying this communication is immense, and a comprehensive discussion of this area is beyond the scope of this chapter (see Chapter 3, “Legal Issues,” Chapter 10, “Suicidality,” and Chapter 40, “Palliative Care”). Is the patient expressing a passive wish to die, planning to commit suicide, rejecting life-sustaining treatments (withdrawal of care), eliciting help in ending his or her life (physician-assisted suicide), or asking to be killed (euthanasia)? Under any circumstances, an expression of suicidal ideation or a request for help with an intentionally arranged death is a complex message that warrants careful clinical assessment.

Muskin (1998) observed that physicians respond to requests to die by focusing predominantly on determinations of the patient’s DMC. He argued persuasively that too often there is inadequate attention to the underlying meaning and importance of these requests. Although it is true that capacitated subjects have the right to refuse life-sustaining treatments (and in Oregon, to request physician-assisted suicide), a compassionate and comprehensive evaluation by the consulting psychiatrist can help frame both the clinical questions and the ethically permissible medical options.

Just as the clinical issues raised by requests to die are frequently reduced to questions of decision-making ca-

capacity, the ethical analysis of physician-assisted suicide is often characterized as a simple matter of autonomy versus nonmaleficence. Miller and Brody (1995) articulated an important distinction in the debate on physician-assisted suicide. In considering whether physician-assisted suicide was morally justifiable, they explored whether the practice of physician-assisted suicide as a last resort could be compatible with the professional integrity of physicians.

Ultimately, Mr. P made a capacitated and deliberate request for a comfortable and dignified death. His choice of terminal dehydration was a legal option that did not compromise the professional integrity of his caretakers (Ganzini et al. 2003; Miller and Meier 1998). In this case, the psychiatrist was able to successfully treat his delirium, manage his depression despite refusal of pharmacotherapy, and help resolve a potential impasse between Mr. P and his oncologist.

## Ethics Training in Psychosomatic Medicine

---

Training in ethics is considered a key component of the educational programs in psychosomatic medicine/consultation-liaison psychiatry fellowships (Academy of Psychosomatic Medicine 2003). Recognizing the importance of the interface between psychosomatic medicine and clinical ethics, a task force of the Academy of Psychosomatic Medicine recently published an annotated bibliography for ethics training (Preisman et al. 1999). Curricula for teaching research ethics in psychiatry have also been developed in recent years (Beresin et al. 2003; Rosenstein et al. 2001). Ethics education should be oriented to developing basic competence in identification of ethical issues in the practice of psychosomatic medicine and in deliberation aimed at satisfactory resolution of moral problems in patient care or research.

## Conclusion

---

The relationship between psychosomatic medicine and bioethics is rich and unique for both historical and conceptual reasons. The ethical issues considered in this chapter are often discussed in purely theoretical terms. We have attempted to illustrate some of the ways in which clinical considerations can color the expression and resolution of these issues as they are encountered at the bedside. All too often optimal patient care is hampered by the presence of psychiatric symptoms in the patient or systems problems among the health care team or family members. Practitioners of psychosomatic medicine are

ideally positioned to facilitate the resolution of both clinical problems and ethical dilemmas as they arise in an increasingly complex health care environment.

# 5 Psychological Responses to Illness

---

Mark S. Groves, M.D.

Philip R. Muskin, M.D.

**A CENTRAL TASK** of the psychiatrist working with the medically ill is to understand patients' subjective experiences of illness in order to design therapeutic interventions that modulate the patients' behavioral or emotional responses, decrease their distress, and improve their medical outcomes. In outpatient practice or in the general hospital, physicians witness tremendous diversity of emotional and behavioral responses to illness. Some individuals seem able to face devastating illnesses for which no cure is currently available with courage and a sense of humor (Cousins 1983; Druss 1995; Druss and Douglas 1988). Others, facing easily treatable illnesses, have difficulty overcoming intense emotions such as anger, fear, or hopelessness. Clinical experience and research demonstrate that illness variables such as severity, chronicity, or organ system involvement cannot predict an individual's response to any given medical illness (Lipowski 1975; Lloyd 1977; Sensky 1997; Westbrook and Viney 1982). Rather, it is in the realm of the individual's subjective experience of an illness that one can begin to understand his or her emotional and behavioral responses (Lipowski 1970; Lloyd 1977).

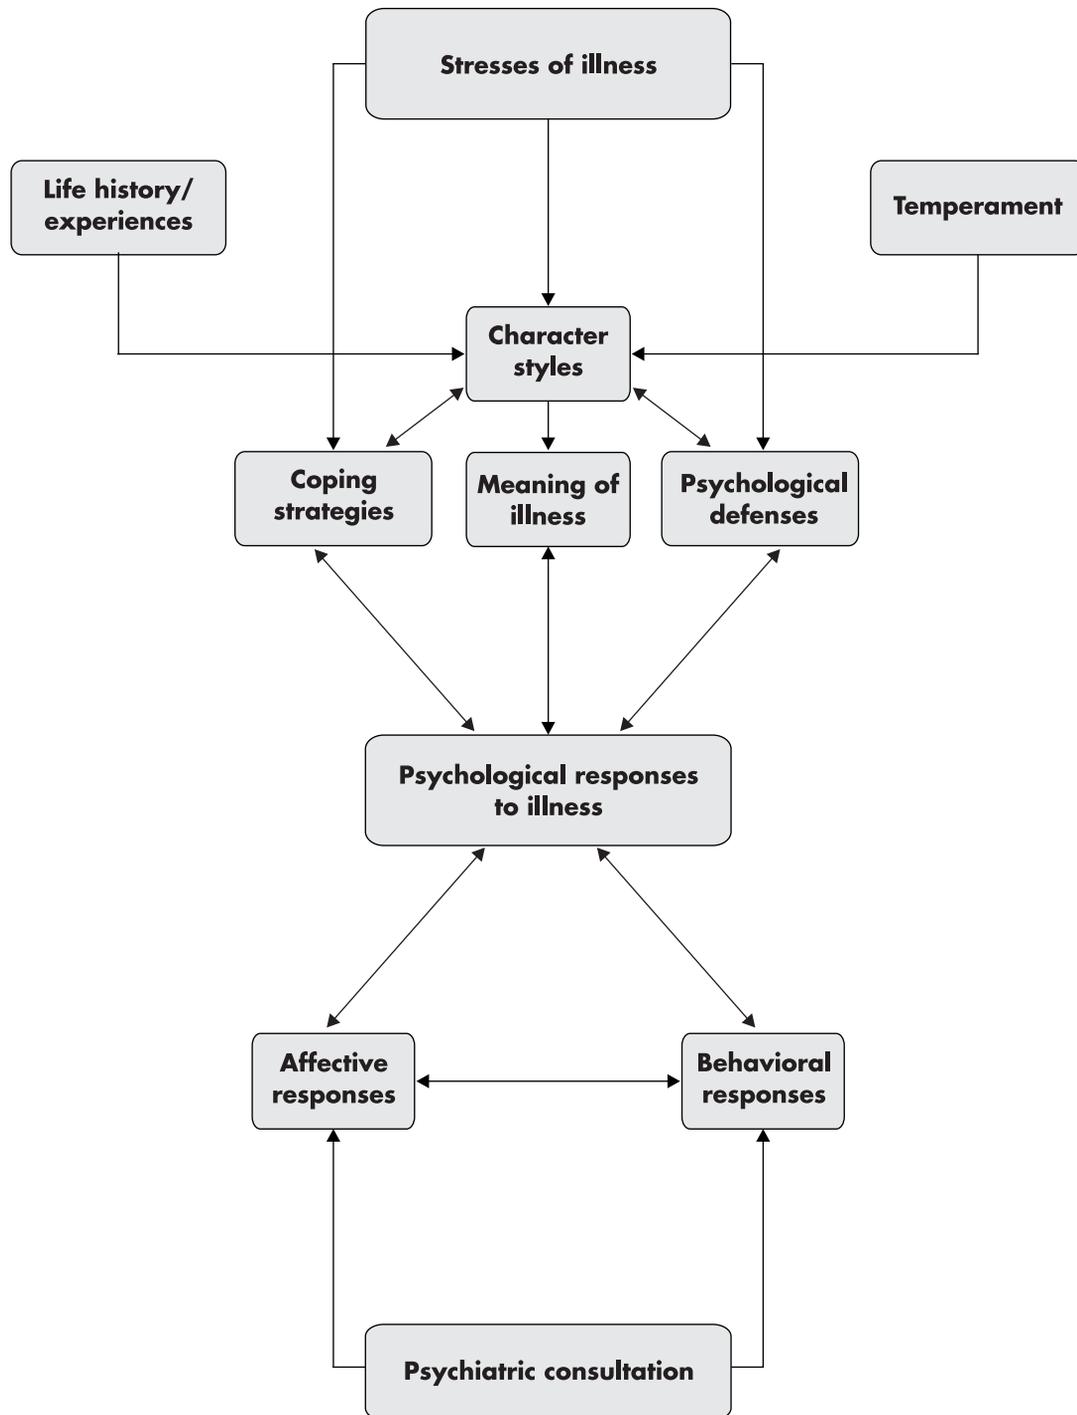

During the past few decades, there has been considerable work in the fields of health psychology and psychiatry attempting to explain the tremendous variety of individual responses to the stresses of illness and to account for these interindividual differences (see, e.g., Druss 1995; Geringer and Stern 1986; Kahana and Bibring 1964; Lazarus 1999; Perry and Viederman 1981; Peterson 1974; Strain and Grossman 1975; Verwoerd 1972). In this chapter, we provide a general overview of the stresses that accompany medical illness and hospitalization and

review some of the psychological, emotional, and behavioral responses that these stresses frequently elicit.

The concepts of stress, personality types, coping strategies, and defense mechanisms can be integrated into a framework that illustrates the complexity of an individual's behavioral or emotional responses to illness (Figure 5-1). This framework, adapted from the work of Lazarus and Folkman (Lazarus 1999; Lazarus and Folkman 1984), attempts to integrate the psychodynamic concepts of character style and intrapsychic defenses with other psychological concepts such as stress and coping. The importance of individual subjectivity is emphasized in this model through the placement of coping styles, defense mechanisms, personality types, and the appraised meaning of illness as central mediators of the behavioral and emotional responses to the stresses of medical illness.

This chapter does not focus solely on maladaptive responses to illness or psychopathology. A coping strategy or defense mechanism may be relatively maladaptive or ineffective in one context, but adaptive and effective in another (Penley et al. 2002). For example, the maladaptive use of denial by a patient just diagnosed with early breast cancer might lead to a long delay in seeking treatment (Zervas et al. 1993). In contrast, the adaptive use of denial by a man diagnosed with untreatable metastatic pancreatic cancer might enable him to maximize his quality of life in the months before his death (Druss 1995).

Psychiatrists do not see most people who become ill, nor will most patients' responses to their illnesses concern their physicians (Patterson et al. 1993; Perry and Viederman 1981). That does not mean, of course, that there is no psychological response to the illness. An overt display

**FIGURE 5–1.** Framework illustrating the complexity of an individual's behavioral or emotional responses to illness.

*Source.* Adapted from Lazarus 1999; Lazarus and Folkman 1984.

of emotion may or may not be appropriate for a patient's racial and cultural background. In addition, patients may feel discouraged from expressing their thoughts and feelings about their illness to family members or physicians.

The determination that a psychological response to illness is problematic must be based on the impact the response has on the patient, the patient's adherence to therapeutic plans, and the patient's social functioning.

There is no one correct way to characterize psychological responses to illness. Psychodynamic formulations, coping styles, and personality types offer different perspectives that may or may not be useful in understanding the response of a particular patient. Therefore, in this chapter, we provide an overview of the following topics without subscribing exclusively to any single theoretical framework: 1) the stresses of medical illness and hospitalization; 2) the influences of personality types, coping styles, and defense mechanisms on patients' subjective experiences of illness; 3) denial; 4) emotional responses to illness; and 5) behavioral responses to illness.

## Stresses of Medical Illness and Hospitalization

The stresses of medical illness and hospitalization are both very significant and numerous (Strain and Grossman 1975). In their frequently cited study from 1967, Holmes and Rahe surveyed many individuals from a number of countries, asking them to rate the impact of various events on their lives. These ratings generated a ranked list of life events based on relative impact, which was used to create the Social Readjustment Rating Scale (Lazarus 1999). In this list of stressors, "personal injury or illness" ranked sixth (after death of spouse, divorce, marital separation, death of close family member, and jail term). Some of the stresses accompanying illness are nearly universal, whereas others vary by illness and are more specific (Druss 1995). In this section, we discuss some of the most common stresses experienced by patients in medical settings.

Apart from medical illness, the hospital environment itself can be stressful (Gazzola and Muskin 2003; Kornfeld 1972). To many, the hospital is a frightening place associated with painful personal or family memories. Hospitalization separates patients from their usual environments and social supports; it is by its very nature isolating. The inpatient is asked to wear a hospital gown, which results in de-individualization, loss of control, and loss of privacy (Gazzola and Muskin 2003). The machines, intravenous lines, blood withdrawals, interactions with strangers, and neighboring ill patients all contribute to the stress of hospitalization regardless of the patient's specific illness. In addition, the hospital demands that the patient be largely dependent on others for the most basic tasks—a change that in itself can be very stressful for many individuals (Kornfeld 1972; Muskin 1995; Perry and Viederman 1981). Perry and Viederman (1981) described three successive (though at times overlapping) tasks that patients facing medical illness must go through: 1) acknowledgment to themselves and others that they

are ill; 2) regressive dependency on others for care; and 3) resumption of normal functioning after recovery. Perry and Viederman proposed that all three tasks bring their own stresses and must be confronted for the patient to successfully cope with the illness and the hospitalization (Perry and Viederman 1981).

On a nearly universal level, medical illness results in narcissistic injury, that is, it demands that patients reexamine their views of themselves (Strain and Grossman 1975). Although most people would not overtly claim that they are invulnerable to serious medical illness, they may hold such a belief consciously. Unconscious fantasies of invulnerability may be unknown until the person is injured or becomes ill. The development of a medical illness shatters any such conscious or unconscious beliefs. The sick patient may feel "defective," "weak," or less desirable to others. Strain and Grossman (1975) have described the effects of illness on the sense of self:

Sudden illness, hospitalization, and the threat of death undermine the universal, albeit irrational, beliefs that we are always capable, independent, and self-sufficient; that our bodies are indestructible; that we can control the world around us and we are the masters of our own destiny. These events challenge the infantile fantasy on which these beliefs are based—the fantasy that our omnipotent parents (and later, the doctor) can ensure our pain-free, pleasurable, and protected existence.... Similarly, the patient's belief in his autonomy and his conviction that he is "in control" of the world around him are challenged and reversed. (p. 25)

One determinant of the impact of an illness is whether it is acute or chronic (Verwoerd 1972). Although an acute, non-life-threatening illness gives the individual little time to adapt, its effects are short term. Chronic illnesses, however, require the individual to more permanently change his or her self-view. The challenges of chronic illness are ongoing and become a part of daily life for the individual. A change in identity or body image is disorienting and often anxiety producing; the patient's previously held self-conception is disturbed, shaken up, or shattered.

Separation from family or friends in the hospital or at home when one is ill produces isolation, disconnection, and stress (Heiskell and Pasnau 1991; Strain and Grossman 1975). This can precipitate conscious or unconscious fears of abandonment. The stress of separation and fear of abandonment are not only experienced by children. Newly diagnosed with AIDS, a 30-year-old Latina mother of three may fear rejection by her community and abandonment by her parents. Or, after many years of chemotherapy for metastatic thyroid cancer, a 55-year-old bank executive may elect to undergo another course of chemo-

therapy despite the low likelihood of success rather than seek hospice care because the latter would signify giving up. Although not desirous of more treatment, the patient might fear that his oncologist who had worked with him for a decade would abandon him.

The lack of privacy in the hospital environment or clinic places additional stresses on the patient (Kornfeld 1972). Bodily exposure evokes discomfort. Given only a thin gown to wear, patients may be subjected to repeated examinations by doctors, nurses, and medical students. Exposure of the most private aspects of life can occur (Perry and Viederman 1981). A woman presenting with symptoms of a sexually transmitted disease must give a detailed account of her sexual history, and a young patient brought in with acute chest pain and hypertension is asked about use of cocaine, an illegal drug. For the vulnerable individual, such experiences of exposure can evoke feelings of shame and thus require the clinician to be tactful and empathic to put the patient at ease and maintain a therapeutic alliance.

Beyond simple exposure, the medical environment often involves experiences of bodily invasion that are very stressful for the patient (Gazzola and Muskin 2003). From the more invasive experiences of a colonoscopy, the placement of a nasogastric tube, or tracheal intubation to ostensibly more benign procedures such as a fine-needle biopsy of a breast lump or a rectal examination, the fear and discomfort of such interventions are often not fully recognized by the physician for whom such procedures have become routine. Individuals certainly vary in their fears; for example, the victim of repeated physical or sexual abuse might be especially fearful of such experiences and require the doctor to use greater care and psychological preparation than usual.

Pain should not be overlooked as a profound stressor that should be dealt with aggressively (Heiskell and Pasnau 1991). Even the most highly adapted patient with effective coping skills and strong social support can be taxed to the limit by extreme pain. Psychiatrists are frequently asked to evaluate patients for depression and hopelessness. On discovering inadequately treated pain, the consultant can facilitate increased pain control, sometimes leading to full remission of hopelessness and depression without any additional intervention. Like pain, sleep disturbances are extremely common in the medically ill, with significant psychological impact. A patient's outlook, emotional expression, and ability to cope may shift dramatically when insomnia is remedied.

When illness leads to disability—whether due to pain, physical limitations, or psychological effects—the disability is an additional stressor that can have a profound impact on the patient's regular activities of daily life (West-

brook and Viney 1982). What was previously routine and required no conscious planning can become tremendously challenging, both psychologically and practically. For example, on the acute rehabilitation unit, patients are assisted in their efforts to learn to walk again. What was previously automatic has become incredibly difficult and requires new techniques, assistive devices, and the help of others. Disabilities frequently preclude the possibility of an immediate return to work. For many this is a significant loss because it removes the natural opportunities to feel productive, which had provided a sense of accomplishment. For many people, feelings of accomplishment, productivity, and usefulness are important for their self-image. Thus, self-esteem is damaged when they lose this important source of gratification.

Although only a small proportion of medical illnesses signify the imminent or near approach of death and force affected individuals to directly confront their mortality, even minor illnesses can evoke a sense of the fragility and impermanence of life (Perry and Viederman 1981). Psychiatrists for the medically ill are often called to consult on patients who are experiencing anxiety or conflicts facing death (or patients whose illnesses evoke these difficulties in caregivers). Patients may refuse to give do-not-resuscitate orders despite clear evidence that resuscitation would be futile, because they equate do-not-resuscitate orders with suicide, which is morally unacceptable to them (Sullivan and Youngner 1993). Facing mortality—whether in the near future or later—can force a person to deeply reflect on life and can shatter previously held dreams of the future. This can stir up regrets and evoke numerous emotions, as described in the work of Elisabeth Kubler-Ross (1969). The various emotions evoked by medical illness are discussed later in this chapter.

## Personality Types, Coping Styles, and Defense Mechanisms

---

There is great individual variation in responses to an environmental stressor such as receiving a diagnosis of cancer (Heim et al. 1993). Models of human behavior that only involve environmental stress and reflexive behavioral responses cannot account for this variation in responses and are therefore considered to have limited utility and explanatory power. Richard Lazarus has reviewed the historical transition in health psychology and other disciplines from the traditional stimulus → response model to the more contemporary stimulus → organism → response model, which emphasizes the importance of understanding individuals' *subjective* experiences (Lazarus 1999). It is

only through understanding individuals' subjective experiences that the interindividual differences in reactions to a stressor can be accounted for.

Although the stressors of a situation and the behavioral responses of the patient may be readily identified by the medical team, the subjective experiences of the patient by their very nature are more elusive and require inquiry. Psychiatrists are often asked to evaluate patients with problematic behavioral or emotional reactions to the hospital setting or to their illnesses. Medical doctors can usually identify the stressors involved—for example, the need for emergent amputation in a 55-year-old diabetic patient with a gangrenous toe. The stated reason for consultation often also identifies the behavioral or emotional responses judged to be problematic, such as displaying anger and threatening to sign out against medical advice. Consulting psychiatrists seek to understand patients' subjective experiences of illness to explain their emotional and behavioral responses and to design interventions to help patients (and their caregivers).

Research investigating subjective variables that influence an individual's response to a given stressor has generally focused on three main areas: personality types, coping styles, and defense mechanisms. These areas are addressed separately in this section.

## Personality Types

It is important to distinguish between the concepts of personality type or character style and personality disorder. As noted at the outset, this chapter is not concerned with psychopathology. Personality types may be understood as existing on a continuum with respective personality disorders (Oldham and Skodol 2000). In addition, most patients do not fit exclusively into one type but may exhibit characteristics of a number of personality types. Although the most accurate and complete understanding of personality may be achieved through a dimensional model, the characterization of discrete personality types is useful in highlighting differences and providing vivid prototypical examples. Much of the literature on personality types has been contributed by psychodynamic psychiatry. Although this rich literature continues to be tremendously useful for psychiatrists working in the medical setting, it is unfortunately often ignored because of the current emphasis on biological and descriptive psychiatry. In recognition of Kahana and Bibring's (1964) classic and still relevant paper "Personality Types in Medical Management," we have organized our discussion around the seven personality types they described (altering their terms to fit with more commonly used modern descriptions): 1) dependent, 2) obsessional, 3) histrionic, 4) masochistic, 5) paranoid, 6) narcissistic, and 7) schizoid.

What makes Kahana and Bibring's paper so valuable is its rich descriptions of these various personality types and the manner in which each type determines the individuals' subjective experiences of the meaning of illness.

Under conditions of stress, an individual's characteristic means of adapting to situations are heightened (Heiskell and Pasnau 1991; Kiely 1972). When confronted with the stress of a medical illness requiring hospitalization, the mildly obsessional patient might appear overly rigid or controlling. Similarly, a moderately dependent individual may appear "clingy" or excessively needy amid the acute stresses of hospitalization. Patients exhibiting extreme forms of these personality types can frustrate caregivers, often evoking intense negative emotions. It is important to recognize these countertransference responses, because they can be diagnostically useful tools. The negative emotions that patients with these extreme personality types evoke in the doctors and nurses may result in responses from the caregivers that aggravate the situation.

In another classic paper, "Taking Care of the Hateful Patient," Groves (1978) characterized four types of patients who most challenge physicians: dependent clingers, entitled demanders, manipulative help-rejecters, and self-destructive deniers. Groves also described the typical countertransference responses to each type and provided helpful tips on the management of these challenging patients. In this subsection, we integrate Groves's astute observations and descriptions of these four types with the seven personality types described by Kahana and Bibring.

Table 5-1 summarizes each of the seven personality types described in detail below—their characteristics, the meaning of illness to each type, frequent countertransference responses evoked among caregivers, and tips on management—drawing on the contributions of Geringer and Stern (1986), Groves (1978), Kahana and Bibring (1964), Muskin and Haase (2001), and others.

### *Dependent*

The dependent patient is needy and demanding, is seemingly unable to independently solve problems or self-soothe, and continually asks for help from others. Patients with a dependent personality may initially evoke positive feelings from their physicians and are more likely to adhere to treatment recommendations (Bornstein 1994). The physician may enjoy feeling needed or powerful, much as a parent might feel toward a child. The dependent patient, however, can feel "sticky" or seem to have insatiable needs (Miller 2001), making it difficult for the caregiver to leave the room or end an interview. Such patients typically have limited frustration tolerance. His-

**TABLE 5-1. Personality types**

<b>Type</b>	<b>Characteristics</b>	<b>Meaning of illness</b>	<b>Countertransference responses</b>	<b>Tips on management</b>
Dependent	Needy, demanding, clingy Unable to reassure self Seeks reassurance from others	Threat of abandonment	Positive: doctor feels powerful and needed Negative: doctor feels overwhelmed and annoyed; may try to avoid patient	Reassure within limits Schedule visits Mobilize other supports Reward efforts toward independence Avoid tendency to withdraw from patient
Obsessional	Meticulous, orderly Likes to feel in control Very concerned with right/wrong	Loss of control over body/emotions/impulses	May admire When extreme: anger—a “battle of wills”	Try to set routine Give patient choices to increase sense of control Provide detailed information and “homework” Foster collaborative approach/avoid battle of wills
Histrionic	Entertaining Melodramatic Seductive, flirtatious	Loss of love or loss of attractiveness	Anxiety, impatience, off-putting Erotic; finds patient attractive	Strike a balance between warmth and formality Maintain clear boundaries Encourage patient to discuss fears Do not confront head-on
Masochistic	“Perpetual victim” Self-sacrificing martyr	Ego-syntonic Conscious or unconscious punishment	Anger, hate, frustration Helplessness, self-doubt	Avoid excessive encouragement Share patient’s pessimism Deemphasize connection between symptoms and frequent visits Suggest that patient consider treatment as another burden to endure, or emphasize treatment’s positive effect on loved ones
Paranoid	Guarded, distrustful Quick to blame or counterattack Sensitive to slights	Proof that world is against patient Medical care is invasive and exploitative	Anger, feeling attacked or accused May become defensive	Avoid defensive stance Acknowledge patient’s feelings without disputing them Maintain interpersonal distance; avoid excessive warmth Do not confront irrational fears
Narcissistic	Arrogant, devaluing Vain, demanding	Threat to self-concept of perfection and invulnerability Shame evoking	Anger, desire to counterattack Activation of feelings of inferiority, or enjoyment of feeling of status of working with an important patient	Resist the desire to challenge patient’s entitlement Reframe entitlement to foster treatment adherence Take a humble stance, provide opportunities for patient to show off, offer consultations if appropriate
Schizoid	Aloof, remote Socially awkward Inhibited	Fear of intrusion	Little connection to patient Difficult to engage	Respect patient’s privacy Prevent patient from completely withdrawing Maintain gentle, quiet interest in patient Encourage routine and regularity

*Source.* Derived in large part from Geringer and Stern 1986; Kahana and Bibring 1964; Perry and Viederman 1981.

torically described as “oral” personalities, the extreme of this personality type corresponds to a DSM-IV-TR diagnosis of dependent personality disorder and sometimes borderline personality disorder (American Psychiatric Association 2000; Geringer and Stern 1986).

For the patient with a dependent personality, illness evokes an increased desire for care from others. Illness stimulates the patient’s fear of abandonment (Perry and Viederman 1981). The person may feel that no one cares about him or her or may frantically cling to caregivers. Extremes of this personality style fit Groves’s (1978) description of dependent clingers. These patients evoke aversion in their caregivers. The caregiver becomes overwhelmed by the patient’s neediness, may feel manipulated, and may wish to avoid the patient, thus confirming the patient’s fear of abandonment (Groves 1978). Tips on managing patients with this personality style, whether in a mild form or at the extreme, include appropriate reassurance that they will be taken care of, setting firm limits regarding what needs will be met, and setting a specific schedule of visits (e.g., 20 minutes three times a week) to set clear expectations regarding the doctor’s time and availability (Miller 2001; Perry and Viederman 1981). For the overdemanding patient, it can be helpful to tactfully convey that behaviors such as incessantly ringing the call bell may have an opposite effect than what is intended and can lead caregivers to avoid the patient (Perry and Viederman 1981).

### ***Obsessional***

Individuals with an obsessional personality style are meticulous and orderly and like to feel in control. They place a strong emphasis on rationality, can be self-righteous at times, and are concerned with issues of right and wrong. These patients may be emotionally reserved and focus on details, sometimes to such an extent as to miss the broader picture. Ritual and regularity of schedule are important to them (Miller 2001). They are easily frustrated by the unpredictability of the hospital environment. Patients at the extreme end of the spectrum with this personality style might meet DSM-IV-TR criteria for obsessive-compulsive personality disorder.

Patients with an obsessional personality style will generally want a lot of information from their physicians regarding their medications, diagnoses, tests, etc. The physician may be pleased by the patient’s desire to learn about his or her illness and its treatments. Under extreme stress, however, the patient may become increasingly rigid and inflexible, and at times the obsessional patient’s only way to feel a sense of control is by refusing treatment or procedures (Kahana and Bibring 1964). A defiant refusal of procedures frequently leads to psychiatric consultation.

For example, the obsessional patient who is frustrated by the unpredictability of his hospital care and is angry after hours of fasting for an endoscopy that is subsequently canceled may refuse to allow a phlebotomist to draw his blood the following morning or refuse the second attempt to send him to the endoscopy suite. Conflicts between the extremes of compliance and defiance are common for these individuals.

Illness is experienced by the obsessional patient as a loss of control over the body, and it evokes a fear of loss of control over emotions or impulses (Heiskell and Pasnau 1991; Kahana and Bibring 1964; Miller 2001). When an inflexible or obstinate patient with this personality style confronts the physician, the physician may be tempted to engage in a battle of wills or try to exert greater control over the patient’s treatment. Such a response, however, becomes counterproductive and often provokes the patient to resist even harder as in a tug-of-war. Instead, it may be helpful to offer detailed explanations of the procedures and tests and the reasons they are necessary. This emphasizes a collaborative approach, encouraging patients to actively participate in their care. Wherever possible, it is helpful to give patients choices and input in their care. This makes the patient a partner, not an opponent (Gazzola and Muskin 2003). Giving patients information, assigning them “homework,” and providing opportunities for their input on decisions, where appropriate, will enable them to feel more in control of their care and will decrease anxiety and interpersonal friction (Muskin and Haase 2001).

### ***Histrionic***

Patients with a histrionic personality style can be entertaining, engaging, and at times seductive. This can be charming at times, or it can be uncomfortable or embarrassing for physicians (Miller 2001). Histrionic patients crave attention, approval, and admiration and tend to avoid anxiety-provoking situations through the use of denial. Illness in the patient with a histrionic personality style is experienced as a threat to the patient’s masculinity or femininity (Geringer and Stern 1986). Illness activates such patients’ fear of loss of love or attractiveness (Kahana and Bibring 1964; Strain and Grossman 1975).

The physician treating the histrionic patient should try to strike a balance between warmth and formality. Maintaining clear boundaries is essential, but an overly formal style will activate the patient’s fear of loss of attractiveness or lovability (Heiskell and Pasnau 1991; Miller 2001). Encouraging the patient to discuss his or her fears will help bring to consciousness the anxiety that the patient is attempting to avoid. It is important, however, not to push patients too hard—a supportive and patient stance

that gently encourages patients to voice fears when ready will be most helpful. “Confronting denial” head-on usually is counterproductive, as discussed in greater detail later in this chapter.

### ***Masochistic***

Patients with a masochistic personality style seem to be perpetual victims and readily recount their woes, experiencing themselves as self-sacrificing martyrs. One typically finds that such patients had miserable, abusive childhoods in which the experiences of physical illness paradoxically may have been bright spots, the only times they may have felt truly loved or cared for by parents or others (Heiskell and Pasnau 1991). The experience of illness, in part, provides reassurance to these patients that they will be able to maintain the attention and care of their physicians. Kahana and Bibring (1964) concretize this wish in the unspoken statement “You have to love me because I suffer so terribly.” The patient may feel that the illness (consciously or unconsciously) is punishment for real or fantasized wrongdoings. Other patients may hold an unconscious wish to defeat their physicians (Douglas and Druss 1987; Heiskell and Pasnau 1991). The masochistic personality style can be particularly resistant to change.

Patients with the masochistic personality style may present with somatoform or factitious disorders. When the masochistic patient has no response (or a negative response) to treatment, or the physician’s attempts to offer reassurance have no impact, the physician may become extremely frustrated. Encouragement and reassurance may actually have a paradoxical effect, provoking the patient to feel more pessimistic and leading to a worsening of symptoms. Those with an extreme version of this personality style have been described as “help-rejecters” (Groves 1978). They evoke feelings of irritation, depression, self-doubt, and hopelessness in their caregivers, who themselves may believe that such patients engineer their own misfortunes. The idea that someone could obtain psychological benefit from suffering is a concept that is difficult to understand, especially for physicians and other health care professionals.

Managing the patient with a masochistic personality should involve regularly scheduled follow-up visits irrespective of symptoms. It is important to deemphasize the connection between severity of symptoms and frequency of physician contact (Perry and Viederman 1981). Rather than encourage and reassure these patients, it is useful to acknowledge the patients’ suffering and to “share their pessimism” (Groves 1978). It is sometimes of benefit for the physician to express to the patient an understanding that the illness and medical treatments are yet another burden for the patient to endure (Gazzola and Muskin

2003). It can also be helpful to emphasize the treatment’s potential positive effect on others dear to the patient. This may reframe the treatment as another opportunity for the patient to suffer for the benefit of others (Heiskell and Pasnau 1991).

### ***Paranoid***

The paranoid patient is not generally a favorite of the physician. This patient maintains a guarded, distrustful stance; is quick to blame; and readily feels attacked (Heiskell and Pasnau 1991). Patients with a paranoid style do not forgive easily and may maintain lists of grievances. When these patients feel slighted, they tend to counterattack. It may not take much to provoke them, because they are extremely sensitive to anything experienced as a slight. When ill, patients with a paranoid personality style may blame others, and they may conceive of the illness as proof that the world is against them. They are prone to feeling hurt, invaded, or exploited by seemingly innocuous medical procedures (Miller 2001). Stress increases such patients’ tendency to be suspicious, guarded, or controlling. This results in a request for psychiatric consultation because these patients evoke feelings of anger in their caregivers. They refuse procedures or tests, threaten to sign out against medical advice, and accuse the staff of doing things against them.

The physician assigned the task of treating a patient with this personality style often feels accused. If the physician is not aware of this, it can lead to defensive countertransference (Kahana and Bibring 1964). This may appear as a temptation to argue with the patient or as an attempt to prove the patient wrong. Taking a defensive stance will be counterproductive and can in essence prove the paranoid patient right; a defensive response will only increase the patient’s paranoia. A more helpful approach is to acknowledge the patient’s feelings without dispute or agreement, explaining in detail the justification for the treatments. Irrational fears often should not be confronted head-on or challenged; the patient will judge caregivers more on their actions and predominant emotional stance than on their words. Avoiding excessive warmth is helpful, as is maintaining sufficient interpersonal distance (Heiskell and Pasnau 1991). A calm, firm, direct stance is preferable to an angry, defensive stance or an intrusive, overly warm stance.

### ***Narcissistic***

Patients with a narcissistic personality style are typically easily recognized. Arrogant, devaluing, vain, and demanding, these patients can often be identified by one’s immediate reaction. The narcissistic patient frequently begins the interview inquiring about the physician’s title and

rank. The patient may refuse to be examined by medical students, residents, or junior faculty members. These patients will devalue those believed to be inferior to them and will idealize the few people perceived to be highest in status. At the extreme, some patients will meet the criteria for narcissistic personality disorder. The patient's self-experience is frequently not validated by actual status in the world.

Narcissistic patients will experience an illness as a threat to their self-concept of perfection and invulnerability (Heiskell and Pasnau 1991; Kahana and Bibring 1964). Under such a threat, the patient's characteristic defense of grandiosity will be heightened. The physician or caregiver who is angered by the patient's devaluations and entitlement will be strongly tempted to put the patient in his or her place (Miller 2001). The psychiatric consultant who is called to assist in the management of a narcissistic patient may hear angry staff members say, "Who does he think he is? He's no better than anyone else!" and hear them put down the patient. Groves (1978) described patients at the extreme of this style as "entitled demanders," noting the intense feelings of anger and the desire to counterattack that these patients can evoke in their caregivers. The narcissistic patient can activate the physician's own feelings of inferiority, adding to the desire to avoid or attack the patient. The "power" of narcissistic V.I.P. patients can be very seductive to physicians, who may be tempted to cater to the unreasonable demands with the fantasy of some special status.

Managing patients with a narcissistic personality can be challenging. Resisting the desire to challenge the patient's entitlement is crucial in forming a therapeutic alliance. According to Groves (1978), "Entitlement is the patient's religion and should not be blasphemed." Although it is counterintuitive, the physician should not reflexively support the patient's entitlement but should reframe it in such a way as to foster the patient's adherence to the treatment regimen and working with the team. Frequent use of phrases such as "You deserve the best" can be very helpful (Muskin and Haase 2001). Taking a humble stance can be effective: "Understandably, Mr. Jones, you want the best care and certainly deserve no less—unfortunately, although we strive to provide you with the best care possible, we aren't perfect. We ask your indulgence to work with us so that we can give you the care that you deserve." Such statements can at times have a dramatic effect if delivered genuinely. Judicious use of "narcissistic strokes"—that is, providing opportunities for the patient to brag or show off—can assist in building rapport. Appropriate acknowledgment of mistakes made by the team and offering consultation by specialists can also assist in the management of these challenging patients. If the patient feels rec-

ognized as someone unique and special, he or she will feel reassured and will have less need to make demands (Heiskell and Pasnau 1991). The psychiatric consultant can assist members of the team not to take the patient's devaluations personally, but to understand them as the patient's frantic efforts to maintain self-esteem. If the caregivers can avoid feeling personally attacked, they will find it easier to work with these patients and will be less likely to engage in a counterattack.

### *Schizoid*

Patients with a schizoid personality are seen as aloof, remote, and socially awkward or inhibited; they frequently avoid obtaining medical care until it is absolutely necessary (Kahana and Bibring 1964; Miller 2001). The physician charged with the care of the schizoid patient will find it difficult to build rapport or engage the patient in treatment.

At one end of the spectrum of this personality style are schizoid and avoidant personality disorders (Geringer and Stern 1986). These two personality disorders are distinguished in part by the apparent interest in social contact. The patient with schizoid personality disorder seems uninterested in social contact, whereas the patient with avoidant personality disorder desires social contact but avoids it out of fear of rejection. In the consultation setting, similar management tips apply to either of these two personality disorders and to patients who fall within this spectrum. In general, illness and hospitalization evoke a fear of intrusion and intense anxiety (Geringer and Stern 1986; Heiskell and Pasnau 1991). The physician should respect the patient's need for privacy but should prevent the patient from withdrawing completely (Gazzola and Muskin 2003). Maintaining a quiet, gentle interest in the patient and encouraging a regular, expectable routine can reassure the patient that he or she is safe and will not be intruded on (Miller 2001). Typically such patients have a fragile sense of self and therefore warrant gentle care, but care at a distance.

### *Summary of Personality Types*

These seven prototypical personality styles cannot claim to capture every patient, and many patients fit into multiple categories. Understanding the common features of each style can aid the consulting psychiatrist. Knowing how each personality style experiences illness will inform interactions with such patients. Close monitoring of one's countertransference can also assist in identifying the patient's predominant personality style (e.g., feeling inferior with narcissistic patients or feeling attacked by paranoid patients). Knowledge of these personality types can assist

the psychiatric consultant in educating the medical team about the proper management of these challenging patients and in assisting them not to react in counterproductive ways. At times, through understanding of the patient's personality style, the consulting psychiatrist is able to achieve rapid and remarkable therapeutic effects by choosing an appropriate intervention. Such effective interventions are impressive to nonpsychiatric physicians and staff members and demonstrate the utility of psychodynamic understanding in the psychiatric care of the medically ill.

## Coping Styles

In the previous subsection, we illustrated how taking into account personality types can account for some of the interindividual variation in response to the stressors of illness. How individuals cope is another rich area of investigation (Jensen et al. 1991; Lazarus 1999; Penley et al. 2002), and problems in coping with illness have been shown to be a frequent reason for psychiatric consultation (Strain et al. 1993). Health psychologists have developed the concepts of appraisal (the assignment of meaning or value to a particular thing or event) and coping (Lazarus and Folkman 1984). An extensive body of literature developed over the past few decades has examined these processes among patients in health care settings. This psychological literature is often underrecognized by the psychiatric and medical communities but is extremely useful and can complement psychodynamic perspectives.

Coping can be defined as "thoughts and behaviors that the person uses to manage or alter the problem that is causing distress (problem-focused coping) and regulate the emotional response to the problem (emotion-focused coping)" (Folkman et al. 1993, pp. 409–410). A comprehensive review of the literature on the many defined coping strategies in medical illness is beyond the scope of this chapter. The reader is referred to the excellent reviews by Lazarus (1999) and Penley et al. (2002). Some important empirical generalizations that have emerged from decades of research on coping are discussed in this section (Lazarus 1999).

### *Use of Multiple Coping Styles in Stressful Situations*

Folkman and colleagues (1986) identified eight categories of coping styles in a factor analysis of the Ways of Coping Questionnaire–Revised: 1) confrontative coping (hostile or aggressive efforts to alter a situation), 2) distancing (attempts to detach oneself mentally from a situation), 3) self-controlling (attempts to regulate one's feelings or actions), 4) seeking social support (efforts to seek emotional

support or information from others), 5) accepting responsibility (acknowledgment of a personal role in the problem), 6) using escape-avoidance (cognitive or behavioral efforts to escape or avoid the problem or situation), 7) planful problem solving (deliberate and carefully thought-out efforts to alter the situation), and 8) conducting positive reappraisal (efforts to reframe the situation in a positive light) (Folkman et al. 1986; Penley et al. 2002). Research has shown that patients use multiple coping strategies in any given situation (Lazarus 1999). Individuals often prefer or habitually use certain strategies over others, but generally multiple strategies are used for a complex stressful situation such as a medical illness or hospitalization. People employ some trial and error in the selection of coping style (Lazarus 1999).

### *Coping as a Trait and a Process*

Preferred coping styles are often tied to personality variables; sometimes they can be viewed as traits as well as processes (Heim et al. 1997; Lazarus 1999). Therefore, it is useful to ask patients how they previously dealt with very stressful situations. This can provide useful information for the physician, because patients are likely to use strategies in the present that are similar to those they used in the past, whether they were effective or not.

Research on women with breast cancer at various stages of illness has demonstrated that coping strategies may change as the nature of the stressor changes (Heim et al. 1993, 1997). For example, on initial detection of breast cancer, a woman may seek social support from her friends and spouse to cope with the uncertainties of her situation. Later, after lumpectomy and staging, she might shift her primary coping strategy to planful problem solving—a plan to follow up regularly for chemotherapy and to fully adhere to her oncologist's prescription of tamoxifen.

### *Problem-Focused Coping Versus Emotion-Focused Coping*

One way in which various coping styles can be organized is whether they are problem focused or emotion focused. Research has shown that patients will tend to choose problem-focused coping strategies when they appraise the situation as being changeable or within their control (Folkman et al. 1993; Schussler 1992). In conditions considered out of their control, patients may choose emotion-focused coping styles (Folkman et al. 1993; Schussler 1992). In the medical setting, consulting psychiatrists can help change the patient's appraisal of the situation and encourage the patient to choose more adaptive coping styles. For example, if a patient newly diagnosed with di-

abetes mellitus misperceives high blood glucose as being unchangeable or out of his control, he might choose an emotion-focused coping strategy such as avoidance or denial. In educating this patient about how treatable hyperglycemia can be, the physician could encourage the patient to change his coping strategy to a problem-focused strategy such as making dietary changes or increasing exercise.

### *Variations in Usefulness of Coping Strategies Over Time*

Coping is a powerful mediator of how a patient responds emotionally to a given stressor (Folkman and Lazarus 1988; Lipowski 1970). Coping strategies have also been demonstrated to have different effects on health outcomes—some positive, others negative (see Penley et al. 2002 for a meta-analysis on this research). Although some coping strategies may be considered more effective than others, they vary in usefulness depending on the situation. A strategy that is initially effective in dealing with a stressor may no longer be effective when the nature of the stressor changes (Penley et al. 2002). The discussion of maladaptive versus adaptive denial under “Denial” below illustrates this point.

### *Relationship Between Coping Styles and the Meaning of Illness*

Lipowski (1970) described eight “illness concepts”: 1) illness as challenge, 2) illness as enemy, 3) illness as punishment, 4) illness as weakness, 5) illness as relief, 6) illness as strategy, 7) illness as irreparable loss or damage, and 8) illness as value (Lipowski 1970). Lipowski proposed that a patient’s choice of coping strategy is partially dependent on the underlying illness concept. In a study of 205 patients with chronic physical illness, the descriptors “illness as challenge/acceptance” and “illness as value” were found to be related to “adaptive coping and mental well-being.” Conversely, “illness as enemy,” “illness as punishment,” and “illness as relief” were associated with psychological symptoms and maladaptive coping (Schusler 1992).

## Defense Mechanisms

The psychoanalytic term *defense mechanism* was first described in the literature by Anna Freud in *The Ego and the Mechanisms of Defense* (Freud 1948). Defense mechanisms are automatic psychological processes by which the mind confronts a psychological threat (e.g., the fear of death or deformity) or conflict between a wish and the demands of reality or the dictates of conscience. There is

a rich history of this psychoanalytic concept that is beyond the scope of this chapter. Although there is some overlap of the concept of coping with that of defenses, the psychological concept of coping is more behavioral; it involves action (e.g., seeking social support, or productive problem solving) and is generally a conscious experience. Defenses are usually conceptualized as intrapsychic processes that are largely out of the individual’s awareness. In *The Wisdom of the Ego*, George Vaillant (1993) emphasized the usefulness of the concept of defenses:

Our lives are at times intolerable. At times we cannot bear reality. At such times our minds play tricks on us. Our minds distort inner and outer reality so that an observer might accuse us of denial, self-deception, even dishonesty. But such mental defenses creatively rearrange the sources of our conflict so that they become manageable and we may survive. The mind’s defenses—like the body’s immune mechanisms—protect us by providing a variety of illusions to filter pain and allow self-soothing. (p. 1)

He further noted that

[a] clearly understood nomenclature of defenses not only enables us to understand adaptation to stress; it also offers us a means of uncoding, of translating if you will, much of what seems irrational in human behavior. (p. 28)

A basic understanding of the concept of defense and various defense mechanisms can provide the psychiatrist in the medical setting with another lens through which to examine a patient and to predict or explain the patient’s emotional or behavioral responses to medical illness.

Vaillant (1993) identified a number of aspects of defenses:

1. *Defenses are generally outside of awareness of the individual or unconscious*—They enable the mind to “play tricks on” the individual to lessen distress or conflict.
2. *Defenses by nature distort inner and outer reality*—As is emphasized below, the degree of this distortion varies among various defense mechanisms, as does the focus of the distortion: some defenses distort a warded-off internal drive or desire, whereas others distort the external reality or interpersonal situation.
3. *Defenses can appear strange or overt to the observer while going unnoticed by the subject*—The psychiatrist must decide whether directing the patient’s awareness to his or her use of certain defenses is indicated.
4. *Defenses are creative*—The mind creates a new perception distinct from reality.

5. *Defenses involve psychological conflict*—Through them the mind attempts to manage the often conflicting demands of inner wishes, conscience, other people, and reality.
6. *Defenses are adaptive and are not all pathological*—Some defenses are more adaptive than others, and the use of defenses is an inherent property of the mind.

Vaillant proposed a hierarchy of defense mechanisms ranked in four levels of adaptivity: psychotic, immature (or borderline), neurotic, and mature (Vaillant 1993). This hierarchy is based on the degree to which each defense distorts reality and how effectively it enables the expression of wishes or needs without untoward external consequences. Patients often employ many different defense mechanisms in different situations or under varying levels of stress. When a patient inflexibly and consistently uses lower-level defenses, this is often consistent with a personality disorder. Table 5-2 lists major defense mechanisms grouped into four levels.

The *psychotic defenses* are characterized by the extreme degree to which they distort external reality. Patients in psychotic states usually employ these defenses; psychotherapy is generally ineffective in altering them, and antipsychotic medication may be indicated.

The *immature defenses* are characteristic of patients with personality disorders, especially the cluster B personality disorders such as borderline personality disorder. Vaillant (1993) emphasized how many of these defenses are irritating to others and get under other people's skin. "Those afflicted with immature defenses often transmit their shame, impulses and anxiety to those around them" (p. 58).

In contrast to the immature defenses, the *neurotic defenses* do not typically irritate others and are more privately experienced—they are less interpersonal and often involve mental inhibitions. They distort reality less than immature or psychotic defenses and may go unnoticed by the observer. With appropriate tact and timing, neurotic defenses can be effectively interpreted in exploratory psychotherapy when it is considered appropriate by the treating psychiatrist. "Over the short haul, neurotic defenses make the user suffer; immature defenses make the observer suffer" (Vaillant 1993, p. 66).

The *mature defenses* "integrate sources of conflict... and thus require no interpretation" (Vaillant 1993, p. 67). The use of mature defenses such as humor or altruism in the confrontation of a stressor such as medical illness often earns admiration from others and can be inspirational. Such mature defenses are not interpreted by the psychiatrist but are praised. These defenses maximize expression of drives or wishes without negative consequences or distortion of reality.

## Denial

Denial is an important and complex concept and a common reason that physicians request psychiatric consultation. Weisman and Hackett (1961) defined denial as "the conscious or unconscious repudiation of part or all of the total available meanings of an event to allay fear, anxiety, or other unpleasant affects" (p. 232). It is to be distinguished from a lack of awareness due to a cognitive deficit such as anosognosia or from the limited insight of a patient with chronic schizophrenia. Psychiatrists are often called to see a patient "in denial" about a newly diagnosed illness and may be asked to assess the patient's capacity to consent to or refuse certain treatments. As discussed below, denial can be adaptive, protecting the patient from being emotionally overwhelmed by an illness, or maladaptive, preventing or delaying diagnosis, treatment, and lifestyle changes.

Denial seems to be a very personal response that is prone to a double standard: we are often capable of—even comfortable with—ignoring our own denial but consider other people's denial abnormal. A smoker may minimize his risk of lung cancer, noting that only a small percentage of smokers get the disease, yet simultaneously criticize his son's obesity as a risk factor for diabetes. Physicians urge their patients to adopt healthy lifestyles yet may routinely overwork and get too little sleep (see Gaba and Howard 2002).

Psychiatrists are most likely to be called on when the patient's denial makes the physician uncomfortable, but health care providers use the term *denial* too often in a loose and inaccurate way (Goldbeck 1997; Havik and Maeland 1988; Jacobsen and Lowery 1992). A physician's statement that a patient is "in denial" may refer to a number of different situations: 1) the patient rejects the diagnosis, 2) the patient minimizes symptoms of the illness or does not seem to appreciate its implications, 3) the patient avoids or delays medical treatment, or 4) the patient appears to have no emotional reaction to the diagnosis or illness (Goldbeck 1997). The first task of the psychiatric consultant is to determine more specifically what the referring physician means by "denial."

The severity of denial varies by the nature of what is denied, by the predominant defense mechanisms at work (e.g., suppression, repression, psychotic denial), and by the degree of accessibility to consciousness (Goldbeck 1997). Patients using the mature defense of *suppression* in confronting an illness are not truly in denial. Rather, they have chosen to put aside their fears about illness and treatment until a later time. Their fears are not deeply unconscious but are easily accessible if patients choose to access them. These patients typically accept treatment,

**TABLE 5-2. Defense mechanisms**

<b>Mature defenses</b>	
<b>Suppression</b>	Consciously putting a disturbing experience out of mind
<b>Altruism</b>	Vicarious but instinctively gratifying service to others
<b>Humor</b>	Overt expression of normally unacceptable feelings without unpleasant effect
<b>Sublimation</b>	Attenuated expression of drives in alternative fields without adverse consequences
<b>Anticipation</b>	Realistic planning for inevitable discomfort
<b>Neurotic defenses</b>	
<b>Repression</b>	Involuntary forgetting of a painful feeling or experience
<b>Control</b>	Manipulation of external events to avoid unconscious anxiety
<b>Displacement</b>	Transfer of an experienced feeling from one person to another or to something else
<b>Reaction formation</b>	Expression of unacceptable impulses as directly opposite attitudes and behaviors
<b>Intellectualization</b>	Replacing of feelings with facts/details
<b>Rationalization</b>	Inventing a convincing, but usually false, reason why one is not bothered
<b>Isolation of affect</b>	Separating a painful idea or event from feelings associated with it
<b>Undoing</b>	Ritualistic “removal” of an offensive act, sometimes by atoning for it
<b>Immature defenses</b>	
<b>Splitting</b>	Experiencing oneself and others as all good or all bad
<b>Idealization</b>	Seeing oneself or others as all-powerful, ideal, or godlike
<b>Devaluation</b>	Depreciating others
<b>Projection</b>	Attributing unacceptable impulses or ideas to others
<b>Projective identification</b>	Causing others to experience one’s unacceptable feelings; one then fears or tries to control the unacceptable behavior in the other person
<b>Acting out</b>	Direct expression of an unconscious wish or impulse to avoid being conscious of the affect, and thoughts that accompany it
<b>Passive aggression</b>	Expressing anger indirectly and passively
<b>Intermediate denial</b>	Refusal to acknowledge painful realities

**TABLE 5-2. Defense mechanisms (continued)**

<b>Psychotic defenses</b>	
<b>Psychotic denial</b>	Obliteration of external reality
<b>Delusional projection</b>	Externalization of inner conflicts and giving them tangible reality—minimal reality testing
<b>Schizoid fantasy</b>	Withdrawal from conflict into social isolation and fantasizing

face their illnesses with courage, and do not let their emotions overtake them. Such “denial” is considered adaptive (Druss and Douglas 1988). Many authors have proposed that some denial is perhaps necessary for very effective coping with an overwhelming illness (see discussions in Druss 1995; Ness and Ende 1994; Schussler 1992; Wool 1988).

In contrast to suppression, the patient using *repression* as a defense is generally unaware of the internal experience (fear, thought, wish, etc.) being warded off. Repressed thoughts or feelings are not easily accessible to consciousness. Such a patient may feel very anxious without understanding why. For example, a 39-year-old man whose father died of a myocardial infarction at age 41 may become increasingly anxious as his 40th birthday approaches without being aware of the connection.

When it is more severe and pervasive, denial can cause patients to flatly deny they are ill and to never seek health care. If they are already in care, they decline treatment or are nonadherent. Repeated attempts by the medical team to educate them about their illness have no impact. Extreme denial may be severe enough to distort the perception of reality, sometimes described as *psychotic denial*. Most patients with pervasive denial of illness are not psychotic in the usual sense of the word and should be distinguished from those who are. The latter usually have a psychotic illness such as schizophrenia and may pay no attention to signs or symptoms of illness or may incorporate them into somatic delusions. Psychotic patients who deny illness usually do not conceal its signs; others often readily recognize they are ill. In contrast, nonpsychotic patients with pervasive denial often conceal signs of their illness from themselves and others. For example, a nonpsychotic woman with pervasive denial of a growing breast mass avoided medical care and undressing in front of others and kept a bandage over what she regarded as a bruise. Although pregnancy is not a medical illness, a dramatic example of pervasive (sometimes psychotic) denial is the denial of pregnancy (see Chapter 33, “Obstetrics and Gynecology”).

Strauss et al. (1990) proposed a new DSM diagnosis, maladaptive denial of physical illness, to describe patients whose denial of illness is maladaptive. How does one determine whether denial is adaptive or maladaptive? For the woman with a growing breast tumor, denial is clearly maladaptive because it has prevented her from receiving potentially life-saving treatment. In other situations denial may be quite adaptive. In determining the adaptivity of a patient's denial, it is important to answer the following questions (Goldbeck 1997):

1. Does the patient's denial impair or prevent the patient from receiving necessary treatment or lead to actions that endanger the patient's health? If so, then the denial is deemed maladaptive. In cases in which no effective treatment is available, the denial might be judged as adaptive to the extent that it decreases distress and improves quality of life, or it may be maladaptive if it prevents critical life planning (e.g., a single parent with little support and a terminal illness who has made no plans for his or her young children).
2. Which component of denial—denial of the facts of illness, denial of the implications of the illness, or denial of the emotional reaction to illness—does the patient exhibit? The latter two components of denial are not as maladaptive as the first component and may be adaptive in some situations. Denying the full implications of a disease, such as inevitable death, might be adaptive because it facilitates hope and improved quality of life. Likewise, denial of certain emotional reactions to the illness such as fear or hopelessness might enable a patient to stay motivated through a completed course of treatment.
3. Is the denial a temporary means of "buying time" to gradually accept a diagnosis so that the immediate impact is not so overwhelming, or has the denial been so protracted that it has prevented adaptive action? Many patients are unable to immediately accept a diagnosis, and denial may be a way for them to slowly adjust their emotional distress during a period of gradual acceptance. In many situations this would be considered adaptive.

Even when denial is adaptive for the patient, it may bother physicians or other caregivers. The following case example illustrates this point.

A psychiatric consultation was requested for a 24-year-old man who was quadriplegic after a gunshot wound to the spine. The physician was insistent that the patient's denial be "broken through" because the patient was convinced he would walk again. The patient demonstrated a thorough understanding of his condition and

maintained that his hard work and faith would restore his physical abilities. The physician was concerned that the patient might commit suicide when he realized that there was no chance of recovery of function. Instead of forcing the patient to face the prognosis, the consultant recommended that the physician offer the patient training in the skills necessary to maintain himself in his current state, because recovery, in whatever form it took, would take a considerable amount of time. The patient continued to cooperate with physical therapy, learned how to use a motorized wheelchair, and discussed the plans for his living arrangements. The physician felt comfortable with this approach because it was "realistic."

All too often, physicians misjudge patients as being in denial. This tends to occur with three types of patients: 1) patients without an overt emotional reaction to an illness or diagnosis, 2) patients whose reactions differ from those expected by their caregivers, and 3) patients who have been inadequately informed about their illness. The absence of an overt reaction to medical illness is a style of psychological response. Although it is not evident to an observer, individuals may actually be aware of their emotions and thoughts about their illness. Some physicians have a tendency to misjudge patients as being in denial who do not express an expected emotional response or who seek alternative treatments than those recommended by the physician (Cousins 1982). An obsessional middle-aged accountant in the coronary care unit, for example, may be acutely aware of his condition and may be quite concerned about it, yet he may not express any of the fears or anxiety that his caregivers would expect, appearing calm and hopeful. This patient is not denying his illness but may be considered to be doing so by caregivers because he "looks too relaxed and in too good a mood."

One must ensure that patients are fully informed about their illness and treatment before assessing patients as being in denial. Gatteleri et al. (1999) demonstrated that a portion of patients judged by their caregivers to be using denial were in fact relatively uninformed about the details of their illness or its prognosis. On the other hand, some patients who say they have not been informed have in fact been repeatedly educated by their health care professionals and are really in denial.

Studies of the impact of denial on medical outcomes have found both beneficial and adverse effects. It is a literature with several methodological limitations, including sometimes failing to clearly define how denial was measured, treating denial as an all-or-nothing phenomenon, and using a lack of observable negative affect as a primary indicator of denial (problematic for the reasons discussed above). The use of different measures of denial and distinct patient populations makes comparisons across studies very difficult (Goldbeck 1997).

A number of studies have demonstrated positive effects of denial of physical illness on outcome. Hackett and Cassem (1974) found that “major deniers” in coronary care units after myocardial infarction had a better outcome than “minor deniers.” Levenson et al. (1989) demonstrated that among patients with unstable angina, “high deniers” had fewer episodes of angina and more favorable outcomes than “low deniers.” Other studies suggest that denial is useful for specific clinical situations such as elective surgery (Cohen and Lazarus 1973) and wound healing (Marucha et al. 1998). Denial was associated with better survival rates in a small study of patients awaiting heart transplantation (Young et al. 1991).

Other research studies have found a mixed or negative impact of denial on medical outcome. “Major deniers” have shorter stays in the intensive care unit but are more likely to be noncompliant after discharge (Levine et al. 1987). Greater denial was associated with a worse medical outcome but was associated with decreased mood symptoms and sleep problems in patients with end-stage renal disease (Fricchione et al. 1992). Denial may be counterproductive in asthma patients (Staudenmeyer et al. 1979). Croog et al. (1971) noted lower treatment adherence among deniers in their large sample of myocardial infarct patients. In a study of women scheduled for breast biopsy, those with a history of habitual use of denial were observed to have been more likely to delay medical evaluation (Greer 1974).

When denial is present and is assessed as maladaptive, interventions should usually be directed toward the underlying emotions provoking the denial (e.g., fear). Direct confrontation of denial should be generally avoided because it is counterproductive (Ness and Ende 1994; Perry and Viederman 1981). For example, a 17-year-old adolescent who is newly diagnosed with diabetes mellitus may not want to accept this diagnosis and the need for changes in his lifestyle because of his painful memories of seeing other family members suffer through complications of diabetes. The physician may be tempted to frighten the patient into compliance with a statement such as, “If you don’t change your diet, measure your blood sugar, and take insulin regularly, you will wind up with complications just like your mother’s.” Such statements are usually counterproductive because they increase anxiety, which is driving the patient’s use of denial in the first place. Instead, a gentle, empathic, and nonjudgmental stance is more effective (Ness and Ende 1994). Diminishing the intensity of negative affects such as anxiety through psychopharmacological or psychotherapeutic interventions can also be helpful because these affects may be driving the patient’s need for denial.

In addition, the consulting psychiatrist should consider whether a patient’s maladaptive denial is fostered by

particular interpersonal relationships, such as those with family members, friends, a religious community, physicians, or other caregivers (Goldbeck 1997). In such cases, interventions aimed solely at the individual patient’s denial without addressing the reinforcing interpersonal relationships are likely to be unsuccessful.

## Emotional Responses to Medical Illness

---

Psychiatrists in the medical setting are frequently called on to help a patient manage emotional responses to illness and hospitalization (e.g., anger, fear, grief, shame). Usually the patient’s emotional response is identified in the consultation request. For example, “Please come see this 25-year-old man just diagnosed with testicular cancer who is angry and refusing treatment.” The 25-year-old man’s internist cannot understand why he would refuse the very treatment needed to treat (and possibly cure) his testicular cancer. With an understanding of the patient’s subjective experience of his illness, his predominant coping styles, and his prominent defense mechanisms, the consulting psychiatrist can help the patient and his internist to understand his anger, facilitating an alliance with which treatment is more likely to be accepted.

Because every patient is unique, empathic listening to a patient’s story of his or her illness will reveal the predominant emotional response, which is a potential clue to the subjective meaning of illness for that patient (Lazarus 1999). Core relational themes for the most common emotions (Lazarus 1999) can serve as hypotheses about the meaning of the illness for the patient (Table 5–3). An illness can evoke multiple emotional responses simultaneously or sequentially. The illness may have multiple meanings, and the meanings may change over the course of the illness. The predominant emotional response should not be the sole focus of the psychiatrist’s attention (although it may demand the most attention). For example, the 25-year-old man just diagnosed with testicular cancer is markedly angry and refuses treatment. One can hypothesize that it might be because he feels frightened, weakened, or emasculated or that he fears castration. In viewing the physician as the bearer of bad news, the patient is not only angry at having been diagnosed with cancer but also angry at his physician. Accepting and attempting to understand the patient’s anger aids the psychiatrist in giving this man permission to express his feelings while tactfully helping him to see that he can do so without forgoing his own treatment. The patient’s refusal of treatment may be also determined by fear of what the treatment will involve. The psychiatrist might also

**TABLE 5-3. Core relational themes underlying affective responses**

<b>Anger</b>	A demeaning offense against me and mine
<b>Anxiety</b>	Facing uncertain, existential threat
<b>Fright</b>	An immediate, concrete, and overwhelming danger
<b>Guilt</b>	Having transgressed a moral imperative
<b>Shame</b>	Failing to live up to an ego ideal
<b>Sadness</b>	Having experienced an irrevocable loss
<b>Happiness</b>	Making reasonable progress toward the realization of a goal
<b>Envy</b>	Wanting what someone else has
<b>Relief</b>	A distressing goal-incongruent condition that has changed for the better or gone away
<b>Hope</b>	Fearing the worst but yearning for better

work with the oncologist and his or her response to the patient's anger. Education by the physicians about the treatment options and the high likelihood of cure could dramatically shift the patient's emotional and behavioral responses and evoke relief and hope. Assisting the patient in naming his emotional responses and understanding *why* they are present can help the patient feel understood. This can facilitate the acceptance of an individualized treatment plan that appropriately involves medication, psychotherapy, psychoeducation, or other interventions.

## Anger

Anger is a common emotional response to medical illness and may be the most difficult emotional response for physicians to confront. This is particularly true when the anger is directed toward them or is expressed as treatment refusal. Patients with paranoid, narcissistic, borderline, or antisocial personality styles or disorders are particularly likely to express anger in the face of medical illness (Muskin and Haase 2001). Common reflexive reactions include counterattacking or distancing oneself from the patient. The psychiatrist who is skilled in psychosomatic medicine will convey appropriate empathy along with necessary limit setting for the angry patient. Many maneuvers are possible, such as a tactful redirection of the patient's anger toward more productive targets (e.g., away from refusal of treatment and toward planning with the oncologist to attack the illness through potentially curative chemotherapy). Helping the team respond appropriately to the patient is just as important. Viewing expressed

anger as natural and diffusing the intensity of affect can help to reestablish collaborative relationships with the patient.

## Anxiety and Fear

Some degree of anxiety is likely to be experienced universally by patients in the medical setting (Lloyd 1977). The degree of anxiety varies tremendously by individual and by situation. Patients with premorbid anxiety disorders are more likely to experience severe anxiety when confronted with medical illness. The patient with a dependent personality style may experience acute anxiety on hospitalization when faced with separation from his or her support system. The obsessional patient is likely to become anxious if the treatment plan or diagnosis remains unclear. The intrusiveness of the medical setting may evoke anxiety in the schizoid patient.

Psychotherapies, education regarding the illness and treatments, and judicious use of medication can greatly diminish the patient's anxiety (Perry and Viederman 1981). Although fear (usually involving a specific threat or danger) and anxiety (the feeling of nervousness or apprehension experienced on facing uncertain threats) are distinct emotions, they are often managed similarly. It is important to specifically elicit what the patient fears—pain, death, abandonment, disfigurement, dependence, disability, etc. Blanket reassurance is usually ineffective and may actually be detrimental because the patient may perceive it as unempathic, superficial, false, or patronizing. Empathy and reassurance tailored to the patient's specific fears can offer significant relief (Perry and Viederman 1981).

## Sadness

Sadness is evoked in situations where there is a loss (Lloyd 1977). Medical illness can lead to multiple types of loss: loss of physical function or social role, loss of ability to work, loss of the pursuit of a goal or dream, or loss of a part of one's body. Internal losses of organs or organ functions can be as significant as external losses such as amputation of a limb. Patients with untreated mood disorders may be more likely to develop clinically significant depression in the face of medical illness. Sadness may be the primary manifestation of an adjustment disorder, which is common in medically ill patients (Strain et al. 1998). Drawing an analogy to the process of mourning is often appropriate and helps to normalize the patient's sadness (Fitzpatrick 1999). Mourning a loss takes time, a fact that is often neglected in medical settings. It is important for the physician to convey a sense of appropriate hope. Describing true examples of other patients' positive out-

comes in similar situations can often be helpful. Even when the patient's sadness represents a normal grieflike reaction, physicians are often tempted to prescribe antidepressant medication, desiring to make the patient feel better. In such cases, the psychosomatic medicine specialist can redirect the treatment plan to interventions that are more likely to be helpful, such as psychotherapy, pastoral care, and—often most important—more time speaking with the primary treating physician.

## Guilt

Some patients experience illness as a punishment for real or imagined sins. Clarifying that illness is not the patient's fault—and thereby confronting the guilt—is a helpful technique. Patients may also experience guilt related to earlier or current illness-promoting behaviors such as smoking cigarettes, nonadherence to medication regimens, or risky sexual practices. Education of family members can be critical if they blame the patient inappropriately for the illness. If the patient is religious, counseling from a hospital chaplain or the appropriate clergy member should be considered.

## Shame

Illness is universally experienced as narcissistic injury to some degree. Narcissistic patients are more susceptible to experiencing shame in the face of medical illness. Patients who view their illness as a result of earlier behaviors—such as contracting HIV through impulsive sexual liaisons, or developing lung cancer after a long history of smoking—may experience shame in the medical setting. It is important for physicians to take a nonjudgmental stance and avoid blaming patients for their illnesses. Critical, disapproving responses are counterproductive, heighten patients' shame, and frequently lead to treatment avoidance. For example, the noncompliant diabetic patient who is repeatedly admitted to the hospital for diabetic ketoacidosis frustrates her doctors and nurses. They are often tempted to scold the patient, thinking that this is necessary to avoid colluding with her acting-out and failure to take her disease seriously. Such responses are typically humiliating for the patient, are ineffective in motivating behavior change, and often worsen the vicious cycle of noncompliance.

## Behavioral Responses to Illness

---

Patients' behavioral responses to illness vary tremendously within a spectrum ranging from maladaptive to adaptive. Adaptive responses may simply warrant encour-

agement or praise. Psychiatrists in the medical setting are often asked to see patients whose behavioral responses to illness or hospitalization are maladaptive and are interfering with their treatment. In understanding the patient's subjective experience, personality style, defense mechanisms, and coping strategies, one can design therapeutic interventions to help change the patient's responses to more adaptive behaviors. This section highlights a few of the common behavioral responses to illness.

## Adaptive Responses

### *Support Seeking*

Facing a new medical illness or hospitalization can be highly taxing for even the most well-adapted individual. Patients who are fortunate to have well-developed social support networks can benefit greatly from support from friends and family. Patients with conflicts about dependency might have more difficulty with this task, and psychotherapy can normalize this need and assist patients in reaching out to others. Referral to patient support groups can also be helpful for many patients; they can learn from the experiences of others facing the same illness and can feel less alone or alienated from other people. Information about self-help organizations can be obtained from various sources on the Internet, such as Dr. John Grohl's "Psych Central" Web site (<http://psychcentral.com>) and the "Self-Help Group Sourcebook Online" of the American Self-Help Group Clearinghouse (<http://mentalhelp.net/selfhelp>).

### *Altruism*

Altruistic behavior such as volunteering to raise money for breast cancer, becoming a transplant advocate who meets with preoperative patients and shares experiences with them, or participating in an AIDS walkathon can represent a highly adaptive response to illness. One of the common stresses of illness is the impact on an individual's self-esteem and sense of productivity. Through helping others, patients feel a sense of purpose and gratification that can help improve their mood. Generally, the consulting psychiatrist needs only to support and encourage such behaviors. For many patients with severe illnesses, voluntary participation in research can have the same effect. Particularly for those with terminal illness, participation in research can provide a sense of purpose and hope by contributing to the potential for new treatment options in the future.

### *Epiphany Regarding Life Priorities*

Although no one would generally claim that a medical illness is beneficial for the affected individual, it often helps

patients regain perspective on what is most important to them in life. Normal daily hassles of living may no longer seem as stressful, and some patients facing a serious illness experience an epiphany and dramatically change their lives for the better. Patient narratives of the life-affirming effects of illness and stories of personal growth abound in literature (Druss 1995). At times, the consultation psychiatrist can witness and support a patient through a personal transformation. A 47-year-old male executive recently diagnosed with a myocardial infarction may dramatically change his diet, embark on a new exercise regimen, and reconfigure his role at work to reduce emotional stress. Similarly, a woman newly diagnosed with HIV who commits herself to taking her medications regularly, seeks treatment for substance use, and rejoins her church also exemplifies this phenomenon.

There can be great opportunities for effective psychotherapy in the medically ill, because patients are under tremendous stress when faced with serious medical illness, and the usual distractions of their daily lives no longer dominate their thoughts. Sometimes a therapeutic alliance can form and work can progress more rapidly than is typical in other settings (Muskin 1990).

### *Becoming an Expert in One's Illness*

For the obsessional patient in particular, learning as much as possible about the illness can be adaptive and can give the individual a greater sense of control. Although the information itself may not be positive, patients often find that reality can seem more manageable than their imagined fears. However, this response to illness is not appealing to all patients. Some will prefer to put their trust in their physicians and to not know everything. The psychiatrist armed with an understanding of the patient's personality style and characteristic coping styles and defense mechanisms will be able to know whether or not increased information and knowledge might reduce the patient's distress and augment a sense of control.

### Maladaptive Responses: Nonadherence to Treatment Regimens

Treatment nonadherence is more common than most physicians recognize. It has been estimated that up to 50% of patients fail to adhere to their prescribed medication regimens (Sackett and Haynes 1976). Patients typically overestimate their own adherence to the treatment, and physicians are often unaware of their patients' lack of adherence (Levenson 1998). Physicians working in all medical settings witness the negative effects of nonadherence, and psychiatrists are frequently called on to see

problem patients who are repetitively noncompliant. For such cases the consulting psychiatrist is often cast in the role of disciplinarian, detective, or magician; medical colleagues may expect the psychiatrist's interventions to bring rapid change to the patient's adherence patterns. Although it is possible in some cases, this scenario is typically unrealistic. It is possible to undertake interventions that improve patient adherence when the underlying factors accounting for nonadherence are correctly identified and addressed.

There are numerous reasons why patients do not fully adhere with treatment regimens. Psychiatric disorders and psychological motivations are not the only factors that may be involved. Other factors, such as cost, side effects, and treatment complexity, may play a role. It is important to determine the degree of a patient's nonadherence and its context. Is the patient occasionally or consistently nonadherent? Is the nonadherence specific to a certain medication or type of recommendation (e.g., dieting), or is it more generalized across different treatments and different physicians? Identifying the context of nonadherence can provide clues to the underlying factors involved when the patient cannot directly give the reasons for nonadherence. In this section we identify some of the most common reasons for treatment nonadherence and offer 11 general principles for management of this common clinical problem.

### *Psychologically Motivated Factors for Nonadherence*

Perry and Viederman (1981) outlined a number of distinct psychological reasons why patients do not adhere with treatment recommendations. One reason they discuss is nonadherence to defend against humiliation (Perry and Viederman 1981). Rather than accept the stigma of his illness, a patient with HIV might stop his medications, which remind him daily of his illness. Active empathic work to counteract the illness concepts that cause shame can diminish this motivation for treatment nonadherence.

Another psychological motivation for nonadherence is to counteract a feeling of helplessness (Perry and Viederman 1981). An adolescent with newly diagnosed diabetes mellitus who is struggling with a developmentally appropriate desire to gain autonomy may believe that the only way to feel autonomous and in control is to rebel against her parents and caregivers by not taking insulin. Such nonadherence may also be motivated by the wish to be healthy like her peers.

Anger toward the treating physician or toward the illness or diagnosis itself may be another psychological mo-

tivator for treatment nonadherence, whether the anger is appropriate to the situation or is a product of character pathology. Varying degrees of denial may also be involved. Specific interventions for clinical situations in which anger and denial are primary motivators for nonadherence were discussed earlier in this chapter in the section “Denial” and in the subsection “Anger” under “Emotional Responses to Medical Illness.”

Patients’ trust in the physicians recommending their treatment is an important determinant of their likelihood of complying with the treatment regimen. Physicians must earn their patients’ trust through building rapport and direct, honest communication. Patients with psychotic disorders or significant character pathology might have particular difficulty placing trust in their caregivers. Mistrust and paranoia may play a role in these patients’ compliance with treatment regimens.

### ***Comorbid Psychiatric Disorders and Nonadherence***

Comorbid psychiatric disorders may also lead to treatment nonadherence. Affective disorders are particularly common. Depressed patients may not have the motivation, concentration, or energy required to fully comply with treatment recommendations. They might even stop treatment as an indirect means of attempting suicide. Manic patients may believe they no longer need treatment, may abuse substances, or may become disorganized or psychotic. Psychotic disorders, anxiety disorders, substance use disorders, and cognitive disorders are other psychiatric conditions that often play a role in treatment nonadherence. Therefore, a thorough psychiatric history and comprehensive review of symptoms are essential parts of the evaluation of the non-compliant patient.

### ***Other Factors in Nonadherence***

Nonadherence may be due to reality factors rather than psychological motivations. Cost of treatment, side effects (whether feared or experienced), and complicated or inconvenient medication dosing schedules are treatment-specific factors that should be considered. Other practical barriers, such as difficulties with transportation, inflexible and lengthy work schedules, or child-care responsibilities, may preclude consistent keeping of appointments (Levenson 1998).

A lack of information about the illness or its treatment should always be ruled out as a factor in nonadherence. Patients should understand their illness, their treatment options, and the reasons that treatment is necessary. Patient education should always be provided in the patient’s primary language to ensure full understanding. To assess patient understanding, physicians should ask patients to

repeat and to explain in their own words what they have been told about their illness. If possible, family members should be involved in the education. Written materials or visual materials may be helpful tools in patient education.

Incongruities between the health beliefs of patients and their physicians can also account for nonadherence and should be identified (Gaw 2001). Physicians of all disciplines must make an effort to understand their patients’ cultural and religious backgrounds, paying particular attention to patients’ beliefs and values about health and illness. Physicians should attempt to elicit their patients’ explanatory models about diseases and the effects of treatments. When possible, attempts can be made to explain treatment plans within patients’ explanatory models for illness and treatment. Or, at the least, mutual acknowledgment and acceptance of the differences between the explanatory models of the physician and the patient may facilitate treatment adherence and build doctor–patient rapport. When they feel that their caregivers accept and understand their cultural or religious beliefs, patients will also be more likely to voluntarily report their concomitant use of alternative or herbal treatments.

### ***Interventions to Increase Treatment Adherence***

The following general principles may assist the physician in facilitating greater patient adherence with treatment regimens (Becker and Maiman 1980; Chen 1991; Gaw 2001; Levenson 1998):

1. Ask patients directly about their adherence, maintaining a nonjudgmental stance. Design a collaborative plan to increase adherence. Normalizing statements and questions—such as “Many patients find it difficult to take their medications on a regular basis. Have you had this experience?”—are more effective in eliciting information about treatment adherence than questions such as “You’ve been taking your medication regularly, right?”
2. Ensure that patients are fully informed about their illness and treatments.
3. Rule out cognitive deficits (e.g., mental retardation or dementia), because they may play a role in nonadherence.
4. Uncover any underlying psychological motivating factors for nonadherence and address them specifically.
5. Diagnose and treat any comorbid psychiatric disorders.
6. Minimize treatment-related factors for nonadherence, such as side effects and cost and complexity of treatment regimens, when possible.

7. Identify, acknowledge, and contend with any cultural reasons for nonadherence.
8. Avoid shaming, scolding, or frightening the patient. Scolding patients or scaring them with statements such as “If you don’t take your medications, you could have a heart attack and die!” is almost always counterproductive (Heiskell and Pasnau 1991). Such statements may shame patients or inflate their fears and can increase the likelihood that they will not return for treatment.
9. Use positive reinforcement as a motivator when possible, because it is generally more effective than negative reinforcement at facilitating behavior change.
10. Involve family members in facilitating patient treatment adherence when they are “on board” with the treatment plan.
11. Attend to doctor–patient rapport and build an effective treatment alliance.

## Maladaptive Responses: Signing Out Against Medical Advice

A common reason for urgent psychiatric consultation in the medical hospital is a patient threatening to sign out against medical advice. Of all hospital discharges in the United States, 0.8%–2% are against medical advice (Hwang et al. 2003; Jeremiah et al. 1995; Weingart et al. 1998). Often the psychiatrist is asked to assess the decisional capacity of a patient who wants to sign out against medical advice. Legal aspects of this important assessment are discussed in Chapter 3, “Legal Issues.” The patient’s threat to sign out is usually not truly motivated by a primary desire to leave but more often reflects another agenda, intense affect, or interpersonal friction with physicians or nursing staff. In some cases, it is a means of expressing anger or frustration toward caregivers (Albert and Kornfeld 1973).

The motivations for signing out against medical advice vary significantly and are similar to those motivating treatment nonadherence. Among the more common motivations are 1) anger at caregivers or dissatisfaction with the treatment received (whether legitimate or partly due to character pathology); 2) overwhelming fear or anxiety; 3) substance craving or withdrawal (sometimes due to the medical team’s inadequate use of prophylactic medications such as benzodiazepines or nicotine patches); 4) delirium or dementia; 5) psychosis or paranoia; 6) desire to leave the hospital to attend to outside responsibilities (e.g., child care, work, court dates, or a pet at home alone); and 7) impatience with discharge planning or feeling well enough to leave. In a classic study of patients threatening to sign out against medical advice, the most common underlying

motivations were overwhelming fear, anger, and psychosis or confusion (Albert and Kornfeld 1973). In most cases there had been a progressive increase in the patient’s distress for days before the threat to sign out that had not been recognized or addressed adequately (Albert and Kornfeld 1973).

Among interventions, *empathic listening* to the patient’s frustrations is critical, in that it provides an opportunity for the patient to ventilate frustrations and to feel understood. Empathic listening will often have a dramatic de-escalating effect and will enable the team to re-engage the patient in treatment. The psychiatrist can also intervene in assisting the team to better understand a patient’s behavior so as to diminish the patient’s feelings of anger and frustration. Other guidelines for intervention are the following:

1. Understand the threat as a communication—Does the patient really want to leave, or is he or she expressing frustration, anger, anxiety, or another affect?
2. If the patient is justifiably angry, apologize on behalf of the system or hospital.
3. Avoid scare tactics or direct confrontation of denial, because these techniques are generally counterproductive.
4. Design interventions using an understanding of the patient’s personality type.
5. Diagnose and treat any comorbid psychiatric disorders.
6. Involve social supports (if they are allied with the treatment plan).
7. Ensure that the patient is adequately informed about the illness and its need for treatment.
8. Assess the patient’s capacity to sign out, if indicated (discussed further in Chapter 3, “Legal Issues”).
9. When patients still sign out against medical advice, encourage them to return for treatment if they change their mind.

## Conclusion

---

How does one integrate these various theoretical concepts into the consultation process? How do the psychological responses to illness guide the consultant to efficiently use his or her time to understand the situation and make useful suggestions? We are aware of no magic formula, but we believe that experienced consultants use their knowledge of human behavior and concepts such as personality types, coping styles, and defense mechanisms to understand their patients and to intervene. Opportunities abound in the medical setting for psychiatric interventions,

which can dramatically modify patients' psychological responses to illness. The key to these interventions lies in the development of an understanding of the patient's subjective experience of illness. A curious inquiry into the internal experience of a patient facing medical illness and the appropriate conveyance of empathy will generally be rewarded. We hope the framework, concepts, and guidelines presented in this chapter will prove useful in assisting psychiatrists who have chosen to work with patients in medical settings.

## **Symptoms and Disorders**

*This page intentionally left blank*

# 6 Delirium

---

Paula T. Trzepacz, M.D.

David J. Meagher, M.D., M.R.C.Psych., M.Sc.

**DELIRIUM IS A** complex neuropsychiatric disorder that occurs commonly among patients in all health care settings, especially among the elderly and those with preexisting brain lesions or cognitive impairment. It is primarily characterized by generalized impairment of cognition, especially orientation and attention, but also involves a range of noncognitive symptoms, including motor behavior, sleep-wake cycle, thinking, language, perception, and affect. It characteristically has an acute onset (hours to days) and a fluctuating course (waxing and waning symptom severity over a 24-hour period), often worsening at night. It may be preceded by a prodromal phase of 2–3 days of malaise, restlessness, poor concentration, anxiety, irritability, sleep disturbances, and nightmares. It has been called *acute organic brain syndrome* and *acute brain failure* because of its breadth of cognitive and behavioral symptoms. Table 6-1 highlights delirium's characteristic features.

Delirium is an abnormal state of consciousness along a continuum between normal alertness and awareness at one extreme and the reduced wakefulness associated with stupor or coma at the other extreme. Consciousness has two main components—level of wakefulness (alertness) and content of higher mental functions (awareness). Because delirium alters both of these components of consciousness, it impairs the person more broadly than most other psychiatric disorders do. Precise delineation between severe hypoactive delirium and stupor can be difficult. Emergence from coma usually involves a period of delirium before normal consciousness is achieved. A prospective study of intensive care unit (ICU) patients found that 89% of survivors of stupor or coma progressed to delirium (McNicoll et al. 2003), whereas the small number who progressed directly to normal consciousness without delirium tended to have had drug-induced comatose states (Ely et al. 2004a).

Although delirium is usually characterized by an acute onset replete with many symptoms, it may be preceded by a subclinical delirium with more insidious changes in sleep pattern or cognition (Harrell and Othmer 1987). Matsushima et al. (1997) prospectively studied 10 critical care unit patients with delirium and 10 nondelirious control subjects with electroencephalography. They found prodromal changes of background slowing on the electroencephalogram (EEG) and sleep disturbance associated with changing consciousness. Cole et al. (2003b) prospectively studied “subsyndromal delirium,” defined as the presence of one or more of four core symptoms (clouding of consciousness, inattention, disorientation, and/or perceptual disturbances) but not meeting DSM-III-R (American Psychiatric Association 1987) criteria, in 164 elderly medical patients. The more symptoms present, especially on admission, the worse the prognosis, suggesting that even subclinical manifestations of delirium are significant.

Delirium also may be a transient state, as when a patient emerges from general anesthesia, during concussion following a head injury, or postictally. Football players who sustain a head injury during a game are removed to the sidelines until the disorienting effects of concussion resolve sufficiently. Most deliria are considered reversible, but in the terminally ill, delirium may be progressive and intractable despite measures to treat it. On the other hand, delirium occurring in patients with serious illness frequently resolves, as evidenced in the study by Breitbart et al. (2002b), in which two-thirds of the cases of delirium occurring in hospitalized patients with cancer resolved completely with treatment. Similarly, Ljubisavljevic and Kelly (2003) found that 85% of the patients admitted with cancer who developed delirium experienced successful symptom reversal.

**TABLE 6-1. Signs and symptoms of delirium**

<b>Diffuse cognitive deficits</b>
Attention
Orientation (time, place, person)
Memory (short- and long-term; verbal and visual)
Visuoconstructional ability
Executive functions
<b>Temporal course</b>
Acute or abrupt onset
Fluctuating severity of symptoms over 24-hour period
Usually reversible
Subclinical syndrome may precede and/or follow
<b>Psychosis</b>
Perceptual disturbances (especially visual), including illusions, hallucinations, metamorphoses
Delusions (usually paranoid and poorly formed)
Thought disorder (tangentiality, circumstantiality, loose associations)
<b>Sleep-wake disturbance</b>
Fragmented throughout 24-hour period
Reversal of normal cycle
Sleeplessness
<b>Psychomotor behavior</b>
Hyperactive
Hypoactive
Mixed
<b>Language impairment</b>
Word-finding difficulty/dysnomia/paraphasia
Dysgraphia
Altered semantic content
Severe forms can mimic expressive or receptive aphasia
<b>Altered or labile affect</b>
Any mood can occur, usually incongruent to context
Anger or increased irritability common
Hypoactive delirium often mislabeled as depression
Lability (rapid shifts) common
Unrelated to mood preceding delirium

Delirium is considered a syndrome and not a unitary disorder because a wide variety of underlying etiologies can cause it. Identification of these etiologies, often multiple or occurring serially over time, is a key part of clinical management. Despite these varied etiologies and physiology, delirium symptoms are characteristic and thus may represent dysfunction of a final common neural pathway that includes perturbations of the various brain regions responsible for the abnormal cognitions, thinking, sleep, and behaviors (see section “Neuropathogenesis” later in this chapter).

Unlike most other psychiatric disorders, delirium symptoms typically fluctuate in intensity over any 24-

hour period. Symptom fluctuation is measurable (Gagnon et al. 2004a, 2004b) and is an important indicator of delirium emphasized in diagnostic classifications such as DSM-IV (American Psychiatric Association 1994, 2000). During this characteristic waxing and waning of symptoms, relative lucid or quiescent periods often occur, which frustrate accurate diagnosis and complicate research severity ratings. In milder cases, such periods involve a significant diminution of delirium symptoms or even a seeming resolution of symptoms, but the latter has not been carefully studied. The underlying reason for this fluctuation in symptom severity is poorly understood—it may relate to shifts between hypoactive and hyperactive periods or fragmentations of the sleep-wake cycle, including daytime rapid eye movement (REM) sleep.

Although not nearly as well studied, the symptom profile of delirium in children appears to be similar to that in adults (Prugh et al. 1980; Turkel et al. 2003, 2004). In the only study of delirium phenomenology in children and adolescents in which a standardized instrument was used, Turkel et al. (2003) retrospectively described 84 consecutively evaluated delirium patients (age 6 months to 19 years) and found scores comparable to those in adults, with the only difference being fewer delusions and hallucinations in younger children. Turkel et al. (2004) also compared delirium symptoms across the life cycle and, despite differences in methodologies, considered them to be largely similar. Prugh et al. (1980) noted the importance of educating nursing staff about the difference between visual hallucinations and imaginary friends. Documentation of all delirium symptoms in preverbal children or noncommunicative adults is difficult. In these patients, more reliance on inference and observation of changed or unusual behaviors—for example, inferring hallucinations or recording sleep-wake cycle changes—is needed.

Delirium symptoms in adults across the age range are comparable, although the co-occurrence of another cognitive mental disorder is particularly likely in the elderly compared with younger adults and is usually related to degenerative or vascular dementia. How the presence of a comorbid dementia alters the phenomenological presentation of delirium in the elderly is not well studied, but existing data suggest that delirium overshadows the dementia symptoms (see section “Differential Diagnosis” later in this chapter). Likewise, diagnosing delirium in mentally retarded patients can be more challenging.

One of the challenges for both clinicians and delirium researchers is the myriad of terms applied to the delirious state. Historically, acute global cognitive disturbances have been labeled according to the setting in which they occurred or the apparent etiology for the confusional state, resulting in the myriad of synonyms (see Table 6-2)

**TABLE 6-2. Terms used to denote delirium**

Acute brain failure	Cerebral insufficiency	Organic brain syndrome
Acute brain syndrome	Confusional state	Posttraumatic amnesia
Acute brain syndrome with psychosis	Dysergastic reaction	Reversible cerebral dysfunction
Acute dementia	Encephalopathy	Reversible cognitive dysfunction
Acute organic psychosis	Exogenous psychosis	Reversible dementia
Acute organic reaction	Infective-exhaustive psychosis	Reversible toxic psychosis
Acute organic syndrome	Intensive care unit (ICU) psychosis	Toxic confusion state
Acute reversible psychosis	Metabolic encephalopathy	Toxic encephalopathy
Acute secondary psychosis	Oneiric state	

that exist in practice and the literature. Little evidence supports these as separate entities, and, as such, *delirium* has been adopted as the accepted umbrella term to denote acute disturbances of global cognitive function as defined in both DSM-IV and ICD-10 (World Health Organization 1992) research classification systems. Even though the term *delirium* has been used since classical Greek medical writings, unfortunately, different terms continue to be used by nonpsychiatric physicians (e.g., *ICU psychosis*, *hepatic encephalopathy*, *toxic psychosis*, *posttraumatic amnesia*). These terms inappropriately suggest the existence of independent psychiatric disorders for each etiology rather than recognize delirium as a unitary syndrome. Terms such as *acute brain failure* and *acute organic brain syndrome* highlight the global nature and acute onset of cerebral cortical deficits in patients with delirium, but they lack specificity in regard to other cognitive mental disorders. The term *delirium* subsumes these many other terms, and its consistent use will enhance medical communication, diagnosis, and research.

Little work has been done with the use of daily delirium ratings to better understand the temporal course of this syndrome. In a study of 432 medical inpatients 65 years or older, Rudberg et al. (1997) found that 15% had delirium, and 69% of those had delirium for only a single day. Mean delirium scores on day 1 were significantly higher (i.e., worse) in those whose delirium occurred for multiple days compared with those whose delirium lasted for 1 day ( $25.4 \pm 3.6$  vs.  $22.6 \pm 4.4$ ), suggesting a relation between severity and duration in delirium episodes.

Delirium continues to be understudied compared with other psychiatric disorders, as well as underrecognized and underdiagnosed. It is commonly misdiagnosed as depression by nonpsychiatrists (Nicholas and Lindsey 1995). Misdiagnosis of delirium is more likely when delirium is hypoactive in presentation and when patients are referred from surgical or intensive care settings (S.C. Armstrong et al. 1997). Van Zyl and Davidson (2003) reviewed charts of 31 delirious patients who were referred for psychiatric consultation and received standardized de-

lirium assessments. They found that delirium or a synonym was noted in 55% of the structured discharge summaries and in none of the unstructured summaries, for an overall rate of 16%. It was more likely mentioned when it occurred in women, was more severe, or was the main reason for admission. Johnson et al. (1992) studied consecutive elderly patients admitted to a general hospital and found that delirium was explicitly documented in 5% of the patients and noted as a synonym in 18%, with a variable but poor recognition of individual delirium symptoms. The missed cases were denoted as dementia (25%), a functional psychiatric disorder (25%), or no diagnosis noted (50%).

Nondetection was associated with poorer outcome, including increased mortality, in a study of detection of delirium in emergency department patients (Kakuma et al. 2003). In contrast, explicit recognition of delirium was associated with better outcome in the form of shorter inpatient stays and lower mortality (Rockwood et al. 1994). Detection can be improved by providing formal educational programs, for example, with house staff (Rockwood et al. 1994). Personal attitudes are important among nursing staff, who often play a key role in identifying and reporting symptoms because the symptoms fluctuate, for example, at night (McCarthy 2003). Detection is a challenge in ICU settings, where the sickest patients are at the highest risk for delirium. Ely et al. (2004b) distributed a survey to 912 physicians, nurses, respiratory therapists, and pharmacists attending international critical care meetings and found that 72% thought that ventilated patients experienced delirium, 92% considered delirium a very serious problem, and 78% acknowledged that it was underdiagnosed. Yet only 40% routinely screened for delirium, and only 16% used a specific tool for assessment. Rincon et al. (2001) reported that critical care unit staff underdiagnosed delirium (and other psychiatric disorders) and used psychotropic medications without any clear documentation.

ICU populations have delirium prevalence rates ranging from 40% to 87% (Ely et al. 2001c). ICU delirium is

understudied and neglected probably because it is “expected” to happen during severe illness, and medical resources are preferentially dedicated to managing the more immediate “life-threatening” problems.

Related to pressures to reduce acute hospital care costs, elderly patients are discharged, often to nursing homes, before delirium resolves. Kiely et al. (2003) studied 2,158 patients from seven Boston, Massachusetts, area skilled nursing facilities and found that 16% had a full-blown delirium. In general, such facilities are even less equipped with health care professionals to diagnose and manage delirium than are acute care settings.

Delirium can have a profound effect on a patient's morbidity and mortality as well as on his or her caregivers and loved ones. Delirious patients have difficulty comprehending and communicating effectively, consenting to procedures, complying with medical management (e.g., removing intravenous lines, tubes, or catheters), benefiting from many therapies, and maintaining expected levels of self-hygiene and eating. They also are at risk for inadvertent self-harm because of confusion about the environment or in response to hallucinations or paranoid delusions. Delirium-recovered patients were uncomfortable discussing their delirium episodes—even to the extent of denial—because they feared that it meant that they were “senile” or “mad” (Schofield 1997). Breitbart et al. (2002a) prospectively interviewed and rated 101 cancer patients with a resolved delirium episode, their spouses, and their nurses (see Figure 6–1). About half (43%) of the patients recalled their episode, with recall dependent on delirium severity (100% of patients with mild delirium vs. 16% of patients with severe delirium recalled the episode). Mean distress levels were high for patients and nurses but were highest for spouses. However, among patients with delirium who did not recall the episode, the mean distress level was half that of those who did recall. The experience of the delirium was frightening and stressful for all involved, but for somewhat different reasons—for patients, the presence of delusions; for nurses, the presence of perceptual disturbances or overall severe delirium; and for spouses, the low ability to function was predictive of distress level. Spouses perceived the delirium as indicating a high risk for death and loss of the loved one, contributing to bereavement. Medical complications, including decubitus ulcers, feeding problems, and urinary incontinence, are common in patients with delirium (Gustafson et al. 1988). Effects on hospital length of stay, “persistence” of cognitive impairment, increased rate of institutionalization, and reduced ambulation and activities of daily living (ADL) level have been reported.

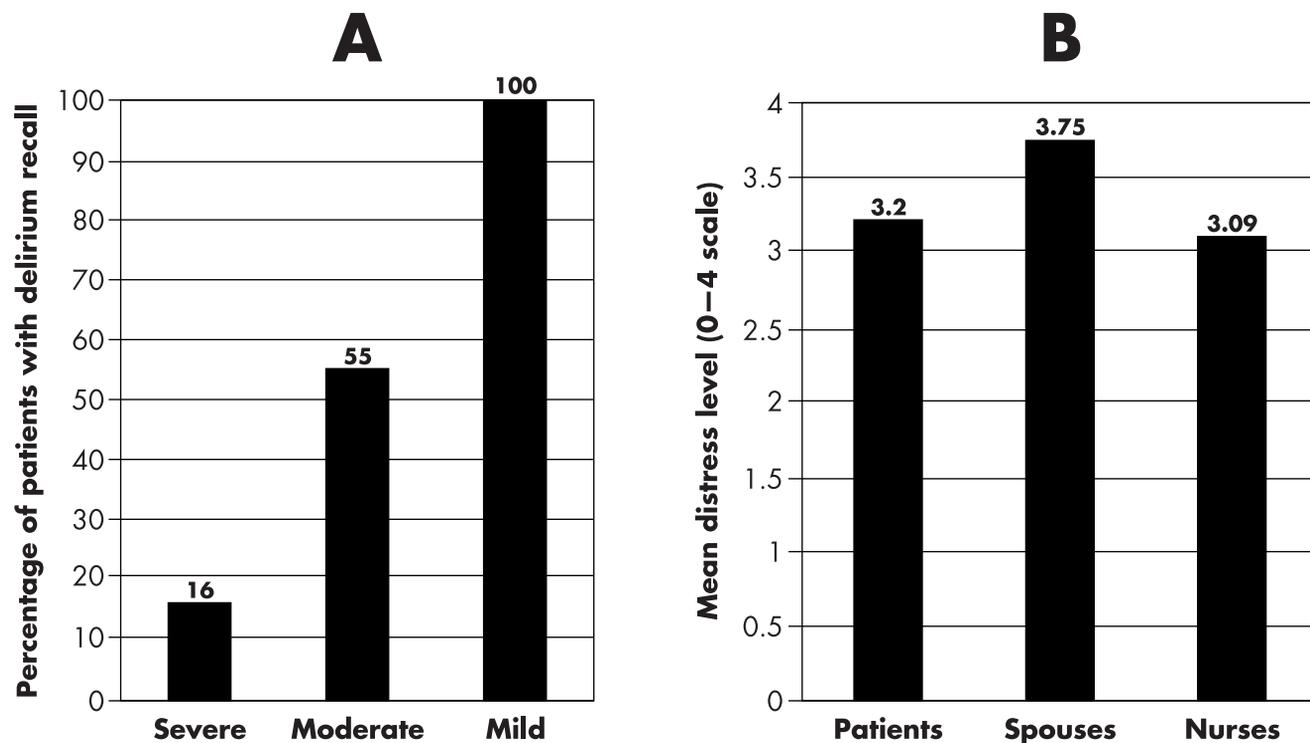

The Academy of Psychosomatic Medicine Task Force on Mental Disorders in General Medical Practice (Saravay

and Strain 1994) reviewed studies finding that comorbid delirium increased hospital length of stay 100% in general medical patients (R.I. Thomas et al. 1988), 114% in elderly patients (Schor et al. 1992), 67% in stroke patients (Cushman 1988), 300% in critical care patients (Kishi et al. 1995), 27% in cardiac surgery patients, and 200%–250% in hip surgery patients (Berggren et al. 1987). The Academy of Psychosomatic Medicine task force noted that delirium contributed to increased length of stay via medical and behavioral mechanisms, including the following: decreased motivation to participate in treatment and rehabilitation, medication refusal, disruptive behavior, incontinence and urinary tract infection, falls and fractures, and decubiti.

Significantly increased length of stay associated with delirium has been reported in many studies (Cushman 1988; Forman et al. 1995; Francis et al. 1990; Gustafson et al. 1988; Hales et al. 1988; Levkoff et al. 1992; Pompei et al. 1994; Schor et al. 1992; R.I. Thomas et al. 1988) but not all (Cole et al. 1994; George et al. 1997; Jitapunkul et al. 1992; Rockwood 1989). A meta-analysis of eight studies (Cole and Primeau 1993) supported statistically significant differences in length of stay between delirium and control groups. Ely et al. (2004a) found that delirium duration was associated with length of stay in both the medical ICU and the hospital ( $P < 0.001$ ) and was the strongest predictor of length of stay even after adjustment for illness severity, age, gender, and days of opiate and narcotic use (see Figure 6–2). McCusker et al. (2003a) studied elderly medical inpatients and found significantly longer length of stay for those with incident, but not prevalent, delirium. Methodological issues often affect interpretation of such studies.

Franco and colleagues (2001) identified the increased costs associated with delirium in a prospective study of 500 elective surgery patients older than 50 years. Delirium occurred in 11.4% of the patients during postoperative days 1–4, and these patients had higher professional, consultation, technical, and routine nursing care costs. Milbrandt and colleagues (2004) compared costs associated with having at least one delirium episode in 183 mechanically ventilated medical ICU patients and nondelirious control subjects after controlling for age, comorbidity of illness, degree of organ dysfunction, nosocomial infection, and hospital mortality. Median ICU costs per patient were \$22,346 for delirious and \$13,332 for nondelirious patients ( $P < 0.001$ ), and total hospital costs were \$41,836 and \$27,106 ( $P = 0.002$ ), respectively; more severe delirium cases resulted in higher costs than did milder ones.

Decreased independent living status and increased institutionalization during follow-up after a delirium epi-

**FIGURE 6–1.** Relation of delirium severity to patient recall of the episode, and comparison of delirium-related distress levels, in cancer patients with a resolved delirium episode and their families and caregivers. (A) Percentage of patients who recalled their episode, by delirium severity. (B) Mean distress levels of patients, spouses or caregivers, and nurses (rated on a 0–4 rating scale).

sode were found in many studies, especially in the elderly (Cole and Primeau 1993; George et al. 1997; Inouye et al. 1998). Reduction in ambulation and/or ADL level at follow-up is also commonly reported (Francis and Kapoor 1992; Gustafson et al. 1988; Inouye et al. 1998; Minagawa et al. 1996; Murray et al. 1993). Delirium also has an effect in nursing home settings, where incident cases are associated with poor 6-month outcome, including behavioral decline, initiation of physical restraints, greater risk of hospitalization, and increased mortality (Murphy 1999). Even subsyndromal delirium is reported to increase index admission length of stay and postdischarge dysfunction and mortality after adjustment for age, sex, marital status, previous living arrangement, comorbidity, dementia status, and clinical and physiological severity of illness (Cole et al. 2003b).

In nursing home patients, better cognitive function at baseline was associated with better outcome from delirium (Murphy 1999), supporting the notion that impaired brain reserve is an important pre-delirium factor that needs to be taken into account in any longitudinal out-

come assessments. Alternatively, longitudinal postdelirium cognitive assessments of younger adults who are not at risk for dementia could help answer the question of persistent cognitive impairment following delirium.

## Epidemiology

Delirium can occur at any age, although it is particularly understudied in children and adolescents. Most epidemiological studies have focused on the elderly, who are at higher risk to develop delirium than are younger adults. This is likely because of age-related changes in the brain, including decreased cholinergic functioning, often referred to as *reduced brain reserve*. The frequent occurrence of central nervous system disorders (e.g., stroke, hypertensive and atherosclerotic vessel changes, tumor, dementias) in the elderly further increases their vulnerability to delirium. Elderly medical ICU patients with dementia were 40% more likely to have delirium, even after various indices of medical comorbidity severity were controlled

**FIGURE 6-2. Hospital length of stay in patients with and without prevalent delirium during medical intensive care unit (ICU) stay.**

*Source.* Reprinted from Ely EW, Shintani A, Truman B, et al.: “Delirium as a Predictor of Mortality in Mechanically Ventilated Patients in the Intensive Care Unit.” *Journal of the American Medical Association* 291:1753–1762, 2004. Used with permission.

for (McNicoll et al. 2003). Frail elderly individuals living in nursing facilities studied for 3 months during and after an acute medical hospitalization had a high incidence of delirium of 55% at 1 month and 25% at 3 months, which persisted until death or hospitalization in 72% (Kelly et al. 2001). Improving our understanding and treatment of delirium is thus a considerable health care challenge in the coming years because the world’s population is aging at a dramatic rate.

Most studies of delirium incidence and prevalence report general hospital populations consisting of either referral samples or consecutive admissions to a given service. Little information is available about the rate of delirium in the general population. Specific patient populations, such as elderly patients who require emergent hip surgery, liver transplant candidates, and hospitalized traumatic brain injury patients, may be responsible for disparate rates reported in studies. In addition, not all studies use sensitive and specific diagnostic and measurement techniques, possibly resulting in overestimates or underestimates of the true occurrence of delirium. A review by Fann (2000) of (mostly) prospective studies found that delirium incidence ranged from 3% to 42%, and prevalence ranged from 5% to 44%, in hospitalized patients. Table 6-3 reviews incidence and prevalence studies

of delirium in which DSM diagnostic criteria or rating scales were used. These studies were done in medical, surgical, palliative care, institutional care, intensive care, and community settings, and most focused on geriatric patients.

Up to 60% of nursing home patients older than 65 years may have delirium when assessed cross-sectionally (Sandberg et al. 1998). When admitted to a hospital, 10%–15% of elderly patients have delirium, and another 10%–40% receive diagnoses of delirium during the hospitalization. A clinical “rule of thumb” seems to be that, on average, approximately one-fifth of general hospital patients have delirium sometime during hospitalization. Terminally ill cancer patients have a very high incidence of delirium, with rates from 28% to 42% on admission to a palliative care unit and up to 88% before death (Lawlor et al. 2000a). Also, about 50% of those undergoing stem cell transplantation have a delirium in the postoperative month (Fann et al. 2002).

In a prospective cohort study of older medical ICU patients, McNicoll et al. (2003) found delirium in 31% on admission and an overall prevalence and incidence of delirium of 62% during the ICU stay and of 70% during the entire hospitalization. In addition, 30% had evidence of prior dementia, and these patients were 40% more likely

**TABLE 6–3. Incidence and prevalence studies of delirium**

<b>Study</b>	<b>N</b>	<b>Sample</b>	<b>Delirium ascertainment</b>	<b>Design</b>	<b>Findings</b>
Erkinjuntti et al. 1986	2,000	Medical inpatients, age ≥ 55 years	SPMSQ, DSM-III criteria on interview and chart review	Prospective	Prevalence 15%
Cameron et al. 1987	133	Medical inpatients, ages 32–97 years	DSM-III criteria on interview	Prospective	Prevalence 14%, incidence 3%
Gustafson et al. 1988	111	Femoral neck fracture patients, age ≥ 65 years	OBS Scale, DSM-III criteria on interview	Prospective	Prevalence 33%, incidence 42%
Rockwood 1989	80	Medical inpatients, age ≥ 65 years	DSM-III criteria on interview	Prospective	Prevalence 16%, incidence 11%
Francis et al. 1990	229	Medical inpatients, age ≥ 70 years	DSM-III-R criteria on interview and chart review	Prospective	Prevalence 16%, incidence 7%
Johnson et al. 1990	235	Medical inpatients, age > 70 years	DSM-III criteria on interview	Prospective	Prevalence 16%, incidence 5%
Folstein et al. 1991	810	Community sample	DSM-III criteria on interview	Cross-sectional	Prevalence 0.4% (1.1%, age ≥ 55)
Williams-Russo et al. 1992	51	Bilateral knee replacement surgery patients receiving postoperative fentanyl	DSM-III-R criteria on interview and chart review	Prospective	Incidence 41%
Jitapunkul et al. 1992	184	Medical inpatients, age ≥ 60 years	DSM-III-R criteria on chart review	Prospective	Prevalence 22%
Snyder et al. 1992	42	Acquired immunodeficiency syndrome inpatients	DSM-III-R criteria on interview	Prospective	Prevalence 17%
Schor et al. 1992	325	Medical and surgical inpatients, age ≥ 65 years	DSI	Prospective	Prevalence 11%, incidence 31%
Leung et al. 1992	569	Male medical inpatients, ages 12–99 years	DSM-III criteria on interview	Prospective	Prevalence 9.5%
Kolbeinsson and Jonsson 1993	331	Medical inpatients, age ≥ 70 years	MSQ, MMSE, and DSM-III-R criteria on interview	Prospective	Prevalence 14%
Rockwood 1993	168	Geriatric medical inpatients, mean age = 79 years	DRS, DSM-III-R criteria on interview	Prospective	Prevalence 18%, incidence 7%
Marcantonio et al. 1994a	1,341	Noncardiac surgery patients, age ≥ 50 years	CAM, medical records, nursing intensity index	Prospective	Incidence 9%
Pompei et al. 1994	432	Medical and surgical inpatients, age ≥ 65 years	Digit Span, Vigilance “A” Test, CAC, CAM, DSM-III-R criteria on interview	Prospective	Prevalence 5%, incidence 10%
Pompei et al. 1994	323	Medical and surgical inpatients, age ≥ 70 years	CAM	Prospective	Prevalence 15%, incidence 12%
Kishi et al. 1995	238	Critical care medical unit patients	DSM-III-R criteria on clinical evaluation	Prospective	Incidence 16%
Fisher and Flowerdew 1995	80	Elective orthopedic surgery inpatients, age ≥ 60 years	CAM	Prospective	Incidence 18%

**TABLE 6-3. Incidence and prevalence studies of delirium (continued)**

Study	N	Sample	Delirium ascertainment	Design	Findings
Forman et al. 1995	95	Community hospital inpatients, age $\geq 65$ years	Delirium diagnosis or DSM-III-R criteria on chart review	Retrospective	Incidence 38%
Inouye and Charpentier 1996	196	Medical inpatients, age $\geq 70$ years	CAM	Prospective	Incidence 18%
	312	Medical inpatients, age $\geq 70$ years	CAM	Prospective	Incidence 15%
Minagawa et al. 1996	93	Terminally ill cancer patients admitted to palliative care unit	MMSE and DSM-III-R criteria on interview	Prospective	Prevalence 28%
Glick et al. 1996	195	Patients receiving intra-aortic balloon pump treatment	DSM-III-R criteria on chart review	Retrospective	Prevalence 34%
Rudberg et al. 1997	432	Medical-surgical patients	DSM-III-R and DRS daily ratings	Prospective	Incidence 15%
Sandberg et al. 1998	717	Institutional care patients, age $\geq 75$ years	OBS Scale	Cross-sectional	Prevalence 44%
Gagnon et al. 2000	89	Hospitalized terminal cancer patients	CAM, CRS	Prospective longitudinal	Incidence 33%, prevalence on admission 20%
Lawlor et al. 2000b	104	Hospitalized advanced cancer patients	DSM-IV, MDAS	Prospective	Incidence 45%, prevalence on admission 42%
Caraceni et al. 2000	393	Multicenter palliative care cancer patients	CAM	Prospective	Prevalence 28%
van der Mast et al. 1999	296	Elective cardiac surgery patients, ages 26-83 years	DSM-III-R criteria on interview and chart review	Prospective	Incidence 14%
Fann et al. 2002	90	Hospitalized hematopoietic stem cell transplant patients	DRS, MDAS	Prospective	Incidence 50%, cumulative incidence 73%
Ely et al. 2004a	275	Consecutive mechanically ventilated medical ICU patients	DSM-IV and CAM-ICU	Prospective	Incidence 82%
McNicoll et al. 2003	118	Elderly medical ICU patients	CAM-ICU	Prospective	Incidence on admission 31%, incidence and prevalence combined 62%
Kiely et al. 2003	2,158	Skilled nursing facility elderly patients in Boston area	CAM	Prospective	Prevalence 16%

*Note.* CAC=Critical Assessment of Confusion; CAM=Confusion Assessment Method; CRS=Confusion Rating Scale; DRS=Delirium Rating Scale; DSI=Delirium Symptom Interview; ICU=intensive care unit; MDAS=Memorial Delirium Assessment Scale; MMSE=Mini-Mental State Examination; MSQ=Mental Status Questionnaire; OBS=Organic Brain Syndrome; SPMSQ=Short Portable Mental Status Questionnaire.

to become delirious, even after comorbidity, baseline functional status, severity of illness, and invasive procedures were controlled for. In a prospective study of 275 consecutive mechanically ventilated medical ICU patients that used daily ratings over 5,353 patient days, 51 (18.5%) were comatose; of the remaining 224 patients, 183 (82%) had a delirium at some point during the hospitalization, with a median duration of 2.1 days (Ely et al. 2004b). Delirious patients had numerically higher admission mean comorbidity and critical illness severity scores compared with those who never became delirious, but mean ages were comparable.

Diagnosis is also an issue for epidemiological studies. Substantial differences in rates can occur—for example, when DSM-III (American Psychiatric Association 1980), DSM-III-R, DSM-IV, and ICD-10 criteria were used, only 25% of the patients with delirium received accurate diagnoses by all four systems (Laurila et al. 2003). Lesser diagnostic emphasis on disorganized thinking in the DSM-IV criteria accounted for that system's greater sensitivity and inclusivity (but lower specificity) in comparison with the other systems, whereas ICD-10 criteria were the least inclusive (Cole et al. 2003a).

Thus, irrespective of the diversity of incidence and prevalence rates reported among studies, delirium is very common, and its rates generally exceed those for any other serious psychiatric disorder in a medical setting.

## Risk Factors

---

Delirium is particularly common during hospitalization when a confluence of both predisposing (vulnerabilities) and precipitating factors is present. Several patient, illness, pharmacological, and environmental factors have been identified as being relevant risk factors for delirium. Although some factors are more relevant in certain settings, age, preexisting cognitive impairment, severe comorbid illness, and medication exposure are particularly strong predictors of delirium risk across a range of populations (Inouye et al. 1999). Terminal illness is a risk factor for delirium (Lawlor et al. 2000a). In stem cell transplant patients, pretransplant risk factors included lower cognition on Trail Making Test B; higher serum levels of urea nitrogen, magnesium, or alkaline phosphatase; and lower physical functioning (Fann et al. 2002).

Stress-vulnerability models for the occurrence of delirium have been long recognized. Henry and Mann (1965) described "delirium readiness." More recent models of causation involve cumulative interactions between predisposing factors and precipitating insults (Inouye and Charpentier 1996; O'Keeffe and Lavan 1996). Baseline

risk is a more potent predictor of delirium likelihood—if baseline vulnerability is low, patients are very resistant to the development of delirium despite exposure to significant precipitating factors, whereas if baseline vulnerability is high, delirium is likely even in response to minor precipitants. Tsutsui et al. (1996), for example, found that in patients older than 80 years, delirium occurred in 52% after emergency surgery and 20% after elective procedures, whereas no case of delirium was noted in patients younger than 50 years undergoing either elective or emergency procedures. In addition to the elderly, children are considered at higher risk for delirium, possibly related to ongoing brain development. For example, maturation of the cholinergic system continues into midadolescence.

Up to two-thirds of the cases of delirium occur superimposed on preexisting cognitive impairment (Wahlund and Bjorlin 1999). Delirium is 2.0–3.5 times more common in patients with dementia compared with nondemented control subjects (Erkinjuntti et al. 1986; Jitapunkul et al. 1992). Delirium risk appears to be greater in Alzheimer's disease of late onset and dementia of vascular origin as compared with other dementias, with this increased risk perhaps reflecting the relatively widespread neuronal disturbance associated with these conditions (Robertsson et al. 1998).

More recently, several studies addressed the influence of genetic factors on delirium vulnerability. To date, these studies have focused on the role of genotype in susceptibility to alcohol withdrawal delirium and suggest positive associations between polymorphisms of both the dopamine transporter gene (Gorwood et al. 2003; Wernicke et al. 2002) and the neuropeptide Y gene (Koehnke et al. 2002) and the risk of delirium tremens.

O'Keeffe and Lavan (1996) stratified patients into four levels of delirium risk based on the presence of three factors (chronic cognitive impairment, severe illness, elevated serum urea) and found that the risk of delirium increased as these factors accumulated. Similarly, Inouye and Charpentier (1996) developed a predictive model that included four predisposing factors (cognitive impairment, severe illness, visual impairment, dehydration) and five precipitating factors (more than three medications added, catheterization, use of restraints, malnutrition, any iatrogenic event). These factors predicted a 17-fold variation in the relative risk of developing delirium. Uremia increases the permeability of the blood-brain barrier, allowing many larger molecules, such as drugs, to enter the brain when they ordinarily would not.

Although the value of reducing risk factors appears self-evident, many may simply be markers of general morbidity; therefore, studies showing preventive effect are important (see section "Prevention Strategies" later in

this chapter). Some risk factors are potentially modifiable and thus are targets for prevention. Even just closer observation of patients at high risk for delirium could mean prompter intervention in emerging delirium. For example, thiamine deficiency is an underappreciated cause of and risk factor for delirium in pediatric intensive care and oncology patients (Seear et al. 1992) and nonalcoholic elderly patients (O'Keeffe et al. 1994).

Medication exposure is probably the most readily modifiable risk factor for delirium, implicated as a cause in 20%–40% of cases. Polypharmacy and drug intoxication and withdrawal may be the most common causes of delirium (Hales et al. 1988; Trzepacz et al. 1985). Benzodiazepines, opiates, and drugs with anticholinergic activity have a particular association with delirium (T.M. Brown 2000; Marcantonio et al. 1994b). Many drugs (and their metabolites) can unexpectedly contribute to delirium as a result of unrecognized anticholinergic effects. Ten of the 25 most commonly prescribed drugs for the elderly had sufficient *in vitro* anticholinergic activity identified by radioreceptor assay to cause memory and attention impairment in nondelirious elderly subjects (Tune et al. 1992). Therefore, drug exposure must be minimized, especially when facing high-risk periods such as the perioperative phase. Although opiates are associated with delirium, Morrison et al. (2003) found in a prospective study of older patients undergoing hip surgery that delirium was nine times more likely in those patients deemed to have undertreated pain.

The temporal relation between exposure to risk factors and development of delirium requires further study. Postoperative delirium (excluding emergence from anesthesia) appears most frequently at day 3. A large multicenter study found age, duration of anesthesia, lower education, second operation, postoperative infection, and respiratory complications to be predictors of postoperative cognitive impairment (Moller et al. 1998).

Low serum albumin is an important risk factor at any age and may signify poor nutrition, chronic disease, or liver or renal insufficiency. Hypoalbuminemia results in a greater bioavailability of many drugs that are transported in the bloodstream by albumin, which is associated with an increased risk of side effects, including delirium (Dickson 1991; Trzepacz and Francis 1990). This increased biological drug activity occurs within the therapeutic range and may not be recognized because increased levels of free drug are not separately reported in most assays. Serum albumin was identified by discriminant analysis, along with Trail Making Test B and EEG dominant posterior rhythm, as sensitively distinguishing delirious from nondelirious liver transplant candidates (Trzepacz et al. 1988b).

Nicotine withdrawal has been implicated as a potential risk factor in the development of delirium, especially in heavy smokers unable to continue their habit during hospital admission. Klein et al. (2002) reported a single case of delirium in such a patient who responded quickly to a transdermal nicotine patch.

## Mortality

---

Delirium appears to be associated with high mortality. Whether this mortality risk is increased during the index admission, at long-term follow-up, or both is not completely clear; this uncertainty is in part related to challenges in research design. It is also not known whether increased mortality is attributable to the underlying etiologies of delirium; to indirect effects on the body related to perturbations of neuronal, endocrine, and immunological function during delirium; or to damaging effects on the brain from neurochemical abnormalities associated with delirium (i.e., similar to glutamate surges after stroke). Additionally, patients with delirium cannot fully cooperate with their medical care or participate in rehabilitative programs during hospitalization. Their behaviors can directly reduce the effectiveness of procedures meant to treat their medical problems (e.g., removing tubes and intravenous lines, climbing out of bed), which adds to morbidity and possibly to further physiological injury and mortality.

Methodological inconsistencies and shortcomings affect the interpretation of studies of mortality risk associated with delirium. Some studies do not compare patients who have delirium with control groups. Many studies include patients with comorbid dementia, and many studies do not control for severity of medical comorbidity (admittedly difficult to measure). In addition, most studies do not address the effects of advanced age as a separate risk factor, and specific delirium rating instruments are rarely used. The effect on reducing mortality risk of treatment for the delirium itself, a potential confound, is also not reported in most studies. Prospective application of DSM criteria by qualified clinicians, attention to whether the sample is incident or prevalent, identification of referral biases, and indication of whether follow-up mortality rates are cumulative to include the original sample are also important issues that vary across study designs. Attention to matching patients to control subjects for numerous factors, including demographics, education and occupation, baseline cognitive functioning, severity of each medical condition, certain laboratory tests, and medications, is a daunting task but probably more accurate than statistical manipulations of data to adjust for confounding factors.

Reported mortality rates during the index hospitalization for a delirium episode range from 4% to 65% (Cameron et al. 1987; Gustafson et al. 1988), depending on the study design and population. One study found significant differences in index mortality among motoric subtypes, with the lowest rate (10%) in hyperactive as compared with hypoactive (38%) and mixed cases (30%) (Olofsson et al. 1996). When delirium present on admission was excluded, index mortality in incident cases was as low as about 1.5% (Inouye et al. 1999). Index mortality for delirious patients did not differ significantly from that for control subjects without delirium in some studies (Forman et al. 1995; George et al. 1997; Gustafson et al. 1988; Inouye et al. 1998, 1999; Kishi et al. 1995), but it did in others (Cameron et al. 1987; Jitapunkul et al. 1992; Pompei et al. 1994; Rabins and Folstein 1982; van Hemert et al. 1994). Many long-term follow-up studies of delirium mortality rates (more than 3 months after discharge) did find worse mortality in delirium groups, including patients with subsyndromal delirium (Cole et al. 2003b). Excess mortality in some reports was attributed to older age (Gustafson et al. 1988; Huang et al. 1998; Kishi et al. 1995; Trzepacz et al. 1985; Weddington 1982), more serious medical problems (Cole and Primeau 1993; Jitapunkul et al. 1992; Magaziner et al. 1989; Trzepacz et al. 1985), and dementia (Cole and Primeau 1993; Gustafson et al. 1988). Some studies did not find cancer as an explanation for higher mortality rates (Rabins and Folstein 1982), whereas studies comparing only cancer inpatients did find significantly poorer survival in patients with delirium as compared with control subjects (Lawlor et al. 2000a; Minagawa et al. 1996). Curyto et al. (2001) found an increased mortality of 75% at 3 years for delirious compared with control (51%) elderly patients despite no differences in prehospital levels of depression, global cognitive performance, physical functioning, or medical comorbidity.

In a prospective study of medically hospitalized elderly, Inouye et al. (1998) found that delirium significantly increased mortality risk, even after controlling for age, gender, dementia, ADL level, and Acute Physiology and Chronic Health Evaluation (APACHE) II scores. Ely et al. (2004a) reported that delirium was independently associated with a greater than 300% increased likelihood of dying at 6 months ( $P=0.008$ ), even after correcting for numerous covariates, including coma and use of psychoactive medications, in a prospective cohort study of medical ICU patients (see Figure 6–3). McCusker et al. (2002) showed that delirium is a significant predictor of 12-month mortality for older inpatients, even after adjusting for age, sex, marital status, living location, comorbidity, acute physiological severity, illness severity, dementia,

and hospital service. Frail elderly living in nursing facilities studied for 3 months during and after an acute medical hospitalization had a high mortality rate of 18% in hospital and 46% at 3 months that was associated with severe and persistent delirium (Kelly et al. 2001).

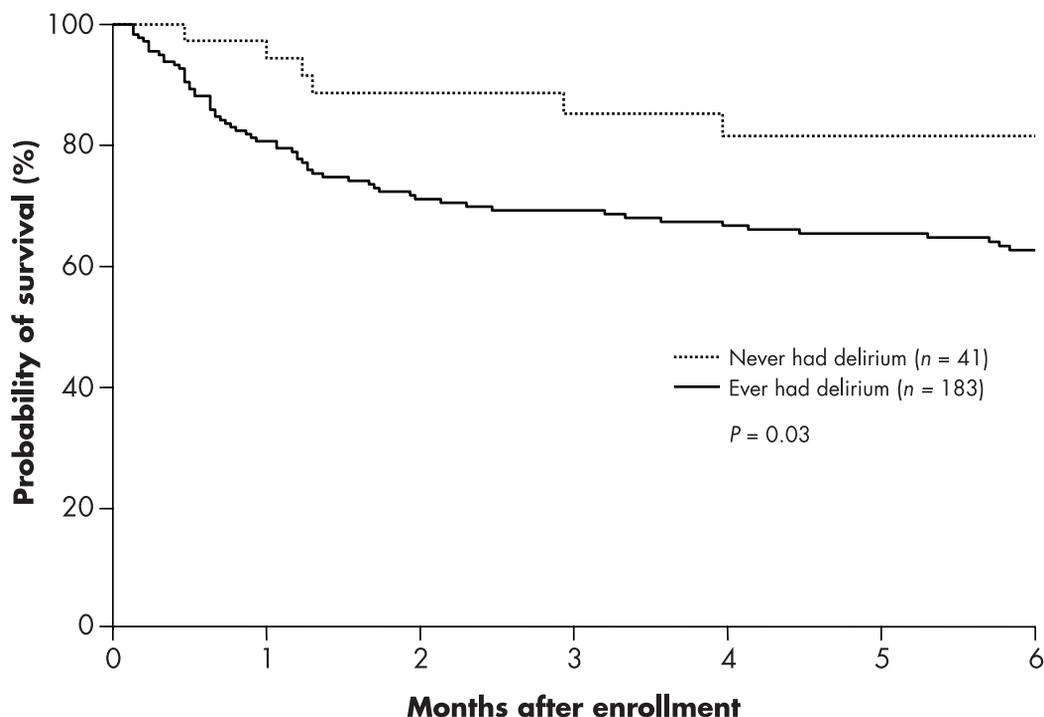

In a prospective cohort study of prevalent delirium in emergency departments, 30 delirious and 77 nondelirious elderly patients who were discharged to home instead of being admitted to the hospital were assessed at 6-month follow-up intervals until 18 months (Kakuma et al. 2003). After adjustment for age, sex, functional level, cognitive status, comorbidity, and number of medications, delirium was significantly associated with mortality (see Figure 6–4). Those whose delirium was not detected by the emergency department staff had the highest mortality over 6 months compared with those whose delirium was detected, for whom no mortality difference from the nondelirious was found, emphasizing the importance of detection.

Thus, although the mechanism is not understood, the presence of delirium does indeed appear to be an adverse prognostic sign that is associated with an increased risk for mortality, extending well beyond the index hospitalization. To what extent aggressive treatment of both the delirium and its comorbid medical problems would reduce morbidity and mortality is not well studied, but at the very least, such treatment makes good clinical sense.

## Reversibility of a Delirium Episode

---

Delirium traditionally has been distinguished from dementia by its potential for reversal. In most cases, delirium is reversible, except in terminal illness or particular examples of severe brain injury. However, evidence that an index episode of delirium may be associated with enduring cognitive deficits suggests that delirium may be more than a transient state. Longer duration of cognitive impairment linked to coma or delirium following traumatic brain injury is associated with poorer recovery, and more severe or prolonged impairments due to delirium from other causes also may be associated with poorer recovery. This association is supported by evidence for worse cognitive outcome in more severe delirium (Wada and Yamaguchi 1993) and episodes of longer duration (Liptzin and Levkoff 1992), but no neurotoxic mechanism has been identified. Moreover, poorer long-term outcome may be related to preexisting comorbidities, including a previously undiagnosed dementia that progresses after delirium resolution. Terminology is also difficult regarding when chronic delirium becomes a dementia. In addition, that many patients continue to

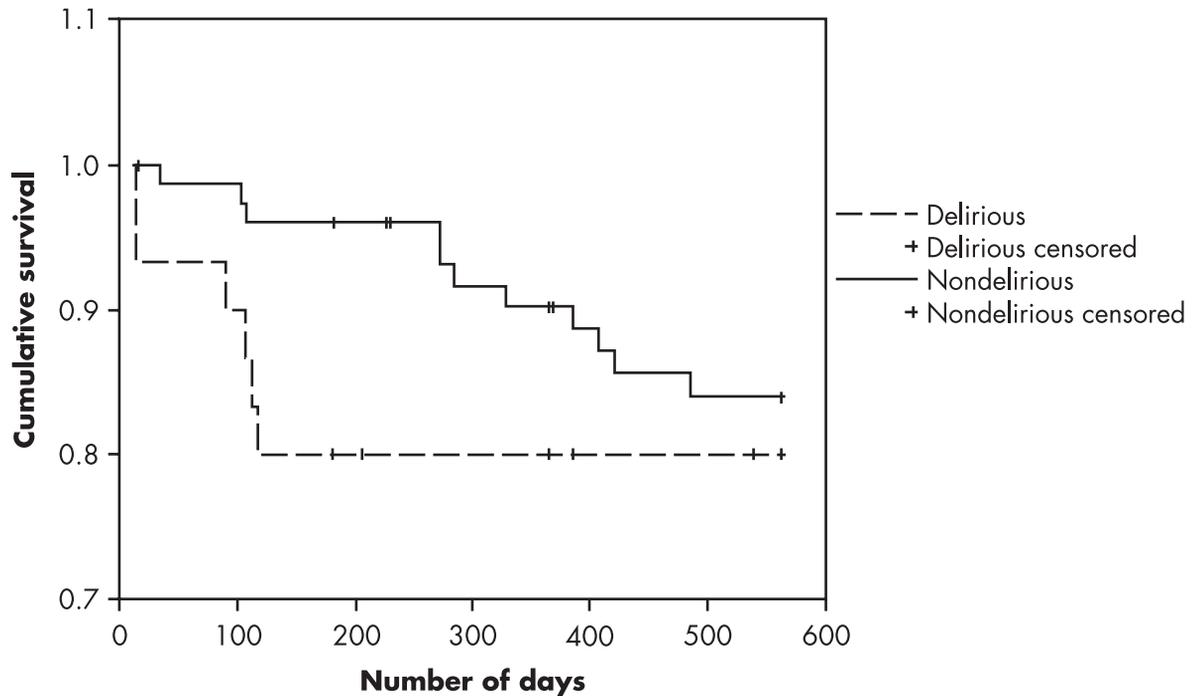

**FIGURE 6-3. Mortality over 6 months in patients with and without prevalent delirium during medical intensive care unit (ICU) stay.**

*Source.* Reprinted from Ely EW, Shintani A, Truman B, et al.: “Delirium as a Predictor of Mortality in Mechanically Ventilated Patients in the Intensive Care Unit.” *Journal of the American Medical Association* 291:1753–1762, 2004. Used with permission.

experience delirium symptoms at hospital discharge (Levkoff et al. 1994) raises the question of incomplete treatment during the index hospitalization as the true cause of persisting symptoms.

In a landmark study of delirium, Bedford (1957) indicated that approximately 5% of the patients were still “confused” at 6-month follow-up, but more recent studies suggested that persistent disturbances may be more frequent after an episode of delirium. Levkoff et al. (1994), in a longitudinal study of elderly patients, found that almost one-third still had delirium after 6 months, with most still having some of its features (disorientation, emotional lability, and sleep disturbances). Full resolution of delirium symptoms at hospital discharge of elderly patients may be the exception rather than the rule (Levkoff et al. 1992; Rockwood 1993). Levkoff et al. (1992) found that only 4% of elderly patients with delirium had complete resolution of symptoms at discharge, 21% at 6 weeks, and 18% at 6 months. However, neither of the studies by Levkoff et al. excluded dementia patients. McCusker et al. (2003b) found that 12 months after diagnosis of delirium in elderly medical inpatients, inattention, disorientation, and poor memory were the most persistent individual symptoms both in those with and in those without concomitant dementia.

Alternatively, others interpret “persisting” cognitive deficits as more related to “diminished brain reserve” associated with aging or preexisting dementia that has simply progressed over time (Francis and Kapoor 1992; Koponen et al. 1994). Camus et al. (2000), in a cross-sectional study of consecutive psychogeriatric admissions, found that the only factor significantly linked to incomplete symptom resolution in delirium was the presence of preexisting cognitive impairment. Rahkonen et al. (2000) found that when the index episode of delirium resolved, a new diagnosis of dementia was made in 27% of 51 prospectively studied community-dwelling elderly, and at 2-year follow-up, a total of 55% had a new diagnosis of dementia. Koponen et al.’s (1994) 5-year longitudinal study of delirium in the elderly found persistence and progression of symptoms to be attributed more to the underlying dementia than to the previous delirium episode. Camus et al. (2000) found that preexisting dementia was associated with only partial or no recovery from delirium in hospitalized elderly patients at 3-week follow-up. Kolbeinsson and Jonsson (1993) found that delirium was complicated by dementia at follow-up in 70% of patients. Thus, “persistent” deficits may instead reflect an underlying disorder and not the delirium. Comorbid dementia may go unrecognized at the time of the delirium index episode in

**FIGURE 6-4.** Long-term follow-up survival differences in emergency department patients with and without delirium who were discharged to home.

part because it is methodologically challenging to adequately assess for preexisting dementia retrospectively. Jackson et al. (2003) used a Modified Blessed Dementia Index during surrogate interviews and review of medical records in their study of long-term cognitive outcome of elderly medical ICU patients with delirium.

In contrast, a longitudinal cohort study of 674 community-dwelling elderly patients with hip fractures assessed delirium, proxy prefracture dementia, and 2- and 12-month follow-up for cognition and social and ADL functioning (Gruber-Baldini et al. 2003). They found that 28% had prefracture dementia or impairment on the Mini-Mental State Exam (MMSE), and another 22% had newly detected cognitive impairment while in the hospital. More than 40% of the latter group had persistent cognitive deficits at follow-up, despite no obvious preexisting dementia, accompanied by poorer physical ADLs and social functioning at 12 months in those still cognitively impaired at 2 months. This supports the notion that an index episode of delirium indeed may be associated with persistent cognitive deficits in almost half the patients in elderly hip surgery populations.

A prospective longitudinal cohort study of 90 stem cell transplant patients addressed the relation between delirium and cognitive outcome posttransplant (Fann et

al. 2003). The mean age of the patients was 42 years; thus, the dementia confound in elderly studies was avoided. After adjustment for age and gender, delirium and its severity predicted executive cognitive impairment at day 80 despite significant improvements in overall vigor and functioning.

Individual delirium symptoms may predict the duration of an episode. Wada and Yamaguchi (1993), in a study of elderly neuropsychiatry consults, found that a longer duration of delirium ( $\geq 1$  week) was predicted by the severity of cognitive disturbance, mood lability, and sleep-wake cycle disruption. Treloar and MacDonald (1997) found that the degree of reversibility of an index episode of delirium was predicted by motor activity, speech and thought disturbances, and a fluctuating course. However, their definition of reversibility was more modest than most clinicians would expect.

Biological measures may correlate with reversibility of delirium. Mach et al. (1995) found that higher levels of serum anticholinergic activity were associated with greater likelihood of full resolution of delirium, perhaps implying that the causes of delirium, such as anticholinergic toxicity, were more reversible, although this was not specifically addressed in this study.

The relation between delirium and persistent symptoms at follow-up may be explained by an index episode of delirium being an actual risk factor for, rather than a cause or marker of, other causes of cognitive impairment. Rockwood et al. (1999) reported an 18% annual incidence of dementia in patients with delirium—a risk more than three times higher than in nondelirious patients when the confounding effects of comorbid illness, severity, and age were adjusted for.

Thus, whether delirium itself causes permanent damage remains controversial. Studies to date do not fully account for the role of underlying etiologies, treatment received, preexisting cognitive impairment, or other confounds. Nonetheless, the concept of delirium as an inherently reversible condition is increasingly questioned.

## Clinical Features

---

### Phenomenology

The classic descriptive study of 106 “dysergastic reaction” (i.e., delirium) patients by Wolff and Curran (1935) is still consistent with current conceptions of delirium phenomenology. Inconsistent and unclear definitions of symptoms and underuse of standardized symptom assessment tools have hampered subsequent efforts to describe delirium phenomenology or to compare symptom incidences across studies and etiological populations. Nearly all studies are cross-sectional, so we lack an understanding of how various symptoms change over the course of an episode. More recent longitudinal research in which daily delirium ratings were used has reported only total scale scores and not the occurrence of individual symptoms and their pattern over time. Relations between symptoms also have not been studied, except through factor analyses of cross-sectional data in a few reports (Trzepacz and Dew 1995; Trzepacz et al. 1998; van der Mast 1994). Although carried out in different populations, these factor analyses had some striking similarities regarding which symptoms clustered together and also suggested that delirium symptoms overshadow dementia symptoms when they are comorbid.

Despite across-study inconsistencies for symptom frequencies, certain symptoms occur more often than others, consistent with the proposal that delirium has core symptoms irrespective of etiology (Trzepacz 1999b, 2000). Multiple etiologies for delirium may “funnel” into a final common neural pathway (Trzepacz 1999b, 2000), so that the phenomenological expression becomes similar despite a breadth of different physiologies. Candidates for *core symptoms* include attention deficits, memory impairment, disorientation, sleep–wake cycle disturbance,

thought process abnormalities, motor alterations, and language disturbances, whereas *associated* or *noncore symptoms* would include perceptual disturbances (illusions, hallucinations), delusions, and affective changes (Trzepacz 1999b). Analysis of Delirium Rating Scale—Revised—98 (DRS-R-98) blinded ratings supports this separation of so-called core from associated symptoms on the basis of their relative prevalence (Trzepacz et al. 2001a). The occurrence of the less frequent associated symptoms might suggest involvement of particular etiologies and their specific pathophysiologies or individual differences in brain circuitry and vulnerability. Characteristic diagnostic features of delirium, such as altered state of consciousness (e.g., called *clouding* by some) and fluctuation of symptom severity over a 24-hour period, may be epiphenomena and not symptoms per se. These features may be more related to *how* the symptoms are expressed, affecting the observed outward appearance of delirium.

Historically, delirium has been viewed by some neurologists primarily as a disturbance of attention; less importance has been attributed to its other cognitive deficits and behavioral symptoms. Disturbance of attention is a key symptom required for diagnosis of delirium yet is unlikely to explain the breadth of delirium symptoms. Distractibility, inattention, and poor environmental awareness can be evident during interview as well as on formal testing. Impairment in attention was found in 100% of the patients with delirium in a blinded assessment in which the DRS-R-98 was used (Trzepacz et al. 2001a). O’Keeffe and Gosney (1997) found that attention deficits discriminated delirium patients from both patients with dementia and elderly inpatients without dementia when sensitive tests such as the Digit Span Backward and Digit Cancellation tests were used.

Memory impairment occurs often in delirium, affecting both short- and long-term memory, although most reports have not distinguished between types of memory impairment. In subclinical hepatic encephalopathy, attention is intact but nonverbal memory is impaired, suggesting that these cognitive functions may be differentially affected during mild delirium (Tarter et al. 1988). In delirium due to posttraumatic brain injury, procedural and declarative memory are impaired, and procedural memory improves first (Ewert et al. 1985). Patients are often amnesic for some or all of their delirium episodes (Breitbart et al. 2002a). Trzepacz et al. (2001a) found a high correlation between the DRS-R-98 short- and long-term memory items ( $r=0.51$ ,  $P=0.01$ ) in delirious patients, with attention correlating with short-term memory ( $r=0.44$ ,  $P=0.03$ ) but not with long-term memory. This is consistent with normally needing to pay attention before information can enter short-term (working) memory, and then

selected data from working memory are stored in long-term memory.

Language disturbances in delirium include dysnomia, paraphasias, impaired comprehension, dysgraphia, and word-finding difficulties. In extreme cases, language resembles a fluent dysphasia. Incoherent speech or speech disturbance is reported commonly. Dysgraphia was once thought to be specific to delirium (Chedru and Geschwind 1972). A more recent comparison with writing samples from patients with other psychiatric disorders reported that dysgraphia was not specific to delirium (Patten and Lamarre 1989). Rather, it appears that the semantic content of language is a more differentiating feature of delirium.

Disorganized thinking was found in 95% of the patients in one study (Rockwood 1993) and was also noted by Cutting (1987) to be different from thought processes in patients with schizophrenia. However, very little work has been done to characterize thought process disorder in patients with delirium, which ranges from tangentiality and circumstantiality to loose associations. When the DRS-R-98 was used, 21% of the patients with delirium exhibited tangentiality or circumstantiality, whereas 58% had loose associations (Trzepacz et al. 2001a).

Disturbances of the sleep-wake cycle are common in patients with delirium. Sleep-wake cycle disturbances may underlie fluctuations in the severity of symptoms during a 24-hour period. Sleep disturbances range from napping and nocturnal disruptions to a more severe disintegration of the normal circadian cycle. The extent to which sleep-wake cycle disturbance confounds the hyperactive-hypoactive subtyping of delirium is not known.

Hallucinations, illusions, and other misperceptions and delusions occur less frequently in delirium than do core symptoms. The type of perceptual disturbance and delusion distinguishes delirium from schizophrenia (Cutting 1987). Clinically, the occurrence of visual (as well as tactile, olfactory, and gustatory) hallucinations heightens the likelihood of delirium, although primary psychiatric disorders occasionally present with visual misperceptions. Visual hallucinations range from patterns or shapes to complex and vivid animations, which may vary according to which part of the brain is affected (Trzepacz 1994). Persecutory delusions that are poorly formed (not systematized) are the most common type in delirium, although other types occur (e.g., somatic or grandiose). Delusions do not seem to be a result of cognitive impairment per se. A retrospective study of 227 patients with delirium found that 26% had delusions, 27% had visual hallucinations, 12% had auditory hallucinations, and 3% had tactile hallucinations (Webster and Holroyd 2000).

Affective lability that changes within minutes is characteristic of delirium. It takes many forms (e.g., anxious,

apathetic, angry, dysphoric), changes from one type to another without obvious relation to the context (i.e., incongruent), and is usually not under self-control.

## Motor Subtypes

There has been much interest in whether there are subtypes of delirium, derived from various parameters such as underlying physiology, etiology, and symptom profile (Trzepacz 1994), similar to the way heart failure is categorized. It is unclear whether such meaningful subtypes exist. Nonetheless, the most studied possible subtype is based on psychomotor behavior. Although not all patients with delirium exhibit psychomotor change, different presentations of activity have been recognized for centuries. Neurologists have differentiated disorientation with reduced motor activity, referred to as “acute confusion,” from the hyperactive disorientation of patients labeled as “delirious” (Mesulam 1985; Mori and Yamadori 1987). In a study of infarctions of the right middle cerebral artery, Mori and Yamadori (1987) suggested that acute confusional states are disturbances of attention resulting from frontostriatal damage, whereas acute agitated deliria are disturbances of emotion and affect resulting from injury to the middle temporal gyrus. However, these distinctions and localizations have not been supported by subsequent studies (Trzepacz 1994).

Lipowski (1990) championed the use of the umbrella term *delirium* and then described three psychomotor subtypes: “hyperactive,” “hypoactive,” and “mixed.” Various definitions of motor subtypes have been subjectively described, are not standardized, and include nonmotor behavioral features such as disturbances of speech, affective changes, and disturbances of thinking and perception (see Table 6-4). With the use of such definitions, motor subtypes are characterized by similar degrees of overall cognitive impairment and EEG slowing (Koponen et al. 1989; Ross et al. 1991) but differ for some nonmotor symptoms. Delusions, hallucinations, mood lability, speech incoherence, and sleep disturbances may be somewhat more frequent in hyperactive patients (Meagher and Trzepacz 2000; Ross et al. 1991). Waxing and waning of symptom severity and sleep-wake cycle abnormalities complicate our understanding of motor subtypes, as does reliance on subjective and retrospective reports of behavior over 24-hour periods. Reports of relative frequencies of motor subtypes vary widely, even when patients with alcohol withdrawal are excluded. In a prospective study of patients with delirium, Meagher (2003) found a remarkably low level of concordance between three different psychomotor schemas. Studies that use objective motor activity level monitoring are needed.

**TABLE 6-4. Features of psychomotor subtypes of delirium**

	<b>Hyperactive</b>	<b>Hypoactive</b>
<b>Motor symptoms</b>	Increased activity levels Increased speed of actions Loss of control of activity Restlessness and wandering	Decreased activity levels Decreased speed of actions Apathy and listlessness
<b>Nonmotor symptoms</b>	Increased amount, speed, and volume of speech Altered content of verbal output (e.g., singing, shouting, laughing) Aggression, combativeness, uncooperativeness Hallucinations Hyperalertness, increased startle	Decreased amount, speed, and volume of speech Hypoalertness Hypersomnolence Social withdrawal
<b>Electroencephalogram</b>	Diffuse slowing	Diffuse slowing
<b>Cognition</b>	Diffuse deficits	Diffuse deficits
<b>Treatment</b>	Neuroleptic responsive	Neuroleptic responsive
<b>Outcome</b>	? Lower mortality	? Increased mortality and closer to stupor

*Note.* Mixed subtype requires evidence of both hyperactive and hypoactive delirium.

In many reports, up to half of the patients have a mixed motor subtype during their episode. Detailed longitudinal study of delirium symptoms is necessary before any definitive conclusion can be reached regarding the stability of motor subtypes. Peterson et al. (2003) used the Richmond Agitation and Aggression Scale to longitudinally rate medical ICU delirium patients by nurses three times per shift. They found very few hyperactive ( $n=4$ ) and mostly hypoactive ( $n=138$ ) or mixed ( $n=255$ ) deliria, but the use of sedating medications confounds these results.

Studies to date have not provided convincing evidence that motor subtypes have distinct neurobiological underpinnings. The delirium symptom profile of patients with localized cerebral insults does not reliably link specific motor subtypes to lesions at particular cerebral sites. Neither EEG nor functional neuroimaging findings distinguish motor subtypes (Trzepacz 1994).

Motor subtypes of delirium may be associated with different etiologies, treatment, or outcome. Delirium due to drug-related causes is most commonly hyperactive, whereas delirium due to metabolic disturbances, including hypoxia, is more frequently hypoactive (Meagher and Trzepacz 1998; O'Keeffe and Lavan 1999; Olofsson et al. 1996; Ross et al. 1991). Patients with a hyperactive subtype may have better outcomes after an episode of delirium, with shorter lengths of stay, lower mortality rates, and higher rates of full recovery (Kobayashi et al. 1992; Liptzin and Levkoff 1992; Olofsson et al. 1996). However, these varied outcomes may reflect differences in

underlying causes, recognition rates, and/or treatment practices. Underdetection and misdiagnosis are especially common in hypoactive patients. Even when hypoactive subtypes are actively screened for, these patients still may have a poorer outcome (O'Keeffe and Lavan 1999). Meagher et al. (1996) found that the use of psychotropic medication and supportive environmental ward strategies were more closely linked to level of hyperactivity than to the degree of cognitive disturbance. In contrast, Olofsson et al. (1996) reported better outcomes in patients with hyperactive delirium but noted that they received less haloperidol than did nonhyperactive patients. O'Keeffe and Lavan (1999) reported greater use of neuroleptics and shorter hospital stays in hyperactive patients but linked these to less severe illness at the onset of delirium and a lower incidence of hospital-acquired infections and bedsores in those who were hyperactive. Others have found that different motor subtypes were associated with similar outcomes (Camus et al. 2000).

Treatment studies have not been designed specifically to assess response of effectiveness for different motor subtypes. In clinical practice, it is often presumed that psychotropic agents are useful in delirium solely for sedative or antipsychotic purposes and thus more effective for hyperactive patients, but the few available data are mixed (Breitbart et al. 2002b; Platt et al. 1994a; Uchiyama et al. 1996). Overall, the relationships among motor subtype, treatment, and outcome remain unclear and confounded by methodological issues.

## Diagnosis and Assessment

---

### Diagnosis

Specific diagnostic criteria for delirium first appeared in DSM-III, around the same time as the first symptom rating scales for delirium. Thus, early clinical reports and research based on the first two editions of DSM (American Psychiatric Association 1952, 1968) or Research Diagnostic Criteria (RDC) were affected by this lack of diagnostic specificity.

DSM-I was first published in 1952 and described acute and chronic brain syndromes (American Psychiatric Association 1952). Most forms of delirium were encompassed within the acute, reversible category and were characterized by impairments of orientation, memory, all intellectual functions, and judgment, as well as lability and shallowness of affect. Other disturbances, such as hallucinations and delusions, were considered secondary to the disturbance of the sensorium. Causes of delirium were specifically noted—for example, “acute brain syndrome associated with cerebrovascular accident.” DSM-II (American Psychiatric Association 1968) described two organic brain syndromes, psychotic and nonpsychotic types, each with an acute or a chronic delineation. DSM-II maintained the same five symptoms as DSM-I. DSM-III (American Psychiatric Association 1987) distinguished delirium from dementia and other organic mental disorders, each identified by its own explicit criteria. Some revisions were made in DSM-III-R, especially to the major criterion involving inattention and altered consciousness.

DSM-IV (American Psychiatric Association 1994), and its text revision, DSM-IV-TR (American Psychiatric Association 2000), have five categories of delirium; the criteria are the same for each category except the one for etiology. The categories are 1) delirium due to a general medical condition, 2) substance intoxication delirium, 3) substance withdrawal delirium, 4) delirium due to multiple etiologies, and 5) delirium not otherwise specified. This notation of etiology in DSM-IV is reminiscent of that used in DSM-I.

DSM-III, DSM-III-R, and DSM-IV included efforts to further clarify the major criterion describing altered state of consciousness, considered as either *a disturbance of consciousness* or *inattention*. Liptzin et al. (1993) found disturbed consciousness in 100% of delirious elderly patients irrespective of whether comorbid dementia was present. Impairment of attention distinguishes delirium from dementia. Attention deficits in delirium range from general, nonspecific reduction in alertness to decreased

selective focusing or sustaining of attention. The contribution of attention deficits to the altered awareness that occurs in delirium is insufficient by itself to account for other prominent symptoms such as formal thought disorder, language and sleep–wake cycle disturbances, and other cognitive-perceptual deficits.

The temporal course of delirium, with acute onset and fluctuation of symptoms, has been a separate criterion in each of the last three editions of DSM. Temporal features assist in distinguishing delirium from dementia, supported by data derived from the DRS-R-98 (Trzepacz et al. 2002b).

Despite the breadth of the symptoms of delirium, not all have been emphasized in the various editions of DSM. Dysexecutive symptoms (impairment of prefrontal executive cognition) are not mentioned in any DSM edition, despite their clinical importance in delirium (Trzepacz 1994). Psychosis has not received much attention, except in DSM-II, despite the occurrence of delusions in about a fifth of patients with delirium (Ross et al. 1991; Sirois 1988). Characteristic features of delusions (usually paranoid and poorly formed) and hallucinations (often visual) have not been specified in DSM criteria, despite their usefulness to the clinician.

The World Health Organization's research diagnostic criteria for delirium in ICD-10 are similar to the DSM-IV criteria. However, ICD-10 diverges from DSM-IV in that cognitive dysfunction is manifested by both “impairment of immediate recall and recent memory, with intact remote memory” and “disorientation in time, place or person.” Additionally, a disturbance in sleep is present and manifested by insomnia, nocturnal worsening of symptoms, or disturbing dreams or nightmares that may continue as hallucinations or illusions when awake, which seems to etiologically link perceptual disturbances to sleep mechanisms. Despite these differences, a study of 80 patients with delirium showed 100% concordance for diagnosis between DSM-III-R and ICD-10 research criteria (Treloar and MacDonald 1997).

Cole et al. (2003a) used DSM-III-R as the gold standard to compare the sensitivity and specificity of DSM-IV, DSM-III, and ICD-10 criteria for delirium in 40 patients with delirium only, 94 with dementia only, and 128 with comorbid delirium and dementia. They found that requiring clouding of consciousness lowered the sensitivity considerably and recommended inattention instead—perhaps because the term *clouding of consciousness* is vague and therefore poorly assessable. Sensitivity and specificity of DSM-IV, DSM-III, and ICD-10 criteria were 100% and 71%, 96% and 91%, and 61% and 91%, respectively. Thus, DSM-IV was found to be the most inclusive.

## Cognitive Assessment

Because delirium is primarily a cognitive disorder, bedside assessment of cognition is critical to proper diagnosis. Although all cognitive domains—orientation, attention, short- and long-term memory, visuoconstructional ability, and executive function—are affected in delirium, attention deficits are the most specifically emphasized in DSM. Pattern and timing of deficits assist in differential diagnosis from dementias and amnesic disorders. Use of bedside screening tests (see also Chapter 1, “Psychiatric Assessment and Consultation”) such as the well-known MMSE (Folstein et al. 1975) is important clinically to document the presence of a cognitive disorder; however, it is alone insufficient to distinguish delirium from dementia (Trzepacz et al. 1988a). The MMSE is too easy for many people (ceiling effect) and has a limited breadth of items, particularly for prefrontal executive and right-hemisphere functions.

The Cognitive Test for Delirium (CTD; Hart et al. 1996) is a more recent bedside test designed specifically for patients with delirium who are often unable to speak or write in a medical setting (e.g., on a ventilator). Unlike the MMSE, the CTD has many nonverbal (nondominant hemisphere) items and abstraction questions. The CTD correlates highly with the MMSE ( $r=0.82$ ) in patients with delirium and was performable in 42% of the ICU patients in whom the MMSE was not. It has two equivalent forms that correlated highly ( $r=0.90$ ) in patients with dementia, which makes it better suited for repeated measurements. However, it correlates less well with symptom rating scales for delirium that also include noncognitive symptoms—for example, the MCV Nurses Rating Scale for Delirium ( $r=-0.02$ ) (Hart et al. 1996) and the DRS-R-98 ( $r=-0.62$ ) (Trzepacz et al. 2001b). An abbreviated version of the CTD, with just two of its nine items (visual attention span and recognition memory for pictures), retained good reliability and discriminant validity (Hart et al. 1997).

The clock drawing test is a useful screen for cognitive impairment in medically ill patients, but it does not discriminate between delirium and dementia (Manos 1997). A global rating of attentiveness and the Digit Span Backward and Digit Cancellation tests differentiated delirium from dementia among elderly medical inpatients, whereas the Vigilance Test, the MMSE, and the Digit Span Forward test did not (O’Keefe and Gosney 1997). However, patients were excluded from the study if their MMSE score was 10 points or less, which effectively rules out applicability to many patients with delirium.

## Delirium Assessment Instruments

Diagnostic criteria are important in diagnosing delirium, and cognitive tests are useful in documenting cognitive impairment. Rating a range of delirium symptoms, however, requires other methods. More than 10 instruments have been proposed to assess symptoms of delirium (Trzepacz 1996b) for screening, diagnosis, or symptom severity rating. Nonvalidated measures, designed for use in a single study, continue to proliferate in the literature. However, relatively few have been used broadly (see later in this section). Three instruments operationalized DSM-III criteria: the Saskatoon Delirium Checklist (Miller et al. 1988), Organic Brain Syndrome Scale (Berggren et al. 1987), and Delirium Assessment Scale (O’Keefe 1994). In these, DSM-III-derived items are rated along a continuum of mild to moderate to severe. None has been well described or validated. The Delirium Assessment Scale could not distinguish delirium from dementia patients. A more recent severity scale, the Confusional State Evaluation (Robertsson 1999), assessed 22 items, but 12 were determined a priori to be “key symptoms.” It was not validated against control groups, and patients with dementia were included in the delirium group.

The Confusion Assessment Method (CAM) is probably the most widely used screening tool for diagnosis of delirium in general hospitals in its 4-item form (Inouye et al. 1990). CAM is based on DSM-III-R criteria and has two forms: 1) a full scale with 11 items rated as present or absent and 2) the more commonly used algorithm that requires the presence of 3 of 4 cardinal symptoms for a diagnosis of delirium. It is intended for use by nonpsychiatric clinicians in hospital settings and is useful for case finding, although nurses’ ratings were much less sensitive than those done by physicians (0.13 vs. 1.00) when compared with an independent physician’s DSM-III-R diagnosis (Rolfson et al. 1999). One study (Rockwood 1993) suggested that lower specificity and sensitivity are the trade-offs for the test’s simplicity, even though in other studies the test performed well compared with physicians’ diagnoses in acute hospital settings. It has not been well studied for its ability to distinguish delirium from dementia, depression, or other psychiatric disorders.

Recently, Cole et al. (2003a) assessed the sensitivity and specificity of the full CAM in patients with DSM-III-R–diagnosed delirium, dementia, or comorbid delirium and dementia. With a cutoff of 6 of 11 items present, the authors found 95% sensitivity and 83% specificity in delirium-only patients and 98% sensitivity and 76% specificity in comorbid patients; however, use of fewer items (e.g., a minimum cutoff of 3 symptoms) greatly reduced

the specificities to 60% for delirium and 47% for comorbid delirium and dementia. The CAM appears to be useful for screening elderly emergency department patients for delirium (Monette et al. 2001). On the basis of a geriatrician's interview, comparison of ratings from the geriatrician interviewer with those from an observing layperson indicated interrater reliability of 0.91, sensitivity of 0.86, and specificity of 1.00.

A recent extension of the CAM is the CAM-ICU (Ely et al. 2001a, 2001b), aimed at use by nurses for severely medically ill patients in the ICU setting. The CAM-ICU uses specific adjunctive tests and standardized administration to enhance reliability and validity; 95% validity and 0.92–0.96 interrater reliability have been reported, compared with expert psychiatric diagnosis of delirium with DSM-IV criteria, in two different validation studies of 150 patients (Ely et al. 2001a, 2001b).

The delirium assessment tool most commonly used by nurses is the NEECHAM Scale (Neelon et al. 1996). It is scored from 0 to 30, with cutoffs for levels of confusion severity, and was originally validated in elderly acute medical and nursing home settings without a control group. Interrater reliability was 0.96, correlation with the MMSE was 0.81, and correlation with nurses' subjective ratings was 0.46. It has three sections, including a physiological measurement section. Internal consistency was between 0.73 and 0.82 (Cronbach  $\alpha$ ) in 73 elderly hip surgery patients, in whom factor analysis identified three factors (Johansson et al. 2002). It has been translated into Swedish, Norwegian, and Japanese.

The Delirium Rating Scale (DRS; Trzepacz et al. 1988a) is a 10-item scale assessing a breadth of delirium features and can function both to clarify diagnosis and to assess symptom severity because of its hierarchical nature (Trzepacz 1999a; van der Mast 1994). It is probably the most widely used delirium rating scale and has been translated into Italian, French, Spanish, Korean, Japanese, Mandarin Chinese, Dutch, Swedish, German, Portuguese, and a language of India for international use. It is generally used by those who have some psychiatric training. The DRS has high interrater reliability and validity, even when compared with other psychiatric patient groups, and distinguishes delirium from dementia. Factor analysis finds a two- or three-factor structure (Trzepacz 1999a; Trzepacz and Dew 1995). However, because of some of its items, it does not function as well for frequent repeated measurements and thus has been modified by some researchers to a seven- or eight-item subscale. In one study (Treloar and MacDonald 1997), the DRS and CAM diagnosed delirium in patients with high level of agreement ( $\kappa=0.81$ ). More recently, it has been useful in children and adolescents (Turkel et al. 2003).

The DRS-R-98 is a substantially revised version that addresses the shortcomings of the DRS (Trzepacz et al. 2001b). It allows for repeated measurements and includes separate or new items for language, thought processes, motor agitation, motor retardation, and five cognitive domains. The DRS-R-98 has 16 items, with 3 diagnostic items separable from 13 severity items that form a severity subscale that also was validated. Severity for a broad range of symptoms known to occur in delirium is described with standard phenomenological definitions, without a priori assumptions about which occur more frequently. The total scale is used for initial evaluation of delirium to allow discrimination from other disorders. The DRS-R-98 total score distinguished ( $P<0.001$ ) delirium from dementia, schizophrenia, depression, and other medical illnesses during blind ratings, with sensitivities ranging from 91% to 100% and specificities from 85% to 100%, depending on the cutoff score chosen. The DRS-R-98 has high internal consistency (Cronbach  $\alpha=0.90$ ), correlates well with the DRS ( $r=0.83$ ) and CTD ( $r=-0.62$ ), and has high interrater reliability (intraclass correlation coefficient [ICC]=0.99). Translations exist or are in progress for Japanese, Korean, Greek, Portuguese, Danish, Dutch, German, Spanish (Mexico and Spain), French, Lithuanian, Norwegian, Italian, and Chinese versions. Japanese and Spanish (Spain) versions have been validated and published (Fonseca et al., in press; Kishi et al. 2001). A Palm Pilot version has been used for clinical research (Hill et al. 2002).

The Memorial Delirium Assessment Scale (MDAS) is a 10-item severity rating scale for use after a diagnosis of delirium has been made (Breitbart et al. 1997). It was intended for repeated ratings within a 24-hour period, as in treatment studies. The MDAS does not include items for temporal onset or fluctuation of symptoms, which helps to distinguish delirium from dementia. The MDAS correlated highly with the DRS ( $r=0.88$ ) and MMSE ( $r=-0.91$ ). The Japanese version of the MDAS was validated in 37 elderly patients with either delirium, dementia, mood disorder, or schizophrenia and found to distinguish among them ( $P<0.001$ ), with mean score of 18 in the delirium group (Matsuoka et al. 2001). It correlated reasonably well with the DRS Japanese version ( $r=0.74$ ) and Clinician's Global Rating of Delirium ( $r=0.67$ ) and less well with the MMSE ( $r=0.54$ ). The Italian version (Grassi et al. 2001) correlated well with the DRS Italian version in a study of 105 consecutive (66 had delirium) cancer patients. With the CAM as the diagnostic standard, the MDAS had high specificity (94%) but low sensitivity (68%), whereas the DRS with a cutoff of 10 had high sensitivity (95%) and low specificity (68%) and with a cutoff of 12 had a sensitivity of 80% and a specificity of

76%. In this same study, the MMSE had a 96% sensitivity but only a 38% specificity. Factor analysis showed a three-factor structure for the DRS and a two-factor structure for the MDAS. Lawlor et al. (2000b) used the MDAS in cancer patients with DSM-IV–diagnosed delirium and found two factors on factor analysis (Cronbach  $\alpha=0.78$  and  $r=0.55$  with the MMSE).

On the basis of issues such as instrument design, purpose, and breadth of use, several of the available instruments are recommended (see Table 6–5). They can be used together or separately, depending on the clinical or research need. For example, a screening tool can be used for case detection, followed by application of DSM criteria, and then a more thorough rating for symptom severity.

## Electroencephalography

In the 1940s, Engel and Romano (1944, 1959; Romano and Engel 1944) wrote a series of classic papers that described the relation of delirium, as measured by cognitive impairment, to EEG generalized slowing. In their seminal work, they showed an association between abnormal electrical activity of the brain and symptoms of delirium, the reversibility of both of these conditions, the ubiquity of EEG changes for different underlying disease states, and the improvement in EEG background rhythm that paralleled clinical improvement. In most cases, EEGs are not needed to make a clinical diagnosis of delirium; instead, they are used when seizures are suspected or differential diagnosis is difficult, as in schizophrenic patients with medical illness. Most often, a careful assessment of behaviors, cognition, and history is sufficient to diagnose delirium. Nonetheless, EEG is the only technological method to assist in delirium diagnosis.

EEG characteristics in delirium include slowing or dropout of the dominant posterior rhythm, diffuse theta or delta waves (i.e., slowing), poor organization of the background rhythm, and loss of reactivity of EEG to eye opening and closing (Jacobson and Jerrier 2000). Similarly, quantitative EEG in delirium shows slowing of power bands' mean frequency, especially in posterior regions (see Figure 6–5).

In burn patients, Andreasen et al. (1977) showed that the time course of EEG slowing could precede or lag behind overt clinical symptoms of delirium, although sensitive delirium symptom ratings were not used. EEG dominant posterior rhythm, along with serum albumin and Trail Making Test B, distinguished delirious from nondelirious cirrhosis patients in another study (Trzepacz et al. 1988b). Although generalized slowing is the typical EEG pattern for both hypoactive and hyperactive presentations

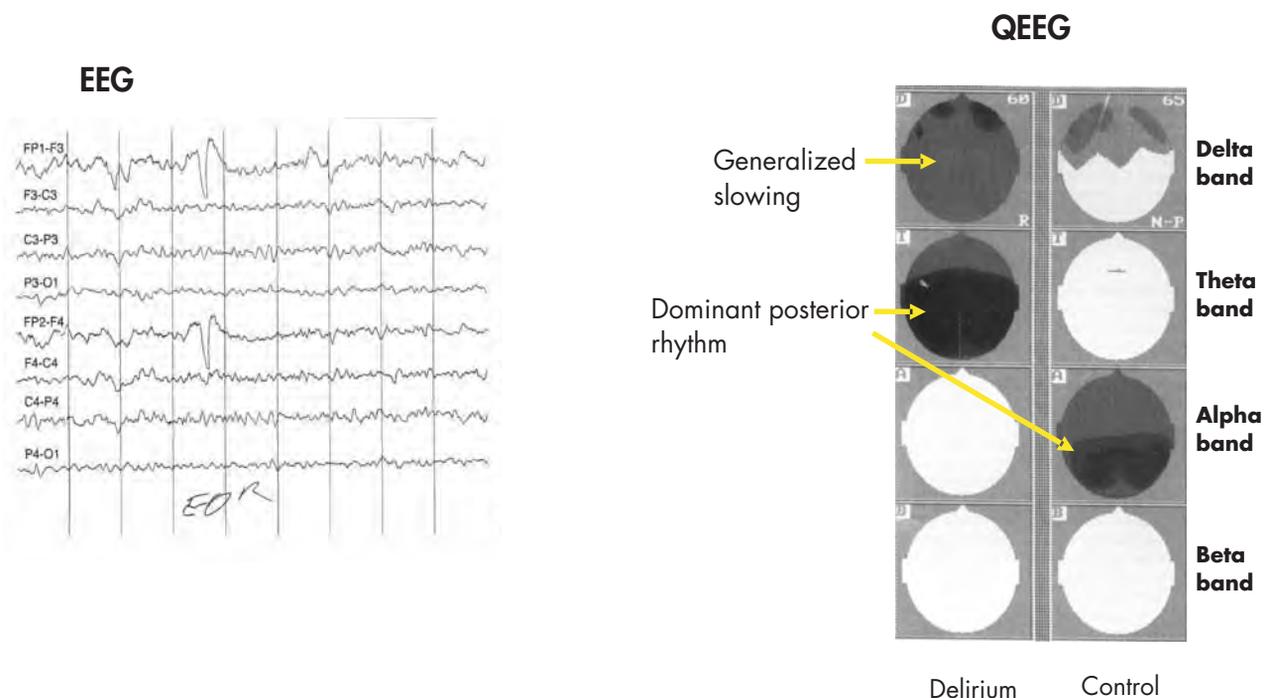

of delirium and for most etiologies, delirium tremens is most prominently associated with low-voltage fast activity (Kennard et al. 1945) that is superimposed on slow waves. Intoxication with sedative-hypnotics is associated with fast beta waves. Although diffuse slowing is the most common presentation, false-negative results occur when a person's characteristic dominant posterior rhythm does not slow sufficiently to drop from the alpha to the theta range, thereby being read as normal despite the presence of abnormal slowing for that individual. (Generally, a change of more than 1 cycle[s] per second [cps] from an individual's baseline is considered abnormal.) Jacobson and Jerrier (2000) warned that it can be difficult to distinguish delirium from drowsiness and light sleep unless the technologist includes standard alerting procedures during the EEG. Comparison with prior baseline EEGs is often helpful to document that slowing has in fact occurred. Less commonly, but nonetheless important, an EEG may detect focal problems, such as ictal and subictal states or a previously unsuspected tumor that presents with prominent confusion (see Table 6–6). These include toxic ictal psychosis, nonconvulsive status, and complex partial status epilepticus (Drake and Coffey 1983; Trzepacz 1994) or focal lesions (Jacobson and Jerrier 2000). Toxic ictal states include tricyclic antidepressant overdose, in which the seizure threshold is lowered and anticholinergic activity contributes to delirium. New-onset complex partial seizures, usually related to ischemic damage (Sundaram and Dostrow 1995), are underrecognized causes of delirium in the elderly, especially when prolonged confusion occurs during status.

Advances in EEG technologies have expanded our knowledge. After spectral analysis of elderly patients with delirium (about 75% of whom also had dementia), Koponen et al. (1989) found significant reductions in alpha percentage, increased theta and delta activity, and slowing of the peak and mean frequencies. All of these findings are consistent with EEG slowing. The study also found a correlation between the severity of cognitive decline and the length of the patient's hospital stay, on the one hand, and the degree of EEG slowing, on the other. Jacobson et al. (1993a) used quantitative EEG to distinguish delirious persons from nondelirious individuals with the relative power of the alpha frequency band and delirious persons from individuals with dementia with the theta activity and relative power of delta. Serial EEGs of patients with delirium showed associations between the relative power of the alpha band and cognitive ability, whereas in patients with dementia, the absolute power of the delta band was associated with cognitive changes (Jacobson et al. 1993b). Quantitative EEG could replace conventional EEG for delirium assessment in the future (Jacobson and Jerrier 2000).

**TABLE 6-5. Recommended delirium assessment instruments**

Instrument <sup>a</sup>	Type	Rater
NEECHAM (Neelon et al. 1996)	Screen for high-risk patients	Nurses
Confusion Assessment Method (Inouye et al. 1990)	4-item diagnostic screen	Nonpsychiatric clinician
Delirium Rating Scale (Trzepacz et al. 1998)	10-item severity/diagnostic scale	Psychiatrically trained clinician
Memorial Delirium Assessment Scale (Breitbart et al. 1997)	10-item severity scale	Clinician
Delirium Rating Scale—Revised-98 (Trzepacz et al. 2001b)	16-item scale (includes severity subscale)	Psychiatrically trained clinician

**FIGURE 6-5. Typical electroencephalogram (EEG) and quantitative EEG (QEEG) findings in delirium.**

Examples of bipolar lead EEG and QEEG in delirium showing diffuse slowing, especially of the dominant posterior rhythm. On QEEG, higher power is shown in darker shading, according to each of the four frequency bands.

Source. Reprinted from Jacobson SA, Jerrier S: "EEG in Delirium." *Seminars in Clinical Neuropsychiatry* 5:86-93, 2000. Used with permission.

Evoked potentials also may be abnormal in delirium. Metabolic causes of delirium precipitate abnormalities in visual, auditory, and somatosensory evoked potentials (Kullmann et al. 1995; Trzepacz 1994), whereas somatosensory evoked potentials are abnormal in patients whose delirium is due to posttraumatic brain injury. In general, normalization of evoked potentials parallels clinical improvement, although evoked potentials are not routinely recorded for clinical purposes.

EEGs and evoked potentials in children with delirium show patterns similar to those in adults, with diffuse slowing on EEG and increased latencies of evoked potentials (J.A. Katz et al. 1988; Prugh et al. 1980; Ruijs et al. 1993, 1994). The degree of slowing on EEGs and evoked potentials performed serially over time in children and adolescents correlates with the severity of delirium and with recovery from delirium (Foley et al. 1981; Montgomery et al. 1991; Onofrij et al. 1991).

**TABLE 6-6. Electroencephalographic patterns in patients with delirium**

Electroencephalographic finding	Comment	Causes
Diffuse slowing	Most typical delirium pattern	Many causes, including anticholinergic, posttraumatic brain injury, hepatic encephalopathy, hypoxia
Low-voltage fast activity	Typical of delirium tremens	Alcohol withdrawal; benzodiazepine intoxication
Spikes/polyspikes, frontocentral	Toxic ictal pattern (nonconvulsive)	Hypnotic drug withdrawal; tricyclic and phenothiazine intoxication
Left/bilateral slowing or delta bursts; frontal intermittent rhythmic delta	Acute confusional migraine	Usually in adolescents
Epileptiform activity, frontotemporal or generalized	Status with prolonged confusional states	Nonconvulsive status and complex partial status epilepticus

## Etiology

Delirium has a wide variety of etiologies, which may occur alone or in combination (see Tables 6-7 and 6-8). These include primary cerebral disorders, systemic disturbances that affect cerebral function, drug and toxin exposure (including intoxication and withdrawal), and a range of factors that can contribute to delirium but have an uncertain role as etiological factors by themselves (psychological and environmental factors). To be considered causal, an etiology should be a recognized possible cause of delirium and be temporally related in onset and course to delirium presentation; also, the delirium should not be better accounted for by other factors. No clear cause is found in approximately 10% of patients, and these cases are categorized as delirium not otherwise specified in DSM-IV-TR.

In those studies in which the possibility of multiple etiologies has been considered, between two and six possible causes are typically identified (Breitbart et al. 1996; Francis et al. 1990; Meagher et al. 1996; O'Keeffe and Lavan 1996; Trzepacz et al. 1985), with a single etiology identified in fewer than 50% of cases (Camus et al. 2000; O'Keeffe and Lavan 1999; Olofsson et al. 1996). Delirium with multiple etiologies is more frequent in the elderly and those with terminal illness. For example, delirium in cancer patients can be due to the direct effect of the primary tumor or the indirect effects of metastases, metabolic problems (organ failure or electrolyte disturbance), chemotherapy, radiation and other treatments, infections, vascular complications, nutritional deficits, and paraneoplastic syndromes. This multifactorial nature has been underemphasized in research—etiological attribution typically is based on clinical impressions that are not standardized (e.g., the most likely cause identified by referring physician) or that are oversimplified by documenting

a single etiology for each case. That delirium due to a single etiology is the exception rather than the rule highlights the importance of multidisciplinary approaches to management and the need for continued vigilance to the possibility of further etiological inputs even when a cause has been identified.

Some causes are more frequently encountered in particular populations. Delirium in children and adolescents involves the same categories of etiologies as in adults, although specific causes may differ. Delirium related to illicit drugs is more common in younger populations, whereas delirium due to prescribed drugs and polypharmacy is more common in older populations. Cerebral hypoxia is common at age extremes—chronic obstructive airway disease, myocardial infarction, and stroke are common in older patients, and hypoxia due to foreign-body inhalation, drowning, and asthma are more frequent in younger patients. Poisonings are also more common in children than in adults, whereas young adults have the highest rates of head trauma.

Once delirium is diagnosed, a careful and thorough, but prioritized, search for causes must be conducted. Ameliorations of specific underlying causes are important in resolving delirium; however, this should not preclude treatment of the delirium itself, which can reduce symptoms even before underlying medical causes are rectified (Breitbart et al. 1996).

## Neuropathogenesis

Even though delirium has many different etiologies, its constellation of symptoms is largely stereotyped, with some considered core symptoms. Somehow, this diversity of physiological perturbations translates into a common clinical expression that may represent dysfunction of

**TABLE 6-7. Selected etiologies of delirium<sup>a</sup>**

<b>Drug intoxication</b>	<b>Intracranial infection</b>
Alcohol	Meningitis
Sedative-hypnotics	Encephalitis
Opiates	Abscess
Psychostimulants	Neurosyphilis
Hallucinogens	Human immunodeficiency virus
Inhalants	<b>Systemic infection</b>
<b>Drug withdrawal</b>	Bacteremia/sepsis
Alcohol	Fungal
Sedative-hypnotics	Protozoal
<b>Metabolic and endocrine disturbance</b>	Viral
Volume depletion or volume overload	<b>Cerebrovascular</b>
Acidosis or alkalosis	Stroke, transient ischemic attack
Hypoxia	Subarachnoid hemorrhage
Uremia	Other central nervous system disorders
Anemia	Cerebral edema
Hepatic failure	Seizures
Hypoglycemia or hyperglycemia	Hypertensive encephalopathy
Hypoalbuminemia	Eclampsia
Bilirubinemia	<b>Autoimmune</b>
Hypocalcemia or hypercalcemia	Central nervous system vasculitis
Hypokalemia or hyperkalemia	Systemic lupus erythematosus
Hyponatremia or hypernatremia	Acute graft rejection
Hypomagnesemia or hypermagnesemia	Acute graft vs. host disease
Hypophosphatemia	<b>Cardiac</b>
Thyroid storm	Heart failure
Hypopituitarism	Endocarditis
Other metabolic disorders (e.g., porphyria, carcinoid syndrome)	<b>Other systemic etiologies</b>
<b>Traumatic</b>	Postoperative state
Traumatic brain injury	Hyperthermia: heatstroke, neuroleptic malignant syndrome, malignant hyperthermia
Subdural hematoma	Hypothermia
Fat emboli	Disseminated intravascular coagulation and other hypercoagulable states
<b>Hypoxic</b>	Radiation
Pulmonary insufficiency	Electrocution
Pulmonary emboli	
<b>Neoplastic disease</b>	
Intracranial primary/metastasis/meningeal carcinomatosis	
Paraneoplastic syndrome	

<sup>a</sup>See Table 6-8 for drugs causing delirium.

certain neural circuits (as well as neurotransmitters)—that is, a final common neural pathway (Trzepacz 1999b, 2000). The involvement of certain specific regions and pathways is largely based on limited structural and functional neuroimaging data. (For more detailed discussion, refer to Trzepacz 2000 and Trzepacz et al. 2002a.) Dysfunction in both cortical and subcortical regions in delirium has been supported by studies of regional cerebral blood flow, single photon emission computed tomography, positron-emission tomography, EEG, and evoked potentials (Trzepacz 1994; Yokota et al. 2003). Whereas some etiologies of delirium alter neurotransmission via general

metabolism, others may antagonize or interfere with specific receptors and neurotransmitters.

The best-established neurotransmitter alteration accounting for many cases of delirium is reduced cholinergic activity (Trzepacz 1996a, 2000). A wide variety of medications and their metabolites have anticholinergic activity and cause delirium. Some act postsynaptically; others act presynaptically; and still others, such as norfentanyl and normeperidine, have anticholinergic metabolites (Coffman and Dilsaver 1988). Tune and colleagues (1992) measured the anticholinergic activity of many medications in “atropine equivalents.” They identified

**TABLE 6-8. Selected drugs causing delirium**

<b>Analgesics</b>	<b>Antiparkinsonian drugs</b>
Opiates (especially meperidine, pentazocine)	Amantadine
Salicylates	Bromocriptine
<b>Antimicrobials</b>	Levodopa
Acyclovir, ganciclovir	<b>Cardiac drugs</b>
Aminoglycosides	Beta-blockers
Amphotericin B	Captopril
Antimalarials	Clonidine
Cephalosporins	Digitalis
Chloramphenicol	Disopyramide
Ethambutol	Lidocaine
Interferon	Methyldopa
Isoniazid	Mexiletine
Metronidazole	Procainamide
Rifampin	Quinidine
Sulfonamides	Tocainide
Vancomycin	<b>Sedative-hypnotics</b>
<b>Anticholinergic drugs</b>	Barbiturates
Antihistamines, H <sub>1</sub> (e.g., diphenhydramine)	Benzodiazepines
Antispasmodics	<b>Stimulants</b>
Atropine and atropine-like drugs (e.g., scopolamine)	Amphetamines
Benztropine	Cocaine
Biperiden	Ephedrine, epinephrine, phenylephrine
Phenothiazines (especially thioridazine)	Theophylline
Tricyclics (especially amitriptyline)	<b>Miscellaneous drugs</b>
Trihexyphenidyl	Antihistamines, H <sub>2</sub> (e.g., cimetidine, ranitidine)
<b>Anticonvulsants</b>	Baclofen
Phenobarbital	Bromides
Phenytoin	Chlorpropamide
Valproic acid	Disulfiram
<b>Anti-inflammatory drugs</b>	Ergotamines
Corticosteroids	Lithium
Nonsteroidal anti-inflammatory drugs	Metrizamide (intrathecal)
<b>Antineoplastic drugs</b>	Podophyllin (by absorption)
Aminoglutethimide	Propylthiouracil
Asparaginase	Quinacrine
Dacarbazine (DTIC)	Timolol ophthalmic
5-Fluorouracil	
Hexamethylenamine	
Methotrexate (intrathecal)	
Procarbazine	
Tamoxifen	
Vinblastine	
Vincristine	

medications usually not recognized as being anticholinergic (e.g., digoxin, nifedipine, cimetidine, and codeine). Delirium induced by anticholinergic drugs is associated with generalized EEG slowing and is reversed by treatment with physostigmine or neuroleptics (Itil and Fink 1966; Stern 1983).

Several causes of delirium thought of as having dif-

fuse, nonspecific effects on neuronal function may at least in part be acting through anticholinergic effects. Thiamine deficiency, hypoxia, and hypoglycemia all may reduce acetylcholine by affecting the oxidative metabolism of glucose and the production of acetyl coenzyme A, the rate-limiting step for acetylcholine synthesis (Trzepacz 1994). Parietal cortex levels of choline are reduced in

chronic hepatic encephalopathy (Kreis et al. 1991). Serum levels of anticholinergic activity are elevated in patients with postoperative delirium and correlate with severity of cognitive impairment (Tune et al. 1981), improving with resolution of the delirium (Mach et al. 1995). Post-electroconvulsive therapy delirium is also associated with higher serum anticholinergic activity (Mondimore et al. 1983). Alzheimer's and vascular dementias reduce cholinergic activity and are associated with increased risk for delirium. Dementia with Lewy bodies, with its fluctuating symptom severity, confusion, hallucinations (especially visual), delusions, and EEG slowing, mimics delirium and is associated with significant loss of cholinergic nucleus basalis neurons. Its delirium symptoms respond to donepezil (Kaufer et al. 1998). Age-associated changes in cholinergic function also increase delirium propensity. Stroke and traumatic brain injury are associated with decreased cholinergic activity (Yamamoto et al. 1988) and have enhanced vulnerability to antimuscarinic drugs (Dixon et al. 1994). The low cholinergic state seems to correlate temporally with delirium following the acute event. Thus, there is broad support for an anticholinergic mechanism for many seemingly diverse mechanisms of delirium.

However, anticholinergic mechanisms cannot explain all deliria, because cholinergic toxicity from organophosphate insecticides, nerve poisons, and tacrine (Trzepacz et al. 1996) also can cause delirium. Increased dopamine also may play a role in some deliria. Delirium can occur from intoxication with dopaminergic drugs (Ames et al. 1992) and cocaine binges (Wetli et al. 1996). Excessive dopaminergic activity also might play a role in delirium (Trzepacz 2000), including during specific states such as alcohol withdrawal (Sander et al. 1997), opiate intoxication, hypoxia (Broderick and Gibson 1989), and hepatic encephalopathy (Knell et al. 1974). The efficacy of antidopaminergic agents, particularly neuroleptics, in treating delirium, including that arising from anticholinergic causes (Itil and Fink 1966; Platt et al. 1994b), also suggests a neuropathogenetic role for dopamine.

Both increased and decreased gamma-aminobutyric acid (GABA) levels have been implicated in causing delirium. Increased GABAergic activity is one of several putative mechanisms implicated in hepatic encephalopathy (Mousseau and Butterworth 1994). GABA activity is reduced during delirium following withdrawal from ethanol and sedative-hypnotic drugs. Decreased GABA activity is also implicated in the mechanism of antibiotic delirium caused by penicillins, cephalosporins, and quinolones (Akaike et al. 1991; Mathers 1987). Both low and excessive levels of serotonin are also associated with delirium (van der Mast and Fekkes 2000). Serotonin syndrome (see Chapter 37, "Psychopharmacology") is the obvious ex-

ample of the latter, but serotonergic activity may be increased in patients with hepatic encephalopathy (Mousseau and Butterworth 1994; van der Mast and Fekkes 2000) and sepsis (Mizock et al. 1990). Histamine may play a role in delirium through its effects on arousal and hypothalamic regulation of sleep-wake circadian rhythms. Both H<sub>1</sub> and H<sub>2</sub> antagonists can cause delirium, although both also have anticholinergic properties (Picotte-Prillmayer et al. 1995; Tejera et al. 1994). Glutamate release is increased during hypoxia, and glutamatergic receptors may be activated by quinolone antibiotics (P.D. Williams and Helton 1991).

Altered ratios of plasma amino acids during severe illness, surgery, and trauma may affect neurotransmitter synthesis in the brain (Trzepacz and van der Mast 2002; van der Mast and Fekkes 2000). In addition to changes in major neurotransmitter systems, neurotoxic metabolites, such as quinolinic acid from tryptophan metabolism (Basile et al. 1995), and false transmitters, such as octopamine in patients with liver failure, have been implicated in the pathogenesis of delirium. Because glia help to regulate neurotransmitter amounts in the synapse, glial dysfunction also may be involved. Increased blood-brain barrier permeability, as occurs in uremia, is another possible mechanism contributing to delirium. Van der Mast and Fekkes (2000) proposed that surgery induces immune activation and a physical stress response, which is characterized by increased hypothalamic-pituitary-adrenocortical axis activity, low triiodothyronine (T<sub>3</sub>) syndrome, and alterations of blood-brain barrier permeability. Cytokines have been implicated as causes of inflammatory or infection-induced delirium, as well as when given as treatment (interferons, interleukins). Cytokines are increased during stress, rapid growth, inflammation, tumor, trauma, and infection (Hopkins and Rothwell 1995; Rothwell and Hopkins 1995; Stefano et al. 1994). The mechanism by which they cause delirium may be as neurotoxins (Lipton and Gendelman 1995), through effects on a variety of neurotransmitters (Rothwell and Hopkins 1995; Stefano et al. 1994), by altering blood-brain barrier permeability, or through effects on glial function.

A final common neural pathway for delirium could have neuroanatomic and neurochemical components. The predominance of evidence supports a low cholinergic-excess dopaminergic state in this final common neural theory (Trzepacz 1999b, 2000). Other neurotransmitter systems are known to be involved for certain etiologies (e.g., hepatic insufficiency or alcohol withdrawal), whereas cholinergic and dopaminergic pathways can be affected by these other neurotransmitters. The role of cholinergic and dopaminergic neurotransmission in delirium has been reviewed in detail elsewhere (Trzepacz 1996a, 2000).

## Differential Diagnosis

The presence of delirium is frequently detected late or not at all in clinical practice. Between one-third and two-thirds of cases are missed across a range of care settings and by a variety of specialists, including psychiatrists and neurologists (Johnson et al. 1992). Nonrecognition represents a failure to recognize the symptoms or diagnosis of delirium and is reflected in poorer outcomes (Kakuma et al. 2003; Rockwood et al. 1994). Poor detection rates in part indicate that delirium is an inherently fluctuating disorder involving multiple cognitive and noncognitive disturbances, which confer great clinical variability.

The stereotyped image of delirium (as in delirium tremens) of an agitated psychotic patient does not represent most patients with delirium, who have either mixed or hypoactive symptom profiles (Meagher and Trzepacz 2000). The hypoactive presentation is less appreciated because the quiet, untroublesome patient is often presumed to have intact cognition and is more easily overlooked in the time-pressured technological environment of modern medicine. It is not surprising that nursing staff, who have the greatest amount of patient and family contact, may have better detection rates than do physicians (Gustafson et al. 1991). Detection can be improved by routinely assessing cognitive function, improving awareness of the varied presentations of delirium, and using one of the currently available screening instruments for

delirium (Rockwood et al. 1994), such as the CAM or CAM-ICU.

Delirium has a wide differential diagnosis. It can be mistaken for dementia, depression, psychosis, anxiety, somatoform disorders, and, particularly in children, behavioral disturbance (see Table 6–9). Accurate diagnosis requires close attention to symptom profile and temporal onset and is further supplemented by a variety of tests (e.g., cognitive, laboratory, EEG). Given that delirium can be the presenting feature of serious medical illness, any patient experiencing a sudden deterioration in cognitive function should be examined for possible delirium.

The most difficult differential diagnosis for delirium is dementia—the other cause of generalized cognitive impairment. Indeed, end-stage dementia has been described as a chronic delirious state. Particularly challenging can be diagnosing dementia with Lewy bodies because it mimics delirium with fluctuation of symptom severity, visual hallucinations, attentional impairment, alteration of consciousness, and delusions (Robinson 2002). Despite this substantial overlap, delirium and dementia can be reliably distinguished by a combination of careful history-taking and interviewing for symptom profile onset and clinical investigation. The tendency for abrupt onset and fluctuating course are highly characteristic of delirium. In addition, level of consciousness and attention are markedly disturbed in delirium but remain relatively intact in uncomplicated dementia. Dementia patients often have

**TABLE 6–9. Differential diagnosis of delirium**

	<b>Delirium</b>	<b>Dementia</b>	<b>Depression</b>	<b>Schizophrenia</b>
Onset	Acute	Insidious <sup>a</sup>	Variable	Variable
Course	Fluctuating	Often progressive	Diurnal variation	Variable
Reversibility	Usually <sup>b</sup>	Not usually	Usually but can be recurrent	No but has exacerbations
Level of consciousness	Impaired	Clear until late stages	Generally unimpaired	Unimpaired (perplexity in acute stage)
Attention/memory	Inattention, poor memory	Poor memory without marked inattention	Poor attention, memory intact	Poor attention, memory intact
Hallucinations	Usually visual; can be auditory, tactile, gustatory, olfactory	Can be visual or auditory	Usually auditory	Usually auditory
Delusions	Fleeting, fragmented, and usually persecutory	Paranoid, often fixed	Complex and mood congruent	Frequent, complex, systematized, and often paranoid

<sup>a</sup>Except for large strokes.

<sup>b</sup>Can be chronic (paraneoplastic syndrome, central nervous system adverse events of medications, severe brain damage).

nocturnal disturbances of sleep, whereas delirium is characterized by varying degrees of disruption of the sleep-wake cycle, including fragmentation and sleeplessness. Overall, the presentation of delirium does not seem to be greatly altered by the presence of dementia, with delirium symptoms dominating the clinical picture when they occur (Trzepacz et al. 1998).

A range of investigative tools can facilitate differentiation of delirium and dementia in clinical practice. The DRS (Trzepacz and Dew 1995), DRS-R-98, and CTD (Hart et al. 1996) have been shown to distinguish delirium from dementia during validation studies. Although abnormalities of the EEG are common to both delirium and dementia, diffuse slowing occurs more frequently in (81% vs. 33%)—and favors a diagnosis of—delirium. EEG slowing occurs later in the course of most degenerative dementias, although slowing occurs sooner with viral and prion dementias. Percentage theta activity on quantitative EEG may aid differentiation of delirium from dementia (Jacobson and Jerrier 2000).

Several studies have addressed the issue of which symptoms may discriminate between patients with delirium and patients with dementia, or patients with both disorders, with varying results (Liptzin et al. 1993; O’Keeffe 1994; Trzepacz and Dew 1995; Trzepacz et al. 1998, 2002b). Overall, their results suggest that when delirium and dementia are comorbid, delirium phenomenology overshadows that of the dementia, but when the two are assessed as individual conditions, several discriminating symptoms are seen. These research findings are consistent with the clinical rule of thumb that “it is delirium until proven otherwise.”

Often, the early behavioral changes of delirium are mistaken for adjustment reactions to adverse events, particularly in patients who have experienced major trauma or who have cancer. Hypoactive delirium is frequently mistaken for depression (Nicholas and Lindsey 1995). Some symptoms of major depression occur in delirium (e.g., psychomotor slowing, sleep disturbances, irritability). It has been estimated that 7% of patients with delirium attempt self-harm during an episode. However, in major depression, symptom onset tends to be less acute, and mood disturbances typically dominate the clinical picture, with any cognitive impairment more reflective of poor effort. Dehydration or malnutrition can precipitate delirium in severely depressed patients who are unable to maintain food or fluid intake. The distinction of delirium from depression is particularly important because, in addition to delayed treatment, some antidepressants have anticholinergic activity (paroxetine and tricyclics) that can aggravate delirium. The overactive, disinhibited presentation of some patients with delirium can closely re-

semble similar disturbances encountered in patients with agitated depression or mania, such as delirious (Bell’s) mania and agitated (“lethal”) catatonia, which typically include cognitive impairment.

Abnormalities of thought and perception can occur in both delirium and schizophrenia but are more fluctuant and fragmentary in delirium. Delusions in delirium are rarely as fixed or complex as in schizophrenia, and first-rank symptoms are uncommon (Cutting 1987). Unlike schizophrenia, hallucinations in delirium tend to be visual rather than auditory. Consciousness, attention, and memory are generally less impaired in schizophrenia, with the exception of the pseudodelirious picture that can occur as a result of marked perplexity in the acute stage of illness. Careful examination, coupled with EEG and/or an instrument such as the DRS, generally distinguishes delirium from these functional disorders.

Despite the fact that delirium is rarely specifically cited as the reason for a request for psychiatric consultation (Francis et al. 1990; Trzepacz et al. 1985), it is very common among patients referred to psychiatric consultation services because of frequent misdiagnosis by referring clinicians. Overall, approximately 10% of the patients referred to psychiatric consultation have delirium, and about 10% of the general hospital patients with delirium receive a psychiatric consultation (Francis et al. 1990; Sirois 1988), with psychiatrist involvement typically reserved for more difficult cases.

## Treatment

---

Delirium is an example par excellence of a disorder requiring a multifaceted biopsychosocial approach to assessment and treatment. After the diagnosis of delirium is made, the process of identifying and reversing suspected etiologies begins. Rapid treatment is important because of the high morbidity and mortality associated with delirium. Treatments include medication, environmental manipulation, and patient and family psychosocial support (American Psychiatric Association 1999). However, no drug has a U.S. Food and Drug Administration indication for the treatment of delirium, and double-blind, placebo-controlled studies of efficacy and safety of drugs in treating delirium are lacking (American Psychiatric Association 1999).

Psychiatric consultation facilitates identification of predisposing and precipitating factors for delirium. Medication exposure, visual and hearing impairments, sleep deprivation, uncontrolled pain, dehydration, malnutrition, catheterization, and use of restraints are all factors that can be modified, but uncertainty remains as to the

precise value of multicomponent interventions that attempt to reduce the incidence and severity of delirium through modification of recognized risk factors (Bogardus et al. 2003; Cole et al. 1998; Inouye et al. 1999) or systematic detection and multidisciplinary care of identified cases (Cole et al. 2002). The effect of such interventions depends on degree of implementation, with evidence that higher adherence leads to lower delirium rates (Inouye et al. 2003). A range of preoperative psychological interventions aimed at patient education and anxiety reduction may have preventive value, but these require more study before they warrant introduction into routine clinical practice.

The principles of management of delirium include ensuring the safety of the patient and his or her immediate surroundings (includes sitters), achieving optimal levels of environmental stimulation, and minimizing the effects of any sensory impediments. The complications of delirium can be minimized by careful attention to the potential for falls and avoidance of prolonged hypostasis. Using orienting techniques (e.g., calendars, night-lights, and reorientation by staff) and familiarizing the patient with the environment (e.g., with photographs of family members) are sometimes comforting, although it is important to remember that environmental manipulations alone do not reverse delirium (American Psychiatric Association 1999; Anderson 1995). It also has been suggested that diurnal cues from natural lighting reduce sensory deprivation and incidence of delirium (Wilson 1972), although sensory deprivation alone is insufficient to cause delirium (Francis 1993). Unfortunately, implementation of these environmental interventions occurs primarily in response to agitation rather than the core disturbances of delirium (Meagher et al. 1996).

Supportive interaction with relatives and caregivers is fundamental to good management of delirium. Relatives can play an integral role in efforts to support and reorient patients with delirium, but ill-informed, critical, or anxious caregivers can add to the burden of a delirious patient. A nontherapeutic triangle can emerge whereby medical staff respond to the distress of relatives by medicating patients, which complicates ongoing cognitive assessment. Clarification of the cause and meaning of symptoms combined with recognition of treatment goals can allow better management of what is a distressing experience for both patient and loved ones (Breitbart et al. 2002a; Meagher 2001).

## Prevention Strategies

Nonpharmacological and pharmacological interventions are available to prevent delirium. Preoperative patient ed-

ucation or preparation was helpful in reducing delirium symptom rates (Chatham 1978; Owens and Hutelmyer 1982; M.A. Williams et al. 1985). However, studies of caregiver education and environmental or risk factor interventions have had mixed results, with two not finding any significant effect on delirium rate (Nagley 1986; Wanich et al. 1992). In contrast, Inouye et al. (1999) studied the effect on delirium of preventive measures that minimized six of the risk factors identified in their previous work with hospitalized elderly patients. They used standardized protocols in a prospective study of 852 elderly inpatients to address cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration, which resulted in significant reductions in the number (62 vs. 90) and duration (105 vs. 161 days) of delirium episodes relative to control subjects. Effects of adherence on delirium risk were subsequently reported for 422 elderly patients during implementation of this standardized protocol (Inouye et al. 2003). Adherence ranged from 10% for the sleep protocol to 86% for orientation. Higher levels of adherence by staff resulted in lower delirium rates, up to a maximum of an 89% reduction, even after controlling for confounding variables. At 6-month follow-up of 705 survivors from this intervention study of six risk factors, no differences were found between groups for any of the 10 outcome measures, except for less frequent incontinence in the intervention group (Bogardus et al. 2003), suggesting that the intervention's effect was essentially during the index hospitalization without any longer-lasting benefits. When a subset of high-risk patients were compared at baseline, however, the intervention group had significantly better self-rated health and functional status at follow-up.

Milisen et al. (2001) compared delirium rates in two cohorts of elderly hip surgery patients ( $N=60$  in each cohort)—before and after implementing an intervention consisting of nurse education, cognitive screening, consultation by a nurse or physician geriatric/delirium specialist, and a scheduled pain protocol. They found no effect on delirium incidence but a shorter duration of delirium (median 1 vs. 4 days) and lower delirium severity in the intervention group. Marcantonio et al. (2001) used a different study design and randomized 62 elderly hip fracture patients to either a perioperative geriatric consultation or usual care. On the basis of daily ratings, they found a lower delirium rate (32% vs. 50%) and fewer cases of severe delirium (12% vs. 29%) in the consultation group. Length of stay was not affected, and the effect of consultation was greatest in those patients without preexisting dementia or poor ADLs.

Some pharmacological prophylaxis trials have been done. Cholinergic agents have engendered the most in-

terest. Citicholine 1.2 mg/day was assessed for delirium prevention in a randomized, placebo-controlled trial of 81 nondemented hip surgery patients, given 1 day before and each of the 4 days after surgery (Diaz et al. 2001). Fewer cases of delirium occurred in the citicholine group (12% vs. 17%), but the difference was not statistically significant. Perioperative piracetam use during anesthesia was reviewed across eight studies, mostly from the 1970s, and was believed to have a positive effect on reducing postoperative delirium symptoms (Gallinat et al. 1999).

Kalisvaart et al. (2003) studied 408 elderly hip surgery patients in a randomized, placebo-controlled comparison of haloperidol and placebo given up to 3 days before and 3 days after surgery. Even though the authors found only a nonsignificant lower numerical difference for delirium incidence (23% vs. 32%) with haloperidol, significant differences were found for shorter delirium duration (4 vs. 12 days), lower DRS scores (13.6 vs. 18.2), and shorter length of stay (12 vs. 24 days) in the active treatment group. This study represents the first double-blind, placebo-controlled trial for delirium prevention with a neuroleptic agent.

Maldonado et al. (2004) reported an interim data analysis showing significantly reduced delirium incidence (5%) when a novel  $\alpha_2$ -adrenergic receptor agonist—dexmedetomidine—was used for postoperative sedation, compared with propofol (54%) or fentanyl/midazolam (46%), in cardiac valve surgery patients. Improved pain control after hepatectomy surgery in elderly patients who used patient-controlled epidural anesthesia with bupivacaine and fentanyl ( $n=14$ ), compared with continuous-epidural mepivacaine ( $n=16$ ), was associated with lower incidences of moderate and severe delirium (36% vs. 75% and 14% vs. 50%, respectively), and antipsychotic drug use also was lower in the former group (Tokita et al. 2001).

## Pharmacological Treatment

Current delirium pharmacotherapies have evolved from use in the treatment of mainstream psychiatric disorders; hence, psychiatrists are well acquainted with the practicalities of their use. Medications are implicated as significant contributing factors in more than one-third of cases and can act as either protective or risk factors for delirium, depending on the drug. Pharmacological treatment with a neuroleptic agent ( $D_2$  antagonist) is the clinical standard for delirium treatment. A survey of intensivists indicated that delirium was treated in the ICU with haloperidol by 66% of the respondents, lorazepam by 12%, and atypical antipsychotics by fewer than 5%. More than 55% administered haloperidol and lorazepam at daily

doses of 10 mg or less, but some used a dosage of more than 50 mg/day of either medication (Ely et al. 2004b).

Haloperidol is the neuroleptic most often chosen for the treatment of delirium. It can be administered orally, intramuscularly, or intravenously (Adams 1984, 1988; Dudley et al. 1979; Gelfand et al. 1992; Moulaert 1989; Sanders and Stern 1993; Tesar et al. 1985), although the intravenous route has not been approved by the U.S. Food and Drug Administration. Intravenously administered haloperidol is twice as potent as that taken orally (Gelfand et al. 1992). Bolus intravenous doses usually range from 0.5 to 20 mg, although larger doses are sometimes given. In severe, refractory cases, continuous intravenous infusions of 15–25 mg/hour (up to 1,000 mg/day) can be given (Fernandez et al. 1988; J.L. Levenson 1995; Riker et al. 1994; Stern 1994).

Based on clinical use, haloperidol traditionally has been considered to be relatively safe in the seriously medically ill and does not cause as much hypotension as droperidol does (Gelfand et al. 1992; Moulaert 1989; Tesar et al. 1985). Haloperidol does not antagonize dopamine-induced increases in renal blood flow (D.H. Armstrong et al. 1986). Even when haloperidol is given intravenously at high doses in delirium, extrapyramidal symptoms (EPS) usually are not a problem, except in more sensitive patients, such as those with HIV or dementia with Lewy bodies (Fernandez et al. 1989; McKeith et al. 1992; Swenson et al. 1989). A case series of five ICU patients receiving 250–500 mg/day of continuous or intermittent intravenous haloperidol had self-limited withdrawal dyskinesia following high-dose haloperidol (Riker et al. 1997). The anticholinergic state of delirium itself may be somewhat protective from EPS (J.L. Levenson, personal communication, January 2004). Intravenous lorazepam is sometimes combined with intravenous haloperidol in critically ill patients to lessen EPS and increase sedation. Cases of prolonged  $QT_c$  interval on electrocardiogram and torsades de pointes tachyarrhythmia (multifocal ventricular tachycardia) have been increasingly recognized and attributed to intravenously administered haloperidol (Hatta et al. 2001; Huyse 1988; Kriwisky et al. 1990; Metzger and Friedman 1993; O'Brien et al. 1999; Perrault et al. 2000; Wilt et al. 1993; Zee-Cheng et al. 1985). The American Psychiatric Association (1999) "Practice Guideline for the Treatment of Patients With Delirium" advised that  $QT_c$  prolongation greater than 450 msec or to greater than 25% over a previous electrocardiogram may warrant telemetry, cardiac consultation, dose reduction, or discontinuation. They also recommend monitoring use of other drugs that also can prolong the  $QT_c$  interval, as well as serum magnesium and potassium, in critically ill patients with delirium whose  $QT_c$  is 450 msec or greater.

Empirical treatment studies of neuroleptics in delirium are rare but support their efficacy. Itil and Fink (1966) found that chlorpromazine reversed anticholinergic delirium. With the use of standardized assessment methods and a double-blind, randomized controlled design, Breitbart et al. (1996) found that delirium in patients with AIDS significantly improved with haloperidol or chlorpromazine but not with lorazepam. Platt et al. (1994b) reported that both hypoactive and hyperactive subtypes responded to treatment with haloperidol or chlorpromazine, and they noted improvement within hours of treatment, even before the underlying medical causes were addressed.

Haloperidol use in pediatric patients with delirium is not well documented, despite its use in adult delirium and in many other childhood psychiatric disorders (Teicher and Gold 1990). Clinical experience with haloperidol in pediatric delirium supports its beneficial effects, but no controlled studies have been done. A retrospective report of 30 children (age 8 months to 18 years; mean age=7 years) with burn injuries supported the use of haloperidol for agitation, disorientation, hallucinations, delusions, and insomnia (R.L. Brown et al. 1996). The mean haloperidol dose was 0.47 mg/kg, with a mean maximum dose in 24 hours of 0.46 mg/kg, administered intravenously, orally, and intramuscularly. Haloperidol was not efficacious in 17% of the patients (4 of 5 of these failures were via the oral route). EPS were not observed, and one episode of hypotension occurred with the intravenous route.

Droperidol is sometimes used to treat acute agitation and confusion from a variety of causes, including mania and delirium (Hooper and Minter 1983; Resnick and Burton 1984; H. Thomas et al. 1992), and is superior to placebo (van Leeuwen et al. 1977). After initial use in patients with severe agitated delirium, droperidol can be replaced by haloperidol for continued treatment. Compared with haloperidol, droperidol has a faster onset of action, but it is more sedating, can be used only parenterally in the United States, and is very hypotensive because of potent  $\alpha$ -adrenergic antagonism, although continuous intravenous infusion of 1–10 mg/hour causes less hypotension than do intravenous boluses (Moulaert 1989). Having the patient lie supine is helpful. Dosing is similar to that for haloperidol, although droperidol may have less antipsychotic effect and fewer EPS (Frye et al. 1995). Prolonged QT<sub>c</sub> intervals can occur with droperidol (Lawrence and Nasraway 1997; Lischke et al. 1994). Oral droperidol (and thioridazine) was recently reported in Europe to significantly prolong the QT<sub>c</sub> interval in a dose-related manner (Reilly et al. 2000); therefore, caution is suggested before use in delirium.

Some atypical antipsychotic agents are being used to treat delirium, and the literature to date includes mostly case reports, retrospective case series, and a few small open-label, prospective trials that used standardized measures (Schwartz and Masand 2002; Torres et al. 2001). Poor response to haloperidol was associated with improvement of delirium in several patients after switching to an atypical antipsychotic (Al-Samarrai et al. 2003; Leso and Schwartz 2002; Passik and Cooper 1999). Haloperidol is avoided in posttraumatic brain injury delirium because dopamine blockade is thought by some clinicians to be deleterious for cognitive recovery; two traumatic brain injury patients with delirium given low-dose olanzapine showed remarkable improvement within a short period (Ovchinsky et al. 2002), suggesting a possible role for atypical antipsychotics in this population. Double-blind, placebo-controlled, randomized studies are necessary to truly establish efficacy and safety profiles.

Clozapine would not be a good choice for treatment of delirium because it has significant anticholinergic side effects, causes sinus tachycardia, lowers seizure threshold, and can cause agranulocytosis. Furthermore, clozapine has itself caused delirium in 8%–10% of psychiatric inpatients (Centorrino et al. 2003; Gaertner et al. 1989). Cholinergic agents can reverse clozapine-induced delirium (Schuster et al. 1977).

Risperidone (mean dosage=1.6 mg/day) has been reported to reduce delirium severity in an open-label case series, with the maximum response on the fifth day (Sipahimalani and Masand 1997). In a prospective open trial in patients with delirium who had been taking haloperidol, risperidone was effective in 80% at a mean dose of 1.7 mg/day (range=0.5–3 mg); adverse events included sleepiness in 30% and mild drug-induced parkinsonism in 10% (Horikawa et al. 2003). Another prospective open trial of risperidone (mean dose=1.4 mg/day) in older patients with delirium also showed that it was effective (Mittal et al. 2004). However, risperidone was reported to cause delirium in four patients (Chen and Cardasis 1996; Ravona-Springer et al. 1998). Risperidone has dose-related EPS beginning at a dosage of about 2 mg/day according to double-blind, placebo-controlled studies (I.R. Katz et al. 1999).

An open-label, nonrandomized delirium case series comparing olanzapine (mean dose=8.2 mg) and haloperidol (mean dose=5.1 mg) showed comparable efficacy; however, there were frequent EPS or excessive sedation with haloperidol compared with olanzapine, which did not have these side effects (Masand and Sipahimalani 1998). Breitbart et al. (2002b) described 82 cancer inpatients with delirium, 81% of whom had metastases (20% in the brain), who were given olanzapine (dose range =

2.5–20 mg); delirium resolved in 79% of the patients by day 3, with overall good tolerability. In a prospective study of olanzapine (mean dose=6 mg) by K.-S. Kim et al. (2001), 70% of the patients had a 50% or greater reduction in delirium symptoms, and the drug was well tolerated without EPS. Olanzapine has a favorable EPS profile and does not appear to have a clinically significant effect on the QT<sub>c</sub> interval at therapeutic doses in schizophrenic patients (Czekalla et al. 2001).

A small uncontrolled study of older patients with delirium treated with quetiapine (mean dose=93 mg) has provided preliminary evidence that quetiapine is well tolerated and reduces symptoms of delirium (K. Y. Kim et al. 2003). In a retrospective case series, quetiapine (mean dose=211 mg/day, range=25–750 mg/day) also was quite effective in improving delirium scores, with sedation in 30% and discontinuation in two elderly patients because of worsening (Schwartz and Masand 2000). Very little is known about ziprasidone or aripiprazole in delirium.

Very few reports include more than one atypical agent. Hill et al. (2002) measured delirium symptoms daily in 50 patients with delirium treated with either haloperidol, olanzapine, or risperidone. They found a significant main effect of drug and time at 3 days; olanzapine was more effective in reducing delirium severity than was either haloperidol or risperidone.

Unlike haloperidol and droperidol, atypical agents had not been available until recently in the United States in parenteral form, a route often needed in treating agitated, uncooperative patients. Intramuscular olanzapine and ziprasidone have been developed for the treatment of agitation in psychiatric patients, and olanzapine has a rapidly dissolving oral formulation that is placed on the tongue, but none of these has yet been studied in delirium.

Other classes of drugs are indicated in particular situations. Benzodiazepines are generally reserved for delirium due to ethanol or sedative-hypnotic withdrawal; lorazepam or clonazepam (the latter for alprazolam withdrawal) is often used. Some physicians use lorazepam as an adjunctive medication with haloperidol in the most severe cases of delirium or when extra assistance with sleep is needed. Anticholinergic poisoning-induced delirium and/or agitation was controlled and reversed with physostigmine (87% and 96%, respectively), whereas benzodiazepines controlled agitation in only 24% and were ineffective in treating delirium (Burns et al. 2000). Patients who received physostigmine had a lower incidence of complications (7% vs. 46%) and a shorter time to recovery (median=12 vs. 24 hours). Ely et al. (2004a) found a significant aggravating effect of lorazepam on delirium in medical ICU patients, but this effect was not found for propofol, morphine, and fentanyl.

The cholinergic deficiency hypothesis of delirium suggests that treatment with a cholinergic enhancer drug could be therapeutic. Physostigmine reverses anticholinergic delirium (Stern 1983), but its side effects (seizures) and short half-life make it unsuitable for routine clinical treatment of delirium. Tacrine also was shown to reverse central anticholinergic syndrome (Mendelson 1977), although it has not been studied formally. Three case reports found that donepezil improved delirium postoperatively, in dementia with Lewy bodies, and in alcohol dementia (Burke et al. 1999; Wengel et al. 1998, 1999). Physostigmine administered in the emergency department to patients suspected of having muscarinic toxicity resulted in reversal of delirium in 22 of 39, including several patients in whom the cause could not be determined (Schneir et al. 2003); only 1 patient in 39 had an adverse event (brief seizure).

Psychostimulants can worsen delirium and are not recommended when depressed mood is present (J. A. Levenson 1992; Rosenberg et al. 1991). Mianserin, a serotonergic tetracyclic antidepressant, has been used in Japan for delirium in elderly medical and postsurgical patients, administered either orally or as a suppository. Several open-label studies found reductions in the DRS scores similar to those seen with haloperidol (Nakamura et al. 1995, 1997a, 1997b; Uchiyama et al. 1996). A single 8-mg intravenous dose of ondansetron, a serotonin<sub>3</sub> receptor antagonist, was reported to reduce agitation in 35 postcardiotomy delirium patients (Bayindir et al. 2000).

Clearly, further delirium treatment research is needed—especially randomized, controlled trials of drug compared with placebo and of drug compared with drug—addressing both efficacy and safety.

# 7 Dementia

---

Antonio Lobo, M.D., Ph.D.

Pedro Saz, M.D., Ph.D.

**CONCERN IS INCREASING** about the frequency and consequences of dementia in Western countries. The high prevalence of dementing conditions in medical settings, often undiagnosed, and the association of dementia with longer hospital stays and greater use of health resources have direct implications for psychosomatic medicine and consultation-liaison psychiatry (Table 7-1). The psychiatric consultant is an invaluable collaborator with other health care professionals in the identification, evaluation, treatment, management, discharge planning, placement, and rehabilitation of the patient with dementia. In this chapter, we focus on the general clinical approach to dementia and its common causes. Some of these and other causes of dementia are also discussed elsewhere in this book: those disorders that are particularly likely to present with other neurological symptoms in Chapter 32, “Neurology and Neurosurgery”; HIV infection in Chapter 28, “HIV/AIDS”; other infections in Chapter 27, “Infectious Diseases”; alcohol and other substance use in Chapter 18, “Substance-Related Disorders”; toxic/metabolic conditions in Chapter 23, “Endocrine and Metabolic Disorders”; rheumatological/inflammatory conditions in Chapter 25, “Rheumatology”; traumatic brain injury in Chapter 35, “Physical Medicine and Rehabilitation”; and paraneoplastic syndromes in Chapter 24, “Oncology.”

## Concept of Dementia and Clinical Approach

---

Dementia is a brain condition and a paradigm of the disease model in psychiatry (McHugh and Slavney 1998). Medically ill patients referred to psychiatrists may require special diagnostic criteria (Malt et al. 1996). *Dementia* may be conveniently defined as a syndrome of global deterioration of intellectual function occurring in clear consciousness and caused by a brain condition. The notion of deterioration emphasizes the acquired nature of the impairment in dementia, to distinguish it from mental retardation, and the requirement of clear consciousness underlines the difference from delirium, if dementia is the only diagnosis. The impairment of memory is the most frequent and important sign or symptom, but deterioration in at least two other cognitive domains is required in our operational definition (Table 7-2). It is also required that, precisely because of cognitive decline, personal activities of daily living (ADLs) and social or occupational activities are impaired.

Deterioration in personality and neuropsychiatric symptoms are very frequent in dementia and are most important for psychiatrists, but there is general agreement that only the cognitive psychopathology should be in-

We gratefully acknowledge research grants from the Fondo de Investigación Sanitaria, Ministry of Health, Spain (98/0103, 01/0255); Instituto de Salud Carlos III (Redes Temáticas de Investigación Cooperativa, Project G03/128), Ministry of Health, Spain; and Ministry of Science and Technology, Spain (PM 1999-0084). We also wish to thank Olga Ibáñez for her administrative help.

**TABLE 7-1. Relevance of dementia in psychosomatic medicine and consultation-liaison psychiatry****General relevance**

- Worldwide epidemic (Plum 1979; World Health Organization 1985)
- High prevalence: 9.6% in the United States elderly community (Breitner et al. 1999); 74% in nursing homes (Macdonald et al. 2002)
- High incidence: 2.8 per 1,000 person-years (age group=65–69 years), increases to 56.1 per 1,000 person-years in the older than 90-year age group (Kukull et al. 2002)
- Dramatic increase in the projected dementia rates is expected in the next decades (Organization for Economic Cooperation and Development, in press)
- Burden of the disease:
  - Patient-related (Teri 1999)
  - Caregiver-related (Colvez et al. 2002; Ory et al. 1999)
  - Leads to earlier institutionalization (Patterson et al. 1999)
  - DAT patients occupy two-thirds of nursing home beds (Macdonald et al. 2002)
  - Gross annual cost of community care in the United States (Rice et al. 1993):
    - \$52,118 for mild to moderate cases; \$69,389 for severe cases
    - Two-thirds of these amounts go to informal care (e.g., family caregivers)
- Mortality rate at least twice that of individuals without dementia (Dewey and Saz 2001)

**Specific relevance to psychosomatic medicine and consultation-liaison psychiatry**

- High prevalence in general hospital patients (Erkinjuntti et al. 1986)
- High prevalence in specific medical conditions
- One-third of elderly referrals to consultation-liaison psychiatrists frequently undiagnosed (Huysse et al. 1996; Lobo et al. 1993)
- Most patients have noncognitive, neuropsychiatric symptoms (Ballard et al. 2001a; Lyketsos et al. 2002)
- Most patients with early dementia go undiagnosed in the general population (Larson et al. 1992; Lobo et al. 1997)
- Longer hospital stays, associated with higher costs; greater use of health resources after discharge (Lyketsos et al. 2000; Saravay and Lavin 1994)

*Note.* DAT=dementia of the Alzheimer's type.

**TABLE 7-2. The dementia syndrome**

- Global deterioration of intellectual function
  - Memory
  - At least two other cognitive functions
- Clear consciousness
- Impairment of personal activities of daily living and social or occupational activities due to the decline in intellectual function
- Deterioration in emotional control, motivation, or personality frequent but not necessary for diagnosis
- Duration of at least 6 months (important exceptions, such as in the general hospital)

cluded in the diagnostic criteria. Persistence of the syndrome is important for the diagnosis, and some international committees require that symptoms be present for at least 6 months (World Health Organization 1992). However, exceptions to this norm occur and are important in settings such as the general hospital. Progression of the syndrome is the norm in most cases of dementia but is not included in the concept because some cases of dementia are stable and reversible.

Recent research has identified “a transitional state” between the cognitive changes of normal aging and dementia, known as *mild cognitive impairment* (Petersen et al. 2001a). Mild cognitive impairment refers to documented memory and other cognitive difficulties of mild severity in individuals who are otherwise functioning well that do not meet the clinical criteria for dementia. Several studies have shown that persons without dementia who have cognitive impairment have a higher chance of progressing to dementia and/or have a higher mortality rate. However, mild cognitive impairment is a heterogeneous concept (Wahlund et al. 2003). Not all individuals with mild cognitive impairment progress to dementia; a portion show improvement in cognition (Palmer et al. 2003).

## Epidemiology, Risk Factors, and Etiology

Dementia has been etiologically associated with numerous heterogeneous conditions, as listed in Table 7-3. The adjusted prevalence estimate was 9.6% for all dementias in the U.S. population after age 65 and 6.5% for dementia

of the Alzheimer's type (DAT) (Breitner et al. 1999). Similar rates have been reported in other United States studies (McDowell 2001), as well as in the EURODEM Study completed in 10 different cities across Europe (Lobo et al. 2000). In all these studies, the proportion of

elderly patients with dementia increases dramatically with age, approximately doubling every 5 years. DAT is the most common type of dementia, accounting for 55%–75% of cases. Vascular dementia (or mixed DAT and vascular dementia) is the second most common cause, ac-

counting for approximately 15%–30% of cases, and the other dementias listed in Table 7–3 account for the remaining 10%–25% of cases of dementia in the general population.

Reports from institutions such as nursing homes consistently document higher prevalence rates of dementia (74%), particularly of severe dementia (38%) (Macdonald et al. 2002). In general hospitals, recent reports also have confirmed that dementia is common. A large-scale study documented that 9.1% of the patients ages 55 years and older admitted to a teaching hospital medical service had dementia, but the prevalence was 31.2% in patients ages 85 years and older. Vascular dementia (75%) was reported to be the most frequent type (Erkinjuntti et al. 1986). Dementia is frequent in elderly patients with alcoholism (60%–70%) (Kasahara et al. 1996), Parkinson's disease (Aarsland et al. 2001), HIV disease (American Academy of Neurology AIDS Task Force 1991), and traumatic brain injury (TBI) (Kraus and Sorenson 1994). Both dementia with Lewy bodies in elderly patients and frontotemporal dementias (E. K. Perry et al. 1990) in cases of earlier onset may prove to be considerably more common than previously recognized (Campbell et al. 2001). The prevalence of *age-associated memory impairment* ranges from 17% to 34%, but this is probably a more inclusive term than *mild cognitive impairment*. Mild cognitive impairment may account for more than one-third of the patients referred to memory clinics (Wahlund et al. 2003).

Epidemiological studies also have shown that most patients with dementia have noncognitive, neuropsychiatric symptoms at some point in the course of the disease (Ballard et al. 2001a), and their potential for serious adverse consequences must be recognized (Eustace et al. 2002). In a recent population-based study, Lyketsos et al. (2002) found that 75% of the individuals with dementia had at least one neuropsychiatric symptom, and 62% were clinically significant. The most frequent disturbances were apathy (36%), depression (32%), and agitation or aggression (30%). The reported prevalence of depressive syndromes in dementia has ranged widely, from 10% to 54%, across recruitment sites (Devanand et al. 1997; Lobo et al. 1995; Zubenko et al. 2003). Similarly, estimates of the prevalence of psychotic symptoms in DAT vary widely, but this heterogeneity may be due to periods of exacerbation and remission of symptoms (Mohs et al. 2000). No differences in psychotic phenomena have been found between DAT and vascular dementia.

In the first population-based estimate among those with mild cognitive impairment, 43% of the individuals reported neuropsychiatric symptoms during the previous month (29% were rated as clinically significant) (Lyketsos et al. 2002).

Incidence estimates of dementia are provided by ambitious cohort studies that follow transversal studies counting prevalent cases. DAT rates rise from 2.8 per 1,000 person-years (age group, 65–69 years) to 56.1 per 1,000 person-years (age group, older than 90 years) (Kukull et al. 2002). These data are consistent with those in comparable studies in the United States (Brookmeyer et al. 1998; McDowell 2001); studies in Japan (Yoshitake et al. 1995); and cross-national European studies (Fratiglioni et al. 2000). All showed that the risk of developing global dementia, and DAT in particular, increases dramatically with age; the proportion also doubles every 5 years. DAT and vascular dementia are the most frequent incident dementias, accounting for 60%–90% in different studies (Fratiglioni et al. 2000). However, it is difficult to draw firm conclusions about both the prevalence and the incidence of vascular dementia because the rates reported vary substantially, suggesting lack of uniformity in implementing diagnostic criteria (Rocca and Kokmen 1999).

The potential of epidemiological research to test environmental hypotheses related to risk and protective factors that might eventually lead to preventive measures has been illustrated in recent studies. North–South differences in the incidence of dementia in Europe have been found, supporting environmental hypotheses in the etiology of dementia (Fratiglioni et al. 2000). Table 7–4 summarizes the results of recent, sophisticated analytic epidemiological research, including case–control studies in incident cases. Confirmed risk factors for DAT are scarce and limited to age, unalterable genetic factors (the apolipoprotein E4 genotype), and mild cognitive impairment. Mild cognitive impairment has important clinical and preventive implications, because recent studies, tending to confirm previous reports (Petersen et al. 2001a), suggest that when persons with mild cognitive impairment are observed longitudinally, they progress to clinically probable DAT at rates three or more times higher than those in persons without cognitive impairment (H.P. Bennett et al. 2002; Tuokko et al. 2003; Wahlund et al. 2003).

Probable risk factors and protective factors in dementia are also listed in Table 7–4 (Cedazo-Minguez and Cowburn 2001; Dartigues et al. 2002; Esposito et al. 2002; Letenneur et al. 2000; McDowell 2001; Verghese et al. 2003). Recent meta-analytic studies have found evidence to support an association between depression and dementia from both case–control studies and prospective studies (Jorm 2001). Several hypotheses have been put forward to explain the association, but depression has to be seriously considered as a probable risk factor for dementia. The attributable risk of DAT related to cardiovascular risk factors is still debated (Posner et al. 2002),

<sup>a</sup>Protective factors also for vascular dementia.

but recent research has suggested that cerebrovascular disease plays an important role in determining the presence of dementia (Vermeer et al. 2003), and specifically DAT (O'Brien et al. 2003; Snowdon et al. 1997). Hypertension may be particularly relevant in this respect because it is very common in the community and may be preventable. Until now, not enough evidence has been found to support some factors hypothesized as increasing the risk for DAT, such as aluminum level, or others thought to be protective, such as low cholesterol level,

moderate alcohol consumption, estrogens, antioxidants in the diet, or lifestyle activities, including leisure and social activities or a supportive social network.

Risk and protective factors for vascular dementia are also listed in Table 7-4. They include hyperhomocysteinemia and low serum folate levels, which are potentially reversible and can be identified early (Kessler et al. 2003; Maxwell et al. 2002).

Genetic knowledge about dementing conditions, most relevant if related to pathophysiology, may be summarized as follows. Huntington's disease is inherited as an autosomal dominant trait with complete penetrance, the mutation responsible being in an elongated and unstable trinucleotide (CAG) repeat on the short arm of chromosome 4 (Haskins and Harrison 2000). In DAT, particularly with early onset, several well-documented cases suggest that the disorder is transmitted in families through an autosomal dominant gene, although such transmission is rare. Possible genetic loci for familial DAT have been documented in chromosomes 21, 19, 14, and 1 (Levy-Lahad et al. 1995; Schellenberg et al. 1992; Whatley and Anderton 1990). Apolipoprotein E is coded on chromosome 19, and evidence is emerging for a late-onset Alzheimer's disease susceptibility gene located on chromosome 12 (Cedazo-Minguez and Cowburn 2001). The gene for beta-amyloid precursor protein is on the long arm of chromosome 21, and a gene carried on chromosome 17 is thought to be related to familial multiple system tauopathy, an early-onset dementia similar to DAT.

Wilson's disease is an autosomal recessively inherited defect in the copper-carrying serum protein ceruloplasmin, resulting in the destructive deposition of copper in the basal nuclei, the defective gene being localized on chromosome 13 (Loudianos and Gitlin 2000). Recent advances in the genetics of other dementias include the identification of *tau* gene mutations on chromosome 17 in some familial cases of frontotemporal dementia (H.J. Rosen et al. 2000) and the identification of genetic loci in other disorders that produce dementia, such as Pick's disease, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, some forms of cerebral amyloid angiopathy, alcoholism, major depression, and some forms of Parkinson's disease (Lev and Melamed 2001).

Important changes in the classification of dementia might soon occur following dramatic advances in the genetics of dementia. Tau aggregates and alpha-synucleinopathy aggregates observed in neurodegenerative disorders have generated the concepts of tauopathies and alpha-synucleinopathies, respectively (Goedert 1998). Most cases of frontotemporal dementia tend now to be classified as tauopathies, related to mutations in the *tau*

gene (Buee et al. 2000), with a large clinical spectrum including Pick's disease, progressive supranuclear palsy (PSP), corticobasal degeneration, and multisystem atrophy (Lebert et al. 2002). Alpha-synucleinopathies include dementia with Lewy bodies and Parkinson's disease (Ferrer and Puig 2003; Ferrer et al. 2002; Litvan 1999), but the findings of both types of pathological aggregates in several diseases have led to some disagreement in classifications (Iseki et al. 2003; Litvan 1999).

## General Clinical Features

---

### The Dementia Syndrome

The clinical picture may differ widely according to the type and severity of dementia, and the characteristics are important in the differential diagnosis. In most cases of degenerative processes—in particular DAT, some types of vascular dementia, and dementias due to endocrinopathies, brain tumors, metabolic disorders, and abuse of medications—the onset of symptoms is gradual, and the signs of the dementia syndrome are subtle and may at first be ignored by both the patient and his or her relatives. In contrast, the onset may be abrupt after severe cerebral infarcts, head trauma, cardiac arrest with cerebral hypoxia, and encephalitis.

The full dementia syndrome progresses through severity levels in degenerative processes and is very characteristic in DAT (Table 7–5). The earliest manifestations, such as impairment of memory, may be very subtle. Individuals with dementia also show impairment in thinking and their capacity for reasoning, but the earliest difficulties can be mistakenly disregarded or explained away as the expression of fatigue, distraction, or discouragement. The deficits may become apparent in the face of more complex problems, or when specifically tested, but patients often attempt to compensate for defects by using strategies to avoid showing failures in intellectual performance. Similarly, language is impoverished if carefully observed, and praxic difficulties for complex tasks may be documented, but special examinations may be necessary. The general loss of efficiency in all aspects of thinking, and disturbances in executive functions necessary to maintain goal-directed behavior, including planning, organizing, and sequencing, may be apparent, and the patient has difficulties in his or her usual occupation and with ADLs, such as using the telephone, managing small amounts of money, cooking, or taking responsibility for medications (Figure 7–1).

The dementia syndrome in degenerative disorders such as DAT relentlessly progresses to severe deteriora-

tion (see Table 7–5). Eventually, the patient may retain only the earliest learned information; he or she is totally disoriented, with extreme impoverishment of thought, and communication with the patient is impossible. Apraxia and agnosia are severe. The patient is incontinent of urine and feces and is entirely dependent on caregivers. He or she may be totally disconnected from their environment, with respect to both input and output. The most severe neurological signs, including primitive reflexes, motor system rigidity, and flexion contractures, are then present, and the patient is confined to bed. The patient may experience a final stage of decortication, but death, from pneumonia or some other infection, commonly occurs before this stage.

Changes in personality and behavior are frequent, usually as a result of the disease. The patient may seem to be less concerned than he or she had been about issues of daily life or about the effects of his or her behavior on others. *Catastrophic reactions*, with agitation or extreme emotion, also may be observed, as a reaction to the subjective awareness of the patient's inability to cope with a problem. In the face of poor judgment, the patient is liable to misinterpret situations and may react inappropriately and emotionally.

Neuropsychiatric symptoms are almost universal in the course of dementia, are often quite disturbing for patients and caregivers, and may be quite persistent unless treated (Ballard et al. 2001a). Neuropsychiatric symptoms have been best studied in DAT (Lyketsos et al. 2001), but no important differences have been found in vascular dementia (Leroi et al. 2003). The modern classification of neuropsychiatric symptoms distinguishes delirium, affective syndrome, psychotic syndrome, drive disturbances (sleep and eating), and specific problem behaviors (usually in late stages). Major depressive episodes are frequent in DAT and other types of dementia (Zubenko et al. 2003) and often have serious adverse consequences for patients and their caregivers. The more severe signs and symptoms, including agitated and psychotic behavior, are more characteristic of advanced disease or of patients with frontal lobe involvement. Paranoid ideas are frequent, often representing "logical" conclusions based on misinterpretations, misperceptions, or memory deficits. They may not be persistent, but complex and well-systematized delusions, as well as hallucinations, are also reported (for all modalities).

The course of the syndrome is also variable according to type of dementia and has implications for the differential diagnosis. An incrementally worsening or stepwise course is common in vascular dementia, whereas the deficits may be stable in some types of dementia, such as in dementia related to head trauma (see also Chapter 35,

**TABLE 7-5. Clinical findings in patients with dementia of the Alzheimer's type, by severity level****Mild (MMSE score=18–23; duration of disease=1–3 years)**

Impaired registration and recent memory (early sign); remote recall mildly impaired  
 Defective temporal orientation  
 Mild impairment of thinking; bewilderment in the face of complexity  
 Impoverishment of language; naming problems  
 Mild apraxia for complex tasks  
 Agnosia not evident unless tested  
 Difficulties in planning, sequencing, and executing instrumental activities of daily living  
 Frequent personality changes: irritability, less apparent concern about issues of daily life and effects of their behavior on others  
 Depression in approximately 20% of patients; mild apathy; loss of initiative; lack of energy  
 Frequent misinterpretations; psychotic phenomena rare  
 Urinary incontinence in fewer than 10%  
 Other neurological signs and primitive reflexes rare

**Moderate (MMSE score=12–17; duration of disease=2–8 years)**

Recent memory and remote recall more severely impaired  
 Severe temporal disorientation, moderate spatial disorientation  
 Obvious impairment of thinking; catastrophic reactions if pressured  
 Fluent aphasia, anomia, paraphasic errors, empty quality of language, perseveration  
 Praxic difficulties to manage dressing, feeding, manipulations  
 Agnosia evident: failure to identify objects, including familiar faces  
 Difficulties in planning, sequencing, and executing extend to basic activities of daily living  
 Evident personality changes: marked irritability, marked lack of concern about issues of daily life and effects of their behavior on others  
 Dysphoric mood, depression less frequent; apathy; loss of initiative  
 Frequent psychotic phenomena (delusions, illusions, hallucinations)  
 Restlessness, pacing, wandering occasionally, agitation, sporadic aggressiveness  
 Urinary incontinence frequent; fecal incontinence rare  
 Gait disorder and frequent primitive reflexes

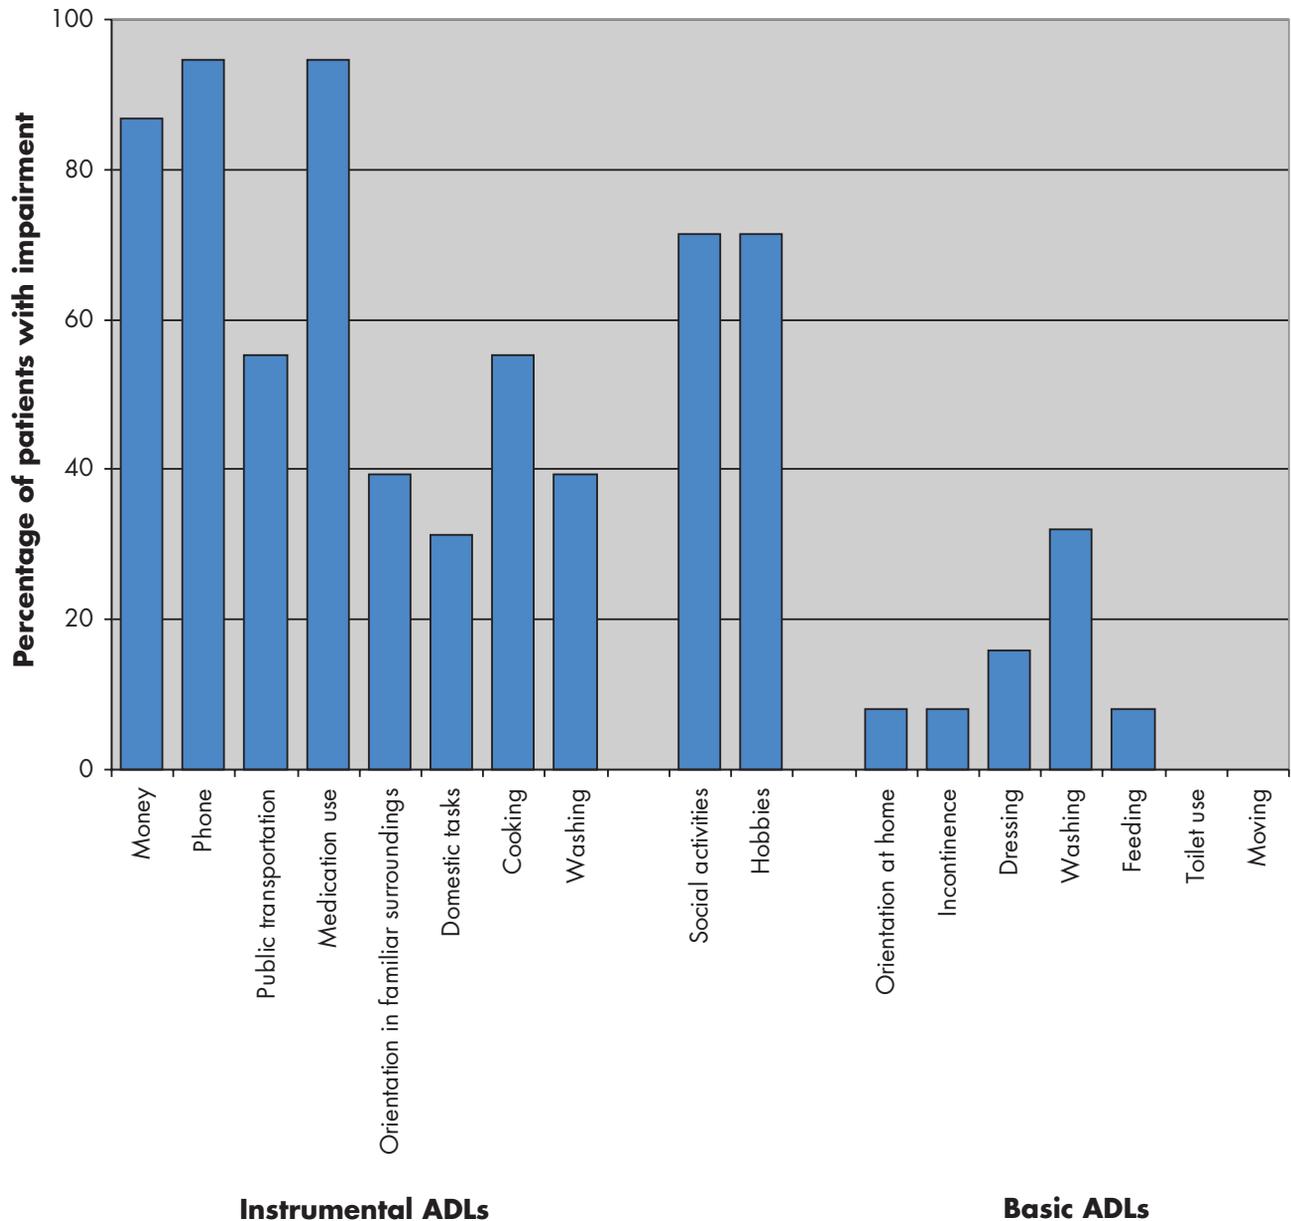

**Severe (MMSE score <12; duration of disease=7–12 years)**

Memory: only earliest learned information retained  
 Total disorientation  
 Severe impairment of thinking; indifference in the face of failures  
 Extreme impoverishment of language; communication impossible  
 Complete incapacity to manage dressing, feeding, simple manipulations  
 Severe agnosia: does not identify close relatives  
 Total dependence for even basic activities of daily living  
 Total disconnection from environment  
 Affective indifference; severe apathy; loss of initiative  
 Double incontinence (urinary and fecal)  
 Motor system rigidity and flexion contractures of all limbs; final stage of decortication

*Note.* MMSE=Mini-Mental State Examination.

“Physical Medicine and Rehabilitation”). Furthermore, the regression of symptoms is a possibility, once treatment is initiated, in dementias caused by potentially reversible disorders, such as normal-pressure hydrocephalus (NPH); metabolic and toxic conditions; or dementias related to the use of medications, to subdural hematoma, or to brain tumors. These conditions have been called *re-*

*versible dementias* and were once considered to be rather frequent (Rabins 1983). In fact, recent studies have found that only 4%–23% of the patients referred to memory clinics had potentially reversible conditions (Freter et al. 1998; Hejl et al. 2002; Norup et al. 2002), and actual reversal of dementia through treatment is rare (Freter et al. 1998; Ovsiew 2003).

## Clinicopathological Correlations

Some clinical characteristics suggest the involvement of specific brain areas and should help in clinical recognition of entities with different implications, as well as in understanding the underlying pathology of cognitive and non-cognitive phenomena (McHugh and Folstein 1979). *Cor-*

*tical dementia* is the conceptual term for those dementias in which the predominance of dysfunction is in the cortex, even if coexisting pathology exists in subcortical regions (Cummings and Benson 1984). Together with amnesia, not helped by cues to remember, the most characteristic signs are aphasia, apraxia, and agnosia, which are often designated as the *A's* (Table 7-6).

**TABLE 7-6. Clinical characteristics of cortical and subcortical dementia syndromes**

	Cortical	Subcortical
Aphasia	Early	No
Agnosia	Late	No
Apraxia	Rather early	Rare
Alexia	Rather late	No
Apathy, inertia	Rare or late	Very marked, early
Loss of initiative	Frequent, late	Marked
Psychomotor retardation	Rare or late	Very marked, early
Amnesia	Recall and recognition not aided by cues to remember	Recognition better preserved, may be aided by cues to remember
Gait	Normal until late	Abnormal, early
Extrapyramidal signs	Rare or late	Very marked, early
Pathological reflexes (grasp, snout, suck, etc.)	Late	Rare
Affective syndromes	Less frequent	Frequent, severe

*Subcortical dementia* describes the predominant involvement of the white and deep gray matter structures, such as basal ganglia, thalamus, and their frontal lobe projections. McHugh and Folstein (1975) were among the first to emphasize that parts of the brain other than the cortex have a role in cognitive activity and described the distinctive combination of three features in what they called the “subcortical dementia syndrome”: a slowly progressive dilapidation of all cognitive powers; prominent psychic apathy and inertia that may worsen to akinetic mutism; and the absence of aphasia, alexia, or agnosia (see Table 7-6). The same authors also emphasized the early appearance in subcortical dementia of prominent noncognitive symptoms, particularly depression and other affective disturbances considered to be a direct consequence of the cerebral pathology. Patients with subcortical dementia commonly present with psychomotor retardation; loss of initiative; and a general loss of vitality, physical energy, and emotional drive (Mandell and Albert 1990). Rabins et al. (1999) have designated some specific features of subcortical dementia as the four *D*'s:

- Dysmnnesia**—patients may benefit from cues to remember
- Dysexecutive**—related to troubles with decision making
- Delay**—related to slowed thinking and moving
- Depletion**—patients have reduced complexity of thought

Finally, the term *mixed dementia* describes the involvement of both cortical and subcortical regions. The clinical characteristics include aspects of cortical dementia, such as aphasia and apraxia, and the apathetic state produced by, and characteristic of, lesions in the subcortical areas.

## Clinical Types and Pathophysiology of Dementia

### Cortical Dementias

#### *Alzheimer's Disease*

Most cases of Alzheimer's disease start after age 65, but an earlier onset is not infrequent. Although some authors consider “presenile” and “senile” clinical forms to be different diseases (Jacobs et al. 1994), most consider them the same disorder with varied age at onset. The characteristic general dementia syndrome has been described and includes the cortical signs (see Tables 7-5 and 7-6). The insidious onset and slowly worsening, relentless course are most characteristic and crucial in the diagnostic process. The early clinical phase (see Table 7-5) is now distinguished from a preclinical phase, with mild cognitive impairment being apparent only on testing, preservation of instrumental ADLs, and specific neuroimaging findings. Other characteristic clinical signs and symptoms are also summarized in Table 7-5. They include 1) a “hippocampal type” of memory difficulty, which is not reliably aided by cues on memory testing and has a high number of intrusions and false recognitions (Petersen et al. 1994); 2) language difficulties, including a fluent aphasia with anomia, paraphasic errors, and a tendency of the patient to perseverate (Cummings and Benson 1986); 3) the patient's being able in many cases to retain the ability to recognize objects and to use them appropriately at a time when he or she can no longer name them accurately (Rapcsak et al. 1989); and 4) agnosia for faces, including family faces in late stages of the disease. Gait disorder in the middle stages is also common, as well as frontal signs such as grasping and sucking reflexes, along with a change in muscular tone.

The neuropathology of this condition is its defining characteristic (M.F. Folstein and McHugh 1983); its extent and severity correlate with the type and severity of the cognitive signs and symptoms (Blessed et al. 1968). Cortical atrophy occurs, with widened sulci and ventricular enlargement. The most severe changes occur in the medial temporal lobe, including the hippocampus. Areas of association cortex in the parietotemporal lobes and, to a lesser degree, the frontal lobes are also involved (Pearlson and Powell 1989). Characteristic microscopic findings are neuronal loss; synaptic loss, particularly in the cortex; senile plaques, with a core of amyloid peptide; neurofibrillary tangles, containing abnormally phosphorylated tau proteins; granulovacuolar degeneration of the neurons; and amyloid angiopathy. The location and abundance of microscopic findings determine the postmortem histological diagnosis of Alzheimer's disease (Cummings et al. 1998; Khachaturian 1985).

Several studies have supported the cholinergic deficit hypothesis in DAT, including specific degeneration of cholinergic neurons in the nucleus basalis of Meynert; decreases in acetylcholine and choline acetyltransferase concentrations in the brain; and observations about the role of cholinergic agonists and antagonists. Other hypotheses are suggested by the decrease in norepinephrine activity and, more recently, by reports of decreased levels of many neurotransmitters, including serotonin and the neuroactive peptides somatostatin and corticotropin. Evidence also indicates that the excitatory activity of L-glutamate plays a role in the pathogenesis of DAT (Greenamyre et al. 1988). However, recent research suggests that vascular factors may play an important role in determining the presence and severity of the clinical symptoms of DAT (de la Torre 2002; Mori 2002; O'Brien et al. 2003; Snowden et al. 1997).

### ***Dementia With Lewy Bodies***

Dementia with Lewy bodies is a condition of uncertain nosological status, with cortical signs suggesting DAT alongside the classic, extrapyramidal features of Parkinson's disease (Lishman 1998a; McKeith et al. 1996). However, the typical neuropathological findings of DAT are much less common in this condition. The distinctive feature is the presence of Lewy bodies in the cortex, particularly in limbic areas, whereas in Parkinson's disease they are typically found in subcortical regions (Lishman 1998a). Some authors now include both dementia with Lewy bodies and Parkinson's disease among the alpha-synucleinopathies on the basis of recent pathological findings (Ferrer and Puig 2003; Ferrer et al. 2002; Litvan 1999). Mean age at disease onset varies between 60 and 80 years. Psychotic, hallucinatory syndromes and confusional states are com-

mon and may be the presenting symptomatology. Other characteristics include relative preponderance of visuospatial and frontal lobe signs, clear day-to-day fluctuations in symptoms and cognitive performance, and episodes resembling acute confusional states with visual and auditory hallucinations and paranoid delusions. Depressive symptoms also occur frequently. Patients who have dementia with Lewy bodies have frequent falls and/or transient, unexplained episodes of loss of consciousness. They have a characteristic vulnerability to neuroleptics, which frequently exacerbate extrapyramidal dysfunction. Such reactions may be severe and may include acute episodes of rigidity, instability, and falls.

### ***Frontotemporal Dementia***

Frontotemporal dementia syndromes, often accompanied by cortical signs, are also the result of neurodegenerative diseases. The most characteristic features that distinguish frontotemporal dementia from DAT are personality changes and neuropsychiatric symptoms, which may be quite marked and precede the cognitive decline by several years (Neary et al. 1998). The psychiatric symptoms in frontotemporal dementia include marked irritability; poor judgment; defective control of impulses, including violent impulses in some cases; disinhibition; and a general disregard for the conventional rules of social conduct. Restlessness and hyperorality also have been reported. Social withdrawal or overt depression may be the first symptom in some patients.

Neuronal loss and gliosis in the frontotemporal areas define this type of neurodegenerative dementia. Pick's disease, characterized by the presence of distinctive intraneuronal Pick bodies and ballooned Pick cells on microscopic examination, may be diagnosed in up to 25% of cases. This disease and the remaining types of frontotemporal dementias tend now to be classified as tauopathies, with a large clinical spectrum including Pick's disease, PSP, corticobasal degeneration, and multisystem atrophy (Lebert et al. 2002). PSP is often classified among subcortical dementias because of the predominance of subcortical signs. Primary progressive aphasia is an atypical dementia typified by insidious and progressive impairment in language, with relative preservation of memory and other cortical functions, once thought to be rare but now recognized as not uncommon (Mesulam 2003).

## **Subcortical Dementias**

### ***Huntington's Disease***

Huntington's disease has the three main characteristics of the subcortical dementia syndrome (M.F. Folstein and McHugh 1983), together with the classic choreoathetoid

movement disorder and a positive family history. Huntington's disease usually has its onset in the third or fourth decade, although juvenile forms occasionally occur. The psychopathology, both cognitive and noncognitive, may appear before the movement abnormalities (McHugh and Folstein 1975). Both cognitive difficulties and mental apathy may be subtle initially. Once they appear, they tend to steadily progress to the point of very severe cognitive loss and profound self-neglect, resembling an akinetic mute state. Several authors also have reported prominent symptoms that may be difficult to differentiate from primary affective disorder, particularly depression (S. E. Folstein et al. 1979; Lieberman et al. 1979). However, demoralization and depressive reactions are also frequent, and the risk of suicide is increased (Huntington 1872; Reed and Chandler 1958). Suspiciousness and misinterpretations are quite common, but delusions and hallucinations with paranoid and catatonic features also have been described (Dewhurst et al. 1969). Huntington's disease also may include Schneiderian first-rank symptoms, making it difficult to differentiate from schizophrenia (McHugh and Folstein 1975).

The neuropathology in Huntington's disease includes atrophy of the caudate nucleus and loss of gamma-aminobutyric acid (GABA) interneurons (Lishman 1998b). The clinical findings are considered to be caused by imbalance of subcortical cholinergic and dopaminergic systems (T. L. Perry et al. 1973).

### *Parkinson's Disease*

A subcortical, progressive dementia syndrome may occur in approximately one-third of patients with Parkinson's disease (Breteler et al. 1995), but contrary to Huntington's disease, it tends to occur late in the course of the illness, after the motor symptoms have advanced significantly. The classic Parkinson's disease neurological signs in a patient with dementia point to the diagnosis. Apathy is particularly prominent and may advance to an akinetic mute state. Individual parkinsonian patients endure a wide variety of psychopathological symptoms, including frequent emotional reactions to the disease, but a depressive disorder identical to that seen in affective illness and responsive to the usual treatments is found in approximately one-third of patients (Faber and Trimble 1991; Loranger et al. 1972).

Nigral pathology alone is probably not sufficient for the development of dementia in Parkinson's disease and requires the spread of pathology to other subcortical nuclei, the limbic system, and the cerebral cortex. The main degenerative pathology seems to be Lewy body type, principally made of alpha-synuclein (Duyckaerts et al.

2003), and some controversy exists with regard to the frequency and implications of DAT-type pathology found in cases of dementia in Parkinson's disease (Apaydin et al. 2002; Emre 2003). Losses of cholinergic, dopaminergic, and noradrenergic innervation have been suggested to be the underlying neurochemical deficits.

### *Wilson's Disease*

Subcortical dementia with characteristic extrapyramidal signs also may be seen in Wilson's disease (Starosta-Rubinstein et al. 1987). This combination of symptoms, together with onset during adolescence or early adulthood, should suggest the diagnosis. Cognitive deficits are usually mild, and psychosis is infrequent. However, depressive syndromes, irritability, disinhibition, personality changes, and poor impulse control are common, with the severity paralleling the severity of the neurological signs (Denning and Berrios 1989). The psychopathological features result from destructive deposition of copper in the basal nuclei (Starosta-Rubinstein 1995) due to an inherited defect in the copper-carrying serum protein ceruloplasmin (Akil and Brewer 1995).

### *Normal-Pressure Hydrocephalus*

NPH can present as a very characteristic neuropsychiatric syndrome, a triad of clinical symptoms combining motoric and psychopathological features (M. F. Folstein and McHugh 1983; McHugh 1964, 1966): 1) an early gait disturbance, resembling the stiff steps of spastic paraparesis; 2) subcortical dementia with particularly severe apathetic features; and 3) urinary incontinence that may not appear until late in the course. An insidious onset with cognitive difficulties is common. Outbursts of hostile behavior occur sometimes (Sandyk 1984), and eventually the illness may progress to a state resembling akinetic mutism if untreated. The neuropsychiatric deficits are considered to be the result of tissue destruction by stretching as a result of the chronic hydrocephalus (McHugh and Folstein 1979).

## Mixed Dementia and Dementia in Disseminated Brain Diseases

### *Vascular Dementia*

Vascular dementia is defined as the dementia resulting from ischemic, ischemic-hypoxic, or hemorrhagic brain lesions due to cerebrovascular or cardiovascular pathology (Roman 2002). Clinical findings in vascular dementia are heterogeneous and depend to a great extent on the speed, total volume, and localization of the lesions. Typically, the onset is in later life, and the dementia syndrome

is the result of small brain infarcts, which lead to cognitive deterioration when they have enough cumulative effects on critical areas of the brain. However, cognitive impairment and probably dementia also can be seen in chronic ischemia without frank infarction (Chui et al. 1992). Acute onset usually develops after stroke, either from thrombosis, from an embolism, or rarely from a single massive hemorrhage. Onset and course of dementia are often more gradual in so-called *multi-infarct dementia*, as a consequence of many minor ischemic episodes, which produce an accumulation of lacunae in the cerebral parenchyma.

Cortical dementia occurs when the infarcts affect primarily the cortex, with focal neurological signs being the norm. Subcortical dementia is typically seen in patients with a history of hypertension and foci of ischemic destruction in the deep white matter of the cerebral hemispheres. A variant of vascular dementia is *Binswanger's disease*, or *subcortical arteriosclerotic encephalopathy*, which is associated with pseudobulbar palsy, spasticity, and weakness (D.A. Bennett et al. 1990). In such cases, extensive, diffuse demyelination of white matter can be seen in periventricular regions, and recent neuroimaging techniques have shown that the condition is more frequent than previously suspected. Mixed cortical and subcortical syndromes are also common in vascular dementia, with neuroimaging findings or autopsy findings suggesting the presence of lesions in both cerebral areas. Mild cognitive impairment of the vascular type also has been described, with an outcome worse than in nonvascular mild cognitive impairment (Frisoni et al. 2002).

The course of vascular dementia has classically been described as stepwise and patchy, but advances in brain imaging techniques have shown that patients with vascular dementia may have clinical courses as gradual and smooth as in patients with DAT. Poststroke depression, independent of the disability caused by the disease, is frequent (M.F. Folstein et al. 1977; Robinson 1997). Emotional lability, with transient depressive mood, weeping, or explosive laughter, is also a classic finding in these patients. Personality is usually relatively preserved, but in a proportion of patients, personality changes may be evident, with apathy or disinhibition or the accentuation of previous traits such as egocentricity, paranoid attitude, or irritability.

Most studies have supported the view that the total volume of infarcted brain and the total number of infarctions with additive or multiplicative effects correlate well with the severity of dementia. However, the location of the infarctions also may be important (Liu et al. 1992). In more than two-thirds of vascular dementia patients, the pathological correlate is the lacunar state, characterized

by multiple lacunar infarctions in subcortical structures such as the basal ganglia and thalamus. Other pathological findings include watershed infarctions due to reduction in brain perfusion, multiple embolic infarcts, diffuse demyelination of white matter in Binswanger's disease, and a mixture of lesions. The term *vascular cognitive impairment* has been proposed to broaden the current definitions of vascular dementia to recognize the important part cerebrovascular disease plays in several cognitive disorders, including DAT and other degenerative dementias (O'Brien et al. 2003). It is now estimated that the prevalence of mixed cases of vascular dementia and DAT has been underestimated; that pure vascular dementia is rare; and that, in addition to simple coexistence, vascular dementia and DAT may share common pathogenetic mechanisms (Erkinjuntti 2002).

### ***Infection-Associated Dementias***

*HIV-associated dementia*, formerly called *AIDS dementia complex*, is now the most common dementia caused by an infectious disease (see also Chapter 27, "Infectious Diseases," and Chapter 28, "HIV/AIDS"). Cognitive deterioration is frequently observed in infection with HIV-1 and may be severe enough to fulfill criteria for dementia (World Health Organization 1990). Cognitive dysfunction may be the earliest or the only clinical manifestation of AIDS. The heterogeneity of psychopathological manifestations and the occurrence of both cortical and subcortical features suggest disseminated brain pathology in this condition (Van Gorp et al. 1993). Noncognitive psychopathology—in particular depressive syndromes associated with the subcortical cognitive psychopathology (Van Gorp et al. 1993)—is also common in patients infected with HIV-1 (S. Perry and Jacobsen 1986).

*Creutzfeldt-Jakob disease* is a dementia with an extremely rapid course, caused by a transmissible infectious agent, the *prion* (Prusiner 2001). Cognitive deterioration is progressive, widespread, very severe, and accompanied by pyramidal and extrapyramidal signs, early characteristic myoclonic jerks, muscle rigidity, and ataxia. Death usually occurs in 6–12 months (Will et al. 1996). Pathological findings are widespread in both the cortex and the subcortical structures (Budka et al. 1995). Spongiform change in neurons is characteristic, and neuronal loss and astrocytic proliferation occur.

*Neurosyphilis* may evolve into different types of dementia if left untreated (Dewhurst 1969). The most severe form is general paresis, which becomes evident 15–20 years after the original infection. The dementia may be easily recognized in the advanced state and is accompanied by characteristic signs, such as pupillary abnormali-

ties, dysarthria, tremor of the tongue, and hypotonia. However, the onset is commonly insidious, and the diagnosis may be suggested when the initial memory difficulties are accompanied by indifference, facial quivering, tremor, and, sometimes, myoclonus. Intellectual deterioration is progressive and severe, with cortical deficits and often signs suggesting frontal lobe involvement, including disinhibited behavior. Psychotic phenomena, such as grandiose or hypochondriacal delusions, are common (Dewhurst 1969).

*Chronic meningitis*, caused by chronic bacterial, parasitic, or fungal infections, can eventually cause progressive dementia, with fluctuations in arousal and cognitive performance, apathy and lethargy, disorientation, and cranial nerve abnormalities.

Immunosuppressed or debilitated, chronically ill patients are at special risk. *Herpes simplex encephalitis* may cause major neurological and cognitive sequelae. Because herpes encephalitis has a predilection for the temporal lobes, amnesic and aphasic syndromes are common, but dementia also can be seen (Hierons et al. 1978). Other cortical signs reflect damage to other cortical areas (Skoldenberg 1991).

*Progressive multifocal leukoencephalopathy* (PML) is a rare complication of a common subacute viral disorder, most commonly seen in immunosuppressed patients (von Einsiedel et al. 1993). Clinical signs and symptoms are quite heterogeneous, and the dementia may include both cortical and subcortical signs and symptoms, reflecting widespread lesions in the central nervous system. PML is usually progressive, with motor dysfunction and blindness sometimes developing; death commonly follows in a few months.

### ***Metabolic and Toxic Dementias***

Metabolic and toxic dementias (see also Chapter 23, "Endocrine and Metabolic Disorders") form a heterogeneous group of diseases (see Table 7-3) of special interest to the consultant psychiatrist because they are relatively frequent in medical settings and are potentially reversible. Dementia in these conditions has predominantly subcortical features but may have mixed characteristics. Psychomotor slowing may be severe in cases of hypothyroidism. Memory deficits are often accompanied by problems in executive function, with impaired attention and concentration also common. Whether the metabolic and toxic encephalopathies are best conceptualized as reversible dementias or as chronic deliria is unclear, and perhaps the distinction is primarily semantic, particularly in cases of hepatic, renal, and cardiopulmonary failure. Progression of the dementia is usually quite insidious, in

relation to the chronicity of the metabolic or toxic condition, and the course tends to be disease-specific.

The neuropathology in these conditions is not well known. Hippocampal neurons are probably most vulnerable to anoxic injury (Zola-Morgan et al. 1986) but are also vulnerable to severe hypercholesterolemia and to repeated or severe episodes of hypoglycemia, such as may occur in type 1 diabetes mellitus (Sachon et al. 1992). Hypothyroidism can produce subcortical damage through a mechanism of relative cerebral hypoxia (Mintzer 1992). Vitamin B<sub>12</sub> deficiency, as seen in pernicious anemia, has been associated with disseminated degeneration in areas of cortical white matter, the optic tracts, and the cerebellar peduncles (Martin et al. 1992). In pellagra, lack of nicotinic acid and probably other vitamin B deficiencies may lead to neuronal destruction.

*Alcoholic dementia*, one possible complication of chronic alcoholism, is more frequent after age 50 years and is likely multifactorial in etiology. Thiamine and other vitamin B deficiencies and multiple TBIs have been found in these patients. Pathological findings at autopsy suggest that this condition is probably underdiagnosed. The cognitive deficits are more global here than in pure amnesic syndrome (e.g., Korsakoff's psychosis), and unlike those patients, alcoholic patients with dementia may complain of decreased efficiency of memory and intellectual functioning. Deterioration of visuo-perceptual and executive functions is commonly found. Neuropathological changes include cortical atrophy and nerve fiber disintegration with dissolution of myelin sheaths (Kril and Harper 1989). Dementing syndromes are also seen in distinct brain diseases related to chronic alcoholism, such as Marchiafava-Bignami disease, with degeneration of the corpus callosum and anterior commissure, or in acquired hepatocerebral degeneration.

Dementing syndromes also may occur in *chronic intoxication with medications*, which can be either prescribed or abused by patients. The onset is insidious, and the course is progressive; physicians should be alert to the possibility of this reversible dementia. Benzodiazepines, including those with high potency and a short half-life, are known to cause anterograde amnesia and impairment of memory consolidation and subsequent memory retrieval (Scharf et al. 1987). Elderly patients are more vulnerable to developing the dementia syndrome. Syndromes of cognitive deterioration have been reported in cocaine users and also in heavy users of cannabis (Deahl 1991).

### ***Neoplastic-Associated Dementias***

Neoplastic disease may affect any part of the brain and produce essentially any kind of neuropsychiatric symp-

toms, depending on tumor location and extent, as well as rapidity of tumor growth and propensity to cause increased intracranial pressure (see also Chapter 24, "Oncology," and Chapter 32, "Neurology and Neurosurgery"). Dementia is one such syndrome, and certain symptom clusters that occur with regularity may suggest the general location of lesions (M.F. Folstein and McHugh 1983; Hecaen and De Ajuriaguera 1956). Such clusters may be apparent before motor symptoms or a full dementia syndrome is suspected.

Initial symptoms of depression and some cognitive loss, with apathy, negativism, and akinesia, suggest the possibility of frontal lobe tumors such as meningioma or some forms of glioblastoma; a low performance on executive function tests further supports a frontal lobe site. Temporal lobe tumors are prone to produce seizures, and the psychiatric symptomatology may be complex and include features such as sexual disturbances, irritability, aggressiveness, and hallucinations. Tumors in the parietal region often cause characteristic language disorders when the location is in the dominant hemisphere. In the non-dominant hemisphere, they tend to produce signs such as unilateral neglect or apraxia. Tumors around the third ventricle, such as craniopharyngiomas and colloid cysts, may obstruct the flow of spinal fluid and cause hydrocephalic, subcortical dementia.

Dementia is one of the *paraneoplastic syndromes* that affect the brain. *Limbic encephalopathy* is a nonmetastatic complication of small cell lung carcinoma (and less commonly some other cancers) and may manifest with dramatic, sudden onset of memory loss (Corsellis et al. 1968). A full dementia syndrome may eventually develop (Bakheit et al. 1990). Mood disturbance, behavior change, and sometimes psychotic symptoms are also common. Pathological findings include neuronal loss, astrocytosis, lymphocytic perivascular infiltration, and glial nodules. The psychiatric symptoms may antedate the diagnosis of malignancy by several years. Early medical intervention might considerably improve the outcome of treatment in some cases (Burton et al. 1988).

### ***Dementia Following Traumatic Brain Injury***

A variety of cognitive difficulties are very frequent after TBI (see also Chapter 35, "Physical Medicine and Rehabilitation"). Posttraumatic amnesia is the norm in cases of severe trauma with loss of consciousness. Cognitive deficits become permanent in more than half of the patients if they do not recover memory and orientation within 2 weeks after injury (Levin 1989). Common difficulties include dysmnnesia, organic personality disorder, dysphasia, attentional disturbances, and impairments suggestive

of frontal lobe damage (Stuss et al. 1989). Dementia also occurs and may be accompanied by seizures and neurological deficits, as well as secondary psychiatric syndromes, including depression, mania, and psychosis (McAllister 1992). Dementia in boxers (*dementia pugilistica*) commonly starts with signs of ataxia, dysarthria, and Parkinson-like extrapyramidal signs before the global cognitive deficits are appreciated. Dementia due to subdural hematoma is notable because it is potentially reversible. In cases of dementia following TBI, diffuse axonal injury, with anatomic disruption and axonal tearing, has been described (Graham et al. 1987), and contusional foci in cortical areas and intracerebral hemorrhage also have been reported.

### **Depression**

The relation between dementia and depression is complex (Mahendra 1985). *Pseudodementia* is a term used to describe the condition of depressed patients who perform poorly on cognitive tasks because of lack of interest and motivation. However, *dementia syndromes of depression* (DSD) occur during episodes of severe mood disorder (M.F. Folstein and McHugh 1978). DSD are probably associated with potentially reversible neurotransmitter dysfunction. They are more frequent in elderly patients with a history of depression, and the presenting depressive syndrome often includes severe psychomotor retardation and other melancholic symptoms (Emery and Oxman 1992), as well as psychotic features such as delusions. Cortical signs such as language disturbances are uncommon, and in DSD, in contrast to DAT, prompting and organization of material tend to improve memory performance (O'Brien et al. 2001). DSD may be potentially reversible and tends to disappear with successful treatment of depression (Rabins et al. 1984). However, cognitive monitoring and follow-up are recommended because a persistent dementia syndrome may develop in a significant proportion of cases (Alexopoulos et al. 1993; Chen et al. 1999). The concept that cognitive dysfunction in elderly depressed patients should be considered a pseudodementia has been undermined by more recent studies reporting that cognitive dysfunction often persists after treatment of depression, suggesting either that the patient had both diagnoses (depression and dementia) or that "treatable" depression was a secondary manifestation of dementia. Furthermore, depressive symptoms in the elderly and a history of late-onset depression have been associated with the severity of subcortical white matter lesions, suggesting an etiological role for vascular disease (de Groot et al. 2000).

## Diagnosis and Differential Diagnosis

---

Early detection of dementia can play an important role in both the social and the health care dimensions of the disease (Organization for Economic Cooperation and Development, in press). A brief interview can detect dementia with reasonable accuracy (Boustani et al. 2003) and can be taught to nonpsychiatrists. However, a systematic search for dementia should follow general screening principles and should be linked ideally to a system prepared to care for all identified patients (Wilson and Junger 1968). Dementia should be suspected in patients at risk referred to psychiatrists, particularly elderly medical patients with delirium or unexpected behavioral disturbances and patients referred by primary care physicians because of subjective complaints or observations of relatives about memory problems or loss of intellectual efficiency. In both cases, the clinical approach to diagnosis follows a classic sequence: first, to identify characteristic signs and symptoms of cognitive impairment; second, to document whether the signs and symptoms cluster in the defined syndrome and to complete a differential diagnosis by discarding false positive cases; and finally, to search for the etiological type of dementia. A search for associated medical conditions, neuropsychiatric symptoms, and special social needs completes the evaluation process.

### Clinical History

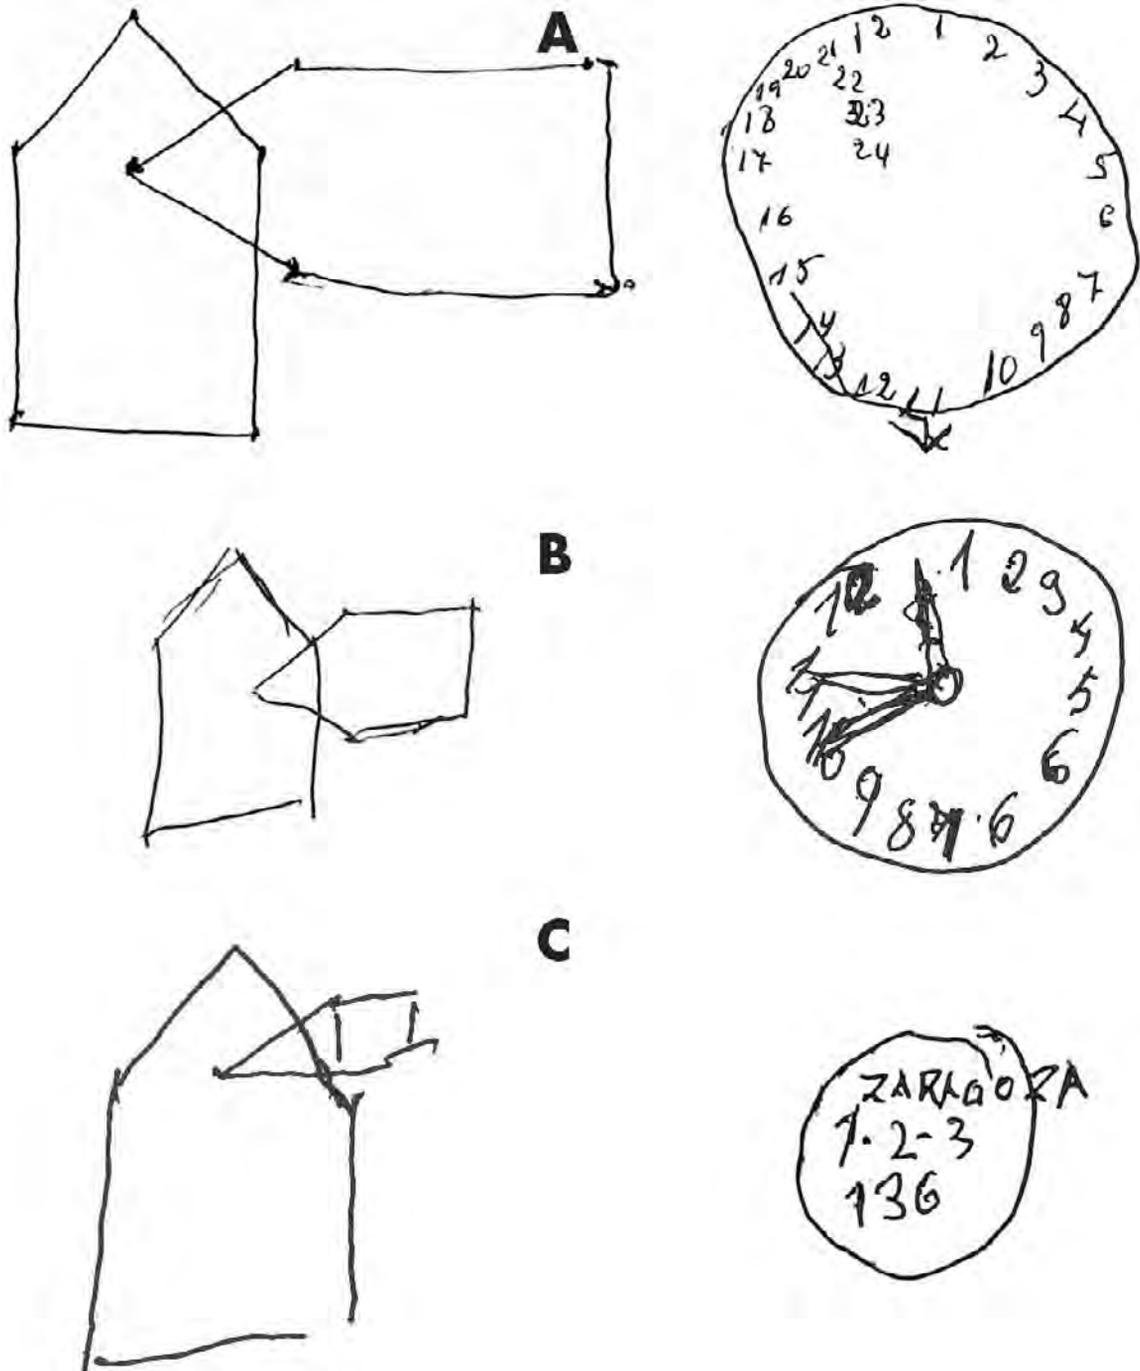

A clinical history corroborated through reliable caregivers and a systematic mental status examination lay the foundation of the diagnostic process. Among different medical specialists involved in the field of dementia, psychiatrists have special advantages because of their expertise in assessing psychopathology, as well as the social consequences of the disease included in the diagnostic criteria (see Table 7-2), including DSM-IV-TR criteria (American Psychiatric Association 2000). In taking the history, it is important to search for specific evidence of deterioration in memory and other cognitive functions summarized in the general dementia syndrome (see Table 7-5). Specific, convincing examples should be required as support for the diagnosis of dementia. Furthermore, the consultant must assess the presence, extent, and consequences of the cognitive problems in occupational activities and ADLs (see Figure 7-1). An outside informant is crucial for obtaining data about decline in cognitive function measured against premorbid abilities. The Informant Questionnaire on Cognitive Decline in the Elderly (IQ-CODE) (Jorm and Jacomb 1989)—and in particular the short form (Jorm 1994)—is suggested as a useful, simple

questionnaire that has good reliability and validity. The dementia questionnaire for DAT is another useful instrument for the same purpose and is also valid in telephone interviews with informants (Ellis et al. 1998). The onset and pattern of progression of the cognitive difficulties also should be carefully documented. Insidious diseases such as DAT can easily go undetected for years before becoming apparent (Larson et al. 1992). Finally, it is also important to determine whether changes in personality and behavior have accompanied the cognitive difficulties and whether psychopathological signs and symptoms, including apathy and loss of initiative, are present.

### Mental Status Examination

A systematic, basic bedside or office mental status examination is a minimum requirement in each case of suspected dementia. The cognitive assessment is relatively easy to complete and should include all relevant domains. Table 1-4 in Chapter 1, “Psychiatric Assessment and Consultation,” summarizes the cognitive areas to cover in the assessment and includes specific questions and items that may be used. Figure 7-2 shows the performance on some construction tasks by patients with dementia. It is strongly recommended that the clinician be familiar with a standard assessment method, ideally one supported by efficiency data. Although no standardized instrument is a substitute for sound clinical assessment, some are quite helpful, provided their limitations are kept in mind.

The Mini-Mental State Examination (MMSE) is one such instrument (sensitivity  $\geq 87\%$ ; positive predictive value  $\geq 79\%$  in clinical populations) (M.F. Folstein et al. 1975, 2001) and is widely considered to be the standard measure in most clinical and research studies (Gray and Cummings 2002). It fares very well in different cultures, if the standardization has been adequate (Lobo et al. 1999). Data on the efficiency of individual items in the MMSE, remarkable in items such as temporal orientation, may help the consultant in interpreting the results of the test (Table 7-7). The limits of the MMSE relate to both floor and ceiling effects, and population norms have to be considered in adjusting the usual cutoff point (23 of 24) (Crum et al. 1993; Lobo et al. 1999; Tombaugh and McIntyre 1992) to avoid false-positive cases in individuals with limited educational background or, conversely, false-negative cases in highly educated, intelligent patients. The Modified Mini-Mental State (3MS) (Teng and Chui 1987), with minor changes introduced to circumvent these difficulties, works well in clinical practice (McDowell et al. 1997). Executive functions, which are not well covered in the MMSE, may be easily assessed at bedside with the Frontal Assessment Battery (FAB) (Dubois et al.

**FIGURE 7-2.** Performance in construction tasks (commands to draw interlocked pentagons and a clock) by patients with increasing severity levels of dementia.

Impairment in performance appears earlier in clock drawing than in pentagon construction and increases with severity level of dementia. **Clock A** (Mini-Mental State Examination [MMSE] score=18) shows executive deficits in planning and organization; construction deficits to place the numbers; probable perseveration (24 hours); and deficits in judgment to correct errors and to place the hands indicating the time (11:10). **Pentagon A** shows nominal construction deficit. **Clock B** (MMSE score=15) shows subtle construction deficits (mild deviation of numbers, but spacing is correct); executive deficits in planning and judgment to indicate the time; and unsuccessful executive attempts to correct errors (in placing number 6; in placing the hands). **Pentagon B** shows mild construction deficit. **Clock C** (MMSE score=14) shows deficits both in remembering and in understanding the command and probable “stimulus dependence syndrome” (the pen in the patient’s hand acts as a stimulus and writes inappropriately inside the circle). **Pentagon C** shows construction and visuomotor coordination deficits.

**TABLE 7-7. Validity of individual items of MMSE (administered by lay interviewers)<sup>a</sup>**

MMSE items	Cutoff score	Sensitivity (%)	Specificity (%)	Misclassifications			AUC
				PPV (%) <sup>b</sup>	NPV (%) <sup>b</sup>	(%)	
Temporal orientation	3/4	81.3	91.5	93.9	96.3	10.1	0.914
Spatial orientation	4/5	70.8	86.4	45.3	92.5	17.4	0.805
Immediate memory	2/3	14.6	97.7	53.8	86.1	15.2	0.565
Calculation	3/4	78.0	71.4	31.4	95.1	27.6	0.794
Delayed memory	1/2	91.7	49.6	25.4	96.9	43.7	0.774
Nomination	1/2	12.2	98.8	66.7	85.3	15.6	0.555
Articulation	0/1	12.8	94.9	31.6	85.5	17.9	0.540
Verbal commands	2/3	41.7	79.5	27.8	87.8	26.5	0.618
Written commands	0/1	29.0	95.1	45.0	90.8	12.8	0.620
Writing	0/1	60.0	58.6	17.1	91.1	41.2	0.595
Pentagon drawing	0/1	91.9	54.4	24.6	97.6	40.4	0.730

2000). The Mini-Cog, which consists of just the three-item recall from the MMSE and the clock drawing test, may perform as well as other longer measures and thus appeal to primary care physicians as an initial screen (Borson et al. 2000).

## Neurological Examination

The neurological examination is also an integral part of, and informs, the diagnosis and differential diagnosis. The examination should be standard but may be focused on the assessment of neurological signs described in the clinical section, including specific gait difficulties, praxias, and pathological reflexes. Other testing should be included if warranted by clinical information.

## Differential Diagnosis

Differential diagnosis starts by ruling out false-positive cases of dementia—namely, previous *mental retardation*; *amnesic syndromes* (such as in Korsakoff's psychosis), without the global deficits required for the diagnosis of dementia; cognitive difficulties due to *general physical frailty*, particularly in elderly patients; and *age-related memory impairment* (or benign senescent forgetfulness), characterized by a minor degree of memory problems observed as a normal part of aging and not significantly interfering with a person's social or occupational behavior. *Pseudodementia syndromes* may be the result of motivational or emotional factors interfering with performance. They include *acute psychotic episodes*, *conversion disorder*, *factitious*

*disorder*, and *malingering*, suggested by reports of relatives, examination, or evidence of primary and/or secondary gains. *Schizophrenia* may present special diagnostic difficulties, both because of the emotional and psychotic features and because of the cognitive deficits (Zakzanis et al. 2003a). The cardinal symptoms of schizophrenia and longitudinal history should help clarify the diagnosis. The central cognitive functions and ADLs that deteriorate in dementia usually are preserved in schizophrenia. *Ganser's syndrome*, or the syndrome of "nearly correct answers," requires special consideration. The complete syndrome, including some disturbance of consciousness and subsequent amnesia, is rare, but "nearly correct answers" are more common. Both the syndrome and its symptoms may occur in association with organic and nonorganic psychiatric disturbances. Association with hysteria or hysterical mechanisms is frequent and must be considered in the differential diagnosis (Lishman 1998c).

*Depressive disorders* in elderly patients also should be considered because these patients may have memory difficulties, slowed thinking, and lack of spontaneity, which suggest dementia (see discussion of DSD earlier in this chapter in the "Depression" subsection). *Delirium* makes it very difficult to determine whether concurrent dementia is present, and delirium without fluctuating level of consciousness may be very difficult to distinguish from dementia. The diagnosis of delirium is suggested when global cognitive disturbance (including immediate and recent memory) is accompanied by rapid onset, fluctuating level of consciousness, impairment of attention, incoherence of thought, visual illusions or hallucinations or

other perceptual disturbances, and disturbances of the sleep-wake cycle, all in the presence of a severe medical condition. Definitive diagnosis often must be postponed until the follow-up after recovery from acute medical illness. A “double” diagnosis of delirium superimposed on dementia is very common in general hospital patients; Lobo and Saz (in press) found that a postdischarge diagnosis of dementia is confirmed in approximately half the cases of uncertain diagnosis.

*Mild cognitive impairment* merits special consideration because of its high prevalence and the high rate of progression to dementia (Petersen et al. 2001a). The following characteristics are all required for the diagnosis: 1) subjective complaints of memory and/or other cognitive functions, preferably corroborated by an informant; 2) objective impairment of cognitive functions of mild severity compared with age and education norms; and 3) preserved ADLs. Clinical judgment is required for the diagnosis, but neuropsychological assessment is helpful. The screening instruments and rating scales presented in this chapter may be used for this purpose. Scores of 2 or 3 on the Global Deterioration Scale (GDS) (Reisberg et al. 1982) or a score of 0.5 on the Clinical Dementia Rating Scale (CDR) (Hughes et al. 1982) has been considered to correspond to mild cognitive impairment (Petersen et al. 2001b). Neuroimaging findings helpful in the diagnosis are described in the following sections.

Once false-positive cases are ruled out and a dementia syndrome is confirmed, the consultant determines whether the syndrome has characteristics of *cortical*, *subcortical*, or *mixed* type (see Table 7-6), as described in the previous sections. The onset and progression of the cognitive difficulties, the other psychopathological features, and whether another medical condition is present will give further clues as to the type of dementia. For diagnostic purposes, clinical differences between types of dementia have been emphasized in the clinical section. The search for potentially reversible types of dementia due to medical conditions or toxic effects (see Table 7-3) has long been emphasized and remains an important step in the diagnostic process. Such conditions are more frequent in general hospital patients (Barry and Moskowitz 1988), although the identification of truly reversible causes has become less common than in the past, and true reversibility has been questioned (Weytingh et al. 1995). No standard dementia workup is applicable to every patient. Table 7-8 lists a screening battery of tests that are commonly used to identify conditions associated with dementia, such as infectious, metabolic, and neoplastic diseases and substance-induced dementia. The specific tests used should be determined by various factors, including the patient's age, medical comorbidities, history, and physical

**TABLE 7-8. Laboratory tests and other diagnostic procedures in the assessment of dementia**

**Screening battery<sup>a</sup>**

- Complete blood cell count with differential cell type count
- Erythrocyte sedimentation rate
- Blood glucose
- Blood urea nitrogen
- Electrolytes, calcium, magnesium
- Thyrotropin
- Vitamin B<sub>12</sub> and folate levels
- Urinalysis
- Fluorescent treponemal antibody absorption<sup>b</sup>
- Liver and renal function tests

**Neuroimaging**

- Computed tomography (CT) head scan
- Magnetic resonance imaging (MRI) head scan<sup>c</sup>
- Single photon emission computed tomography<sup>b,c</sup>

**Other tests and procedures<sup>a</sup>**

- Blood tests
  - Arterial blood gases
  - Blood and urine screens for alcohol, drugs, and heavy metals
  - Serum HIV test<sup>b,c</sup>
  - Homocysteine level
  - Antinuclear antibody, C3, C4, anti-double-stranded DNA, anticardiolipin antibody
- Other
  - Chest X ray
  - Electrocardiogram
  - Disease-specific tests (e.g., serum copper and ceruloplasmin for Wilson's disease)
  - Lumbar puncture<sup>c</sup> (usually after CT or MRI)

<sup>a</sup>Tests may be selected on the basis of patient age.

<sup>b</sup>May require special consent and counseling.

<sup>c</sup>Tests selected on the basis of specific symptoms (history and physical examination) or patient populations.

examination. Neuroimaging is often obtained, and neuropsychological testing may be very useful in some cases (Table 7-9). Lumbar puncture should be considered for patients with early onset or atypical clinical features, as well as for patients with positive syphilis serology or suspected hydrocephalus, central nervous system infection, vasculitis, immunosuppression, or metastatic cancer.

Most cases of dementia are DAT or vascular dementia. The DSM-IV-TR criteria overlap with the ICD-10 criteria (World Health Organization 1992), and the latter also have been adapted for use in general hospital patients (Malt et al. 1996). However, the strict application of the norms in both the American and the World Health Organization classifications in the same sample of patients may lead to important differences in diagnostic estimates (Er-

**TABLE 7–9. Neuroimaging findings in dementia syndromes**

<b>Syndrome and findings</b>	<b>Neuroimaging modalities</b>
<b>Dementias treatable by surgical procedures</b>	
Normal-pressure hydrocephalus, brain tumors, subdural hematoma	CT, MRI
<b>Dementia of the Alzheimer's type</b>	
Enlarged ventricles	CT, MRI
General atrophy	CT, MRI
Medial temporal lobe or hippocampus atrophy (early markers)	CT, MRI (combined with SPECT)
Temporoparietal (and sometimes frontal) hypoperfusion	SPECT
Temporoparietal (and sometimes frontal) hypometabolism; relative sparing of visual and sensorimotor cortex	PET
Absence of signs of vascular dementia	CT, MRI
<b>Vascular dementia</b>	
Leukoaraiosis in white matter (very frequent)	CT
Areas of infarct (very characteristic, only half the cases)	CT
Hyperintensities in white matter (more sensitive)	MRI
<b>Frontal dementia</b>	
Frontal (and temporal) atrophy	CT, MRI
Frontal (and temporal) hypoperfusion	SPECT
<b>Normal-pressure hydrocephalus</b>	
Very enlarged ventricles	CT, MRI
<b>Huntington's disease</b>	
Atrophy of caudate nucleus	CT, MRI
<b>Alcoholic dementia</b>	
Enlarged ventricles and atrophy	CT, MRI
<b>HIV dementia</b>	
Atrophy	CT, MRI
Demyelination of subcortical white matter	MRI
Hypermetabolism of thalamus and basal ganglia	PET
<b>Depression</b>	
Frontal hypometabolism, asymmetric (reversible)	PET
<b>Mild cognitive impairment</b>	
Hippocampal and entorhinal volume reduction	MRI, CT
Hypoperfusion or hypometabolism	SPECT, PET

*Note.* Structural imaging: CT=computed tomography; MRI=magnetic resonance imaging. Functional imaging: PET=positron emission tomography; SPECT=single photon emission computed tomography.

kinjuntti et al. 1997). Although stringent diagnostic criteria are fundamental for research purposes, clinicians may need a more flexible application to classify all patients assessed.

Previous diagnostic guidelines tended to emphasize that the diagnosis of DAT was a process of exclusion. It is also accepted that a definitive diagnosis of Alzheimer's disease requires histological evidence in the brain at autopsy (McKhann et al. 1984). Biopsy of brain or extraneural tissues may be recommended only in very special circumstances (Reichman and Cummings 1990). DAT is currently considered to be a very characteristic clinico-

pathological process, amenable to clinical diagnosis (Reisberg et al. 1997). This view is based on the presence of a cortical type of dementia syndrome, an insidious onset with slow deterioration (although plateaus may occur in the progression), and characteristic psychopathological and neurological signs and symptoms (see Table 7–5). The diagnosis is further supported by neuroimaging findings (see Table 7–9); the absence of clinical evidence; or findings from special investigations, which suggest that the mental state may be due to vascular dementia (Table 7–10) or another systemic disease that can induce a dementia syndrome.

**TABLE 7-10. Clinical characteristics suggesting vascular dementia**

---

Mixed type of dementia syndrome
Uneven cognitive deterioration
Relative preservation of insight and judgment
Abrupt onset, stepwise course
Emotional incontinence and lability
History of strokes
History of cardiovascular risk factors
Focal neurological signs and symptoms

---

Genetic testing for DAT is promising and relies on the fact that two general groups of genes are associated with this disease. Presenilin 1 (PS1) is a fairly accurate predictor of early-onset Alzheimer's disease, but genetic testing for mutations in presenilin has proven to be ineffective as a screening tool because of its low sensitivity (Kurz et al. 2002). The *APOE* genotype is statistically associated with late-onset Alzheimer's disease, but current genetic testing for the *APOE*  $\epsilon$ 4 allele can at best be used as an adjunct to clinical assessment for symptomatic patients (McConnell et al. 1999).

The clinical characteristics supporting a diagnosis of vascular dementia are summarized in Table 7-10, and Table 7-9 includes the characteristic and differential neuroimaging findings. More stringent diagnostic criteria are also available (Roman et al. 1993) and are widely considered important for research purposes. A diagnosis of a mixed DAT and vascular type of dementia or a double diagnosis is usually made when clinical and imaging characteristics of both coexist. This may happen, for example, when cerebrovascular episodes are superimposed on a clinical picture and history suggesting Alzheimer's disease. Vascular dementia also may precede neurodegenerative changes of DAT, but in such cases, it may not be possible to make the diagnosis of the latter on clinical grounds. The presence of cerebrovascular lesions in patients with DAT has been confirmed by recent evidence, including postmortem findings (Kalaria 2000).

### Neuroimaging and Electroencephalography

Neuroimaging has revolutionized the ability of clinicians to diagnose dementia (Burns 1990). It is a useful adjunct to clinical diagnosis and is considered to be mandatory in some stringent diagnostic systems (McKhann et al. 1984; Roman et al. 1993). Computed tomography (CT) and magnetic resonance imaging (MRI) are very useful in ruling out reversible conditions such as NPH, subdural hematoma, and brain tumors. Therefore, these imaging modalities should be routinely considered in patients with

history or findings suggesting those conditions, specifically when such patients have cognitive impairment with rapid onset or recent head trauma; focal neurological signs or abnormalities in gait; severe headache, papilloedema, or visual field defect; early appearance of incontinence; or history of stroke or seizures without known risk factors.

In DAT, both CT and MRI are helpful diagnostic tools (see Table 7-9). However, the findings are not totally specific, in particular general atrophy, which may be found in elderly patients without dementia. Images of enlarged ventricles are considered to be better discriminators (Giacometti et al. 1994). Early markers of the disease may be the CT—and particularly the MRI—views of the medial temporal lobe and hippocampus (Convit et al. 1997; De Leon et al. 1989). Single photon emission computed tomography (SPECT) is also a promising technique (see Table 7-9), as is positron emission tomography (PET), although not all hospitals have adequate facilities. The utility of both functional techniques has been supported by a recent meta-analytic review (Zakzanis et al. 2003b). However, the costs of tests, and whether the results will make a difference in management of the patient, should be considered before routine recommendation in clinical practice. In vascular dementia, neuroimaging can provide strong support for the diagnosis, especially the MRI finding of hyperintensities in the white matter, and some authors suggest that the diagnosis is excluded in the absence of vascular lesions (Roman 2002). However, some hyperintensities are also found in DAT and other degenerative dementias, as well as in control subjects (Pantoni and Garcia 1995). PET is promising in patients with DSD (Martinot et al. 1990).

A review of the literature suggests that MRI and PET or SPECT are currently the most commonly used neuroimaging modalities in studies focusing on mild cognitive impairment (Wolf et al. 2003). Significant hippocampal and entorhinal cortex volume reductions were consistently found in subjects with mild cognitive impairment as compared with cognitively unimpaired control subjects. However, these measures cannot be regarded as being of high predictive value in an individual case, and neuroimaging measures of change are more informative (Petersen et al. 2001b). In PET and SPECT studies, reduced blood flow and/or glucose metabolism in temporoparietal association areas, posterior cingulate, and hippocampus have been associated with a higher risk of progressive cognitive decline in patients with mild cognitive impairment (Wolf et al. 2003).

The electroencephalogram (EEG) has limited utility in the differential diagnosis of dementia because abnormalities are frequent but relatively nonspecific. Slow wave

activity characteristic of delirium does not appear until late in the course of DAT (Reisberg et al. 1997). Characteristic tracings may be seen in patients with Creutzfeldt-Jakob disease (triphasic, periodic burst patterns) and in patients with some metabolic dementias, such as hepatic encephalopathy (triphasic waves) (Brown et al. 1986), although in neither case is the finding pathognomonic.

## Neuropsychological Testing

Neuropsychological testing (see also Chapter 2, “Neuropsychological and Psychological Evaluation”) is valuable as an adjunct to the clinical examination but is no substitute for sound clinical judgment. Any battery of tests for the evaluation of dementia should assess a wide range of cognitive abilities, with special emphasis on memory (W.G. Rosen 1983). The age, education, and culture of the population must be considered in standardizing the instruments and interpreting the results. Neuropsychological testing may be particularly useful to differentiate dementia from age-related cognitive impairment and to provide both quantitative and qualitative information that helps differentiate types of dementia. Batteries commonly used include measures of memory, intellect, language, and visuospatial function. Some are exhaustive, with the administration taking several hours—a feature that limits their utility. A rather short battery has been standardized by the Consortium to Establish a Registry for Alzheimer’s Disease (Welsh et al. 1992) and has been used in different countries.

## Dementia Rating Scales

Aside from the MMSE, screening and assessment instruments for dementia include classic scales, such as the Blessed Mental Status Examination (Blessed et al. 1968), and new brief tests for discriminating dementia from nondementia in samples of persons with heterogeneous educational and cultural backgrounds, such as the Mini-Cog (Borson et al. 2000). Instruments for specific purposes have been designed; one such instrument, the Alzheimer’s Disease Assessment Scale (ADAS) (W.G. Rosen et al. 1984), is considered to have improved sensitivity for DAT. The use of these instruments does not replace a careful mental status examination. Educational and cultural factors must be taken into account in interpreting the results of cognitive assessment with any of these instruments (Tombaugh and McIntyre 1992). Primary care physicians and nurse practitioners can be trained in their use.

Global staging procedures, such as the GDS (Reisberg et al. 1982) and, in particular, the CDR (Hughes et

al. 1982), have come into wide use. Scales for measuring neuropsychiatric symptoms, such as the Neuropsychiatric Inventory (NPI) (Cummings et al. 1994), are also becoming widely used, and some can be recommended for clinical practice. A variety of assessments are also available for documenting functional deficits, such as the classic instruments of Lawton and Brody (1969), the Katz Index (Katz et al. 1970), or the Functional Assessment Staging (FAST) procedure, which can be used in conjunction with the GDS staging system (Reisberg et al. 1993). Some reports suggest that these scales can better assess the temporal variance of DAT than cognitive instruments can (Reisberg et al. 1996).

## Clinical Course, Prognosis, and Outcome

---

The course and prognosis of dementia are generally disease-specific but may be influenced by a variety of factors. Timely surgical treatment, before irreversible brain damage occurs, may have spectacular results in subdural hematoma or brain tumors, depending on type and location. Classical studies suggested the improvement of severe apathy in NPH by surgical shunting, although cognitive improvement was not as evident. However, this remains a controversial issue, and a recent systematic review concluded that no evidence indicates whether placement of a shunt is effective (Esmonde and Cooke 2004). One would expect that dementia associated with medications or metabolic conditions should be reversible, but this is not always the case in practice (Clarfield 1988).

Medical comorbidity may be present in two-thirds of DAT patients and is strongly associated with greater impairment in cognition and in self-care (Doraiswamy et al. 2002). Optimal management of medical illnesses may offer potential to improve cognition in Alzheimer’s disease. Dementias associated with infections have disease-specific prognoses. Untreated HIV dementia generally progresses quickly (over months) to severe global dementia, mutism, and death. However, the course may be variable, and with careful antiretroviral treatment, patients may survive for years. The course of dementia in central nervous system syphilis or chronic inflammatory diseases is also variable; cognitive improvement may be seen if early treatment is implemented. Adequate treatment with dopamine agonists and other standard treatments significantly improves the prognosis of dementia in Parkinson’s disease. Early treatment with thiamine is vital in alcoholic patients with cognitive dysfunction (Blansjaar and van Dijk 1992).

Important events or changes in a patient's routine may precipitate episodes of behavioral disturbance. Medical illness (most often urinary tract infection or pneumonia) or the use of benzodiazepines or alcohol also may precipitate episodes of delirium. Psychosocial and pharmacological treatments may be beneficial, and the symptoms of degenerative processes may progress slowly for a time or may even recede somewhat. Patients with good premorbid adjustment and greater intelligence and education are in general more able to compensate for intellectual deficits and disability. Support from family and caregivers may determine to an important extent the presence or absence of affective and other psychological symptoms, as well as the course of dementia.

Recent studies suggest that median survival after the onset of DAT is much shorter than has previously been estimated and is strongly associated with age. In the study by Brookmeyer et al. (2002), median survival ranged from 8.3 years for persons who received the diagnosis at age 65 years to 3.4 years for persons who received the diagnosis at age 90 years. No important differences in mean survival have been found between DAT and vascular dementia (Wolfson et al. 2001).

The relative risk of death for DAT is two to three times higher than in persons without DAT, particularly in older women (Dewey and Saz 2001; Dodge et al. 2003). The mean annual rate of progression of cognitive impairment is approximately 2–4 points when degree of impairment is assessed with the MMSE (Ballard et al. 2001b). Although there are some discrepant reports (Mortimer et al. 1992), most researchers have found faster rates of decline in early-onset DAT (Jacobs et al. 1994; Stern et al. 1997). A more recent review (Sarazin et al. 2002) suggested that an increased rate of deterioration was associated with the following factors: low baseline cognitive status, presence of Lewy bodies, language deficits, lower scores on nonverbal neuropsychological tests, extrapyramidal signs, and myoclonus. The relation between *APOE*  $\epsilon$ 4 and the course of DAT is still debated (Frisoni et al. 1995; Galasko et al. 2000), but the presence of psychotic symptoms at baseline is strongly and independently predictive of a more rapid decline (Levy et al. 1996; Paulsen et al. 2000). However, some reports consider that cognitive decline in such cases might be related to neuroleptic treatment (McShane et al. 1997). Neuropsychiatric symptoms tend to fluctuate in the course of dementia in most patients, but depression, agitation, and aggression may show greater persistence as compared with delusions and hallucinations (Devanand et al. 1997). Dysthymia has been reported to be less persistent in DAT patients (Starkstein et al. 1997).

Functional impairment in DAT is highly correlated with the severity of cognitive impairment (Mohs et al.

2000), but the rate of functional decline may be slower for patients with mild and severe dementia than for patients with moderate dementia (Schmeidler et al. 1998). Instrumental ADLs demand higher cognitive functions than do the basic ADLs, and, as expected, the former are impaired earlier (Green et al. 1993; Lawton and Brody 1969). Functional impairment occurs more quickly in patients with severe neuropsychiatric symptoms (Stern et al. 1997). As expected, nursing home placement has consistently been related not only to severity of dementia but also to severity of both functional impairment and neuropsychiatric symptoms (Smith et al. 2001; Steele et al. 1990; Stern et al. 1997). Strong evidence suggests that caring for patients with dementia has a negative effect on caregivers, often more negative than when caring for a person with physical disabilities (Morris et al. 1988); the ability of caregivers to tolerate neuropsychiatric symptoms reduces the probability of nursing home placement (Smith et al. 2001).

Considerably less evidence is available regarding the course of other degenerative diseases, but clinical experience and some reports suggest that disease progression is similar to that in DAT. Early studies of dementia with Lewy bodies suggested that the mean duration of illness was shorter than in DAT patients, but this finding has been questioned (Ballard et al. 2001b). Duration of dementia with Lewy bodies ranges from 1.8 to 9.5 years (Walker et al. 2000), and early-onset cases might have a more rapid decline. Visual hallucinations tend to be persistent in dementia with Lewy bodies (Ballard et al. 2001b), but psychosis does not appear to predict accelerated decline (Mohs et al. 2000). The increased survival reported in studies might be related to a decrease in the prescription of neuroleptics in patients with dementia with Lewy bodies (McShane et al. 1997), in view of the greater awareness of their negative side effects, which include rapid cognitive decline.

A faster rate of deterioration in executive functions, but not of other cognitive functions, has been reported in patients with frontotemporal dementia when compared with DAT (Galasko et al. 2000). Loss of autonomy appears early in the course of frontotemporal dementia and is frequently accompanied by behavior changes.

In the late stages of subcortical dementias, such as Huntington's disease, apathy may be quite severe and cause profound self-neglect; the patient's condition may resemble the akinetic mute state. Duration of disease varies from 5–10 years in PSP to 10–15 years in Huntington's disease. Survival in Parkinson's disease might be 12–14 years, provided the treatment is adequate, and patients with Wilson's disease may have a normal survival time if their symptoms are adequately treated with penicillamine

before irreversible liver and brain damage occur. The course of vascular dementia is typically stepwise but varies significantly depending on the type of vascular problem. Prognosis is poor, and patients usually die as a result of new cardiovascular events or strokes, but considerable individual variation is seen.

## Treatment

---

### General Principles

The general principles for treatment of dementia are summarized in Table 7–11. Patients with dementia very often have a broad range of medical problems, neuropsychiatric symptoms, and social needs accompanying their cognitive deterioration. Therefore, they usually need a multimodal plan, which should be adapted to the individual and to the specific stage of the disease. Specific recommendations are discussed in the following sections.

Adequate medical care is crucial in all dementias because both cognitive function and behavior may be adversely influenced by medical problems. Specific and frequent problems that must be addressed include the management of pain, urinary tract infections, and decubitus ulcers. Tube feeding to improve survival in hospitalized patients with advanced dementia is controversial, if not contraindicated, because it lacks demonstrated benefits (Meier et al. 2001). Treatment in nonreversible dementia aims at controlling the underlying condition as much as possible and slowing the progression of symptoms. Increasing evidence indicates that adequate prevention and treatment of vascular problems are also important in both vascular dementia and DAT. The treatment of cognitive loss with new pharmacological agents has become a major focus, but these medications have not supplanted the value of other measures. Identification and treatment of neuropsychiatric symptoms are especially relevant for psychiatrists. General measures include mandatory restrictions on driving. Both patients and families should be informed that dementia increases the risk for accidents, even in the early stages, and patients certainly should not be driving when dementia reaches a moderately severe stage. Psychological and social support and treatment always should be considered for patients. Psychiatrists also should be alert to the potential needs of caregivers. Long-term treatment must be considered in most dementias, and psychiatrists should participate in public health, including public awareness campaigns that stress the importance of early detection and treatment of dementia (Organization for Economic Cooperation and Development, in press).

### Pharmacological Treatment

General guidelines for psychotropic medication use in frail elderly patients are applicable (American Psychiatric Association 1997; Ryan et al. 2002; Spar and La Rue 2002). Specific suggestions for dementia patients are summarized in Table 7–12. Systematic evidence to support the effectiveness of particular psychotropic drugs in dementia patients is limited. Therefore, choice of drug class may be based on clinical evidence, and choice of agent is often based on the side-effect profile and on the characteristics of a given patient. Noncognitive, psychopathological, and behavioral manifestations in patients with dementia may be early targets for psychiatric intervention.

#### *Treatment of Psychosis and Agitation*

There is some evidence of the effectiveness of antipsychotics to control agitation, aggressiveness, wandering, and psychotic symptoms in patients with dementia (Olin and Schneider 2002; Stoppe et al. 1999). The data suggest that improvement is greater for psychosis than for other symptoms. Antipsychotics are often administered in the evening so that maximum levels occur at sleep time. Most antipsychotics have long half-lives, so once-a-day doses may be sufficient. Oral administration is preferred, except in cases of emergency or when the patient is unable to take the medication by mouth. Initial treatment with low doses of a high-potency agent, such as haloperidol (0.5–2.0 mg/day; maximum dosage=5 mg/day), may be recommended, and evidence indicates that it is effective in reducing aggressiveness in agitated dementia (Lonergan et al. 2004). However, the atypical antipsychotics cause fewer extrapyramidal effects, and their use in dementia has been supported by studies of risperidone (0.5–2.0 mg/day; maximum dosage=6 mg/day) (Brodaty et al. 2003), olanzapine (5–10 mg/day) (Motsinger et al. 2003), quetiapine (25–100 mg/day) (Takahashi et al. 2003), and ziprasidone (20–40 mg/day) (Byerly et al. 2001). Another option is clozapine (maximum dose=100 mg/day), which may be the best choice for Parkinson's disease (Motsinger et al. 2003) or dementia with Lewy bodies (Chacko et al. 1993) but carries risk of agranulocytosis. Thioridazine has been in wide clinical use in some countries for controlling behavior in patients with dementia. However, it has high anticholinergic activity and may cause worrisome QT prolongation. Furthermore, a systematic review suggested that no evidence supports its use in dementia (Kirchner et al. 2004).

There is less empirical support for, but considerable clinical experience with, the use of other medications in cases of agitated behavior, particularly in milder cases or

**TABLE 7-11. General principles for treatment of dementia and bases for consultation-liaison programs**

Use a multimodal treatment plan and individualize it for each patient.

Adjust treatment to stage of disease.

Provide adequate care of emergencies.

Evaluate for suicidal potential, self-harm (e.g., falling or wandering), or accidents (e.g., fires).

Treat agitation and potential for violence.

Initiate early treatment of potentially reversible medical or surgical conditions etiologically related to dementia (e.g., hypothyroidism, subdural hematoma).

See patient on regular basis.

Frequent visits when starting therapy; routine follow-up every 4–6 months thereafter (more frequent visits may be required in special circumstances).

Ensure adequate medical care.

Maintain the patient's physical health: nutritious diet, proper exercise.

Identify and treat comorbid medical conditions: cardiopulmonary dysfunction, pain, urinary tract infections, decubitus ulcers, visual and auditory problems, etc.

Care for iatrogenic events, pressure sores, aspiration pneumonia, fecal impaction.

Exert stringent control of unnecessary drugs taken for other medical disorders.

Try to control underlying disease and slow progression in nonreversible dementias.

Prevent and treat vascular problems (in both vascular dementia and dementia of the Alzheimer's type): hypertension, hyperlipidemia, obesity, cardiac disease, diabetes, alcohol dependence, smoking cessation, etc.

Treat cognitive loss: pharmacological, other measures.

Use other general measures.

Use general health measures: recreational and activity therapies, etc.

Restrict driving and use of other dangerous equipment.

Identify neuropsychiatric symptoms; provide vigorous treatment if needed.

Provide psychological support and treatment for patient.

Provide orientation aids (calendars, clocks, television).

Assess activities of daily living and provide assistance as needed.

Use special techniques: stimulation-oriented, reminiscence therapy, cognitive or reality therapy.

Provide social treatment.

Educate family caregivers.

Give advice with arrangements for wills, power of attorney, and general estate matters.

Suggest support groups, community organizations.

Provide support for caregivers and treatment if needed (e.g., for depression).

Arrange long-term treatment and coordinate with care organizations.

Memory clinics

Community resources, geriatric day hospitals

Multidisciplinary rehabilitation in an outpatient setting

Support groups, Alzheimer's Association

Respite care

Long-term facility (including nursing homes, hospice) necessary if caregivers not available

Vigilance regarding neglect or abuse

Incorporate health care strategies.

Public awareness campaigns; campaigns for early detection and treatment of dementia

cases unresponsive to neuroleptics. These medications include trazodone (50–400 mg/day; higher doses have been reported by some clinicians) (Rojas-Fernández et al. 2003), buspirone (15–50 mg/day) (Salzman 2001), carbamazepine (400–1,200 mg/day; maximum blood levels=8–

12 ng/mL) (Olin et al. 2001), and gabapentin (400–1,200 mg/day) (Miller 2001). These medications may be particularly useful in cases of dementia with Lewy bodies because the likelihood of severe adverse side effects with the use of neuroleptics is quite high (McKeith et al. 1992).

**TABLE 7-12. Suggested guidelines for psychotropic medication use**

Consider that agitation and/or behavioral disturbances may be due to

A medical condition, pain, other psychiatric condition, or sleep loss, which would resolve with treatment of the primary condition.

Hunger, constipation, stressful atmosphere, change in living conditions, or interpersonal difficulties.

Use strategies to minimize the total amount of medication required.

Instruction of caregivers to appropriately administer sedatives when warranted.

Mild symptoms or limited risk often may resolve with support, reassurance, and distraction.

Remember that dementia patients are often physically frail and have decreased renal clearance and slowed hepatic metabolism.

Be specific in selecting target symptoms.

Use low initial doses, one-quarter to one-third of the usual initial dose; dose increments should be smaller and between-dose intervals longer. Seek lowest effective dose.

Avoid polypharmacy.

Keep especially alert to

Medical conditions and drug interactions.

Frequent and worrying side effects: orthostatic hypotension and central nervous system sedation (may worsen cognition and cause falls); susceptibility to extrapyramidal side effects.

Idiosyncratic drug effects: mental confusion; restlessness; increased sedation; and vulnerability to anticholinergic effects of psychotropic medication.

In cases of extrapyramidal effects, reduce the dose or change to another drug rather than use anticholinergic drugs.

Reassess risks and benefits of psychotropic treatment on an ongoing basis.

Anticonvulsants require close monitoring because of potential toxic effects. Several other agents have been proposed for the treatment of agitation in patients with dementia, including benzodiazepines and beta-blockers, but evidence of efficacy is very limited, and potential side effects preclude routine recommendation.

### ***Treatment of Depression***

Both well-designed studies (Lyketsos et al. 2003) and reviews of randomized controlled trials (Olin and Schneider 2002) suggest that antidepressants may be effective for treating depressive syndromes in patients with dementia. Improvement of both cognitive function and apathy, especially in frontal lobe dementias, is also a frequent target in the treatment of depression. However, because antidepressants do have side effects, clinicians should prescribe with due caution (Bains et al. 2004). The newer antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs), are widely considered to be first-line treatment and should be preferred because of their favorable side-effect profile (Giron et al. 2001). SSRIs used in dementia include fluoxetine (initial dosage=5–10 mg/day, increase at several-week intervals to 40–60 mg/day); paroxetine (same dosages, increase every 1–2 weeks because of shorter half-life); sertraline (initial dosage=25 mg/day, increase at 1- to 2-week intervals to 150–200 mg/day); and

citalopram (initial dosage=10 mg/day, increase at weekly intervals to a maximum dosage of 40 mg/day). Escitalopram (10–20 mg/day) is promising (Lepola et al. 2003). Aside from well-known gastrointestinal symptoms, some potential SSRI side effects, such as agitation, akathisia and other extrapyramidal symptoms, dizziness, and weight loss, require monitoring in dementia patients. Venlafaxine (initial dosage=18.75–37.50 mg twice a day, increase at weekly intervals to 350–375 mg/day) is also recommended, particularly in apathetic patients because of stimulating effects, but it may elevate blood pressure at higher doses. Trazodone (initial dosage=25–50 mg/day, increase at weekly intervals to 300–400 mg/day) is often recommended when sedation and improved sleep are desired. Trazodone's main risks in elderly patients with dementia are orthostatic hypotension and excessive sedation.

Classic cyclic antidepressants usually are not considered first-line treatment because they have more adverse effects such as orthostatic hypotension, delays in cardiac conduction, anticholinergic effects, impaired cognition, and delirium. However, some clinicians prefer these drugs, particularly in treating severe depressive syndromes. In such cases, because of a more favorable side-effect profile, the recommended drugs are nortriptyline, particularly when sedation is needed (initial dosage=10–25 mg/day,

increase at weekly intervals to 100–150 mg/day; blood levels should not exceed 100–150 ng/mL), and desipramine (initial dosage=25–50 mg/day, increase at weekly intervals to 200 mg/day; blood levels should not exceed 150–200 ng/mL). There is also considerable experience with nortriptyline in “organic” depression (Robinson 1998), and clinical experience and some reports support the use of SSRIs and nortriptyline in pathological crying (Robinson et al. 1993). In depressed patients with frontotemporal dementia, both SSRIs (Swartz et al. 1997) and trazodone (Lebert et al. 1999) have shown some benefit.

Evidence is limited on the beneficial effects of other drugs recommended in the treatment of depression or depression-associated symptoms in dementia patients, such as bupropion, which may increase the risk of seizures at high doses, or buspirone for the treatment of agitation and anxiety associated with depression. Monoamine oxidase inhibitors (MAOIs) should be used only if other drugs fail, because postural hypotension is a serious problem in frail elderly, and patients with dementia cannot be trusted to avoid restricted foods. Psychostimulants, such as D-amphetamine and methylphenidate, are sometimes useful in patients with medical illness and depression; potential side effects of restlessness, agitation, sleep disturbances, and appetite suppression are uncommon at low doses. Apathy in depressed dementia patients also has been treated with bromocriptine, whereas potential side effects, such as psychosis, confusion, dyskinesias, and anticholinergic effects, including delirium, have been reported after treatment with amantadine. Clinical experience suggests that electroconvulsive therapy (ECT) may be useful in treating severe depression associated with dementia that does not respond to drugs, but the data are limited. In such cases, ECT should be given twice rather than thrice weekly, and less memory loss has been documented with unilateral than with bilateral placement of electrodes (American Psychiatric Association 1997) (see also Chapter 39, “Electroconvulsive Therapy”).

### *Treatment of Insomnia and Anxiety*

Sleep disturbances, which are frequent in patients with dementia, should be primarily managed by careful attention to sleep hygiene. When the disturbances occur in patients with other neuropsychiatric symptoms requiring psychotropic treatment, a drug with sedating properties, given at bedtime, probably should be selected. Otherwise, trazodone (50–100 mg, once at bedtime) is often prescribed. Clinical experience suggests that low-dose antipsychotics (haloperidol 0.5–1.0 mg or the atypical antipsychotics) can be helpful. Chloral hydrate (250–500 mg/day) and zolpidem (5–10 mg at bedtime) are good alternatives for short-term use. Clonazepam (0.5 mg/day, with

increases in dosage up to 2 mg/day) is recommended by some clinicians in patients with frequent awakening or nocturnal wandering. However, all hypnotics have the potential risk of causing nocturnal confusion, daytime sedation, tolerance, rebound insomnia, worsening cognition, disinhibition, and delirium. Triazolam is not recommended because of its association with amnesia. Many patients use diphenhydramine because it is available in a variety of nonprescription preparations and therefore is erroneously believed to be safe. It is not a good choice because of its anticholinergic properties, which may exacerbate confusion and also counteract the effects of cholinesterase inhibitors.

The use of benzodiazepines for anxiety in patients with dementia is controversial because of the side-effect profile described, which also includes ataxia and accidental falls, respiratory depression, and agitation among the most disturbing effects in dementia patients. Low dosages of relatively short-acting drugs, such as lorazepam (0.5–1.0 mg every 4–6 hours) or oxazepam (7.5–15.0 mg four times per day), are preferred when using benzodiazepines and may be beneficial for brief periods. Antidepressants should be considered for long-term treatment, but empirical evidence is very limited regarding their use for anxiety in dementia patients.

### *Treatment of Cognitive Deficits*

Pharmacological treatment of DAT also should aim at restoring cognitive function and associated functional losses. Currently, the main drugs approved act by inhibiting acetylcholinesterase and thus providing cholinergic augmentation. They may improve cognitive and behavioral symptoms, as well as functional ADLs, in patients with mild to moderate DAT. However, the degree of benefit achieved is limited (Doody et al. 2001) or symptomatic (Cochrane reviews, see Table 7–13; Mayeux and Sano 1999)—that is, with little proven effect on the ultimate outcome. Tacrine, which was approved for treating DAT in 1993, has since been replaced by a group of drugs with fewer adverse effects, which include donepezil, rivastigmine, and galantamine (Mayeux and Sano 1999).

To date, there are no head-to-head comparisons of cholinesterase inhibitors, and the main differences between these drugs are in safety profiles and ease of administration (one to two times daily administration) (Grutzendler and Morris 2001). Donepezil is the most widely prescribed, probably because it was the first one to appear (Organization for Economic Cooperation and Development, in press). One cost-effectiveness analysis of cholinesterase inhibitors supported their use (Clegg et al. 2001), but medical guidelines in many countries recommend that cholinergic augmentation therapy be used

only in patients with mild to moderate forms of DAT (MMSE score >10 or 12 points or the equivalent score on the Alzheimer's Disease Assessment Scale—cognitive subscale [ADAS-Cog]) (Gillen et al. 2001). However, positive results have been documented in moderate to severe cases of DAT with a new drug, memantine (Reisberg et al. 2003) (see Table 7–13). It blocks the effects of glutamate in stimulating the *N*-methyl-D-aspartate receptor. A Cochrane review concluded that the evidence to date shows that in moderate to severe DAT, memantine improves measures of cognition and functional decline but does not affect clinically discernible change or improve global measures of dementia (Areosa Sastre and Sherriff 2004). A randomized, placebo-controlled trial of memantine in patients with moderate to severe Alzheimer's disease who were already receiving donepezil found statistically significant but clinically modest benefits (Tariot et al. 2004).

Cholinesterase inhibitors show some promise in the treatment of other dementias, such as dementia with Lewy bodies (McKeith et al. 2000) and Parkinson's disease (Emre 2003). Furthermore, pharmacological studies supporting the use of these and other agents have heuristic value in stimulating research on the pathogenesis of neurodegenerative dementias.

An antioxidant, vitamin E (200–2,000 IU/day), is frequently recommended for DAT patients to prevent further decline (American Psychiatric Association 1997). Recommendations were based on both empirical evidence and clinical experience. Although a recent, systematic review found no evidence to support its use (Tabet et al. 2003), vitamin E appears to be very safe and is still considered by some clinicians for treatment of DAT, particularly in the moderately severe stage, alone or in combination with an anticholinergic agent. Lower dosages should be used in patients with vitamin K deficiency because vitamin E may worsen coagulation deficits.

Positive results with a wide variety of agents to treat DAT have been reported, and systematic reviews support the benefits of nimodipine (90 mg/day), a calcium channel blocker (López-Arrieta and Birks 2004); nicergoline, an ergot derivative (Fioravanti et al. 2004); and selegiline, a monoamine oxidase-B (MAO-B) inhibitor (Birks and Flicker 2004). Selegiline (5–10 mg/day) may delay cognitive deterioration and may be worth considering in patients who are intolerant of, or unresponsive to, cholinesterase inhibitors. It requires no dietary limitations as with other MAOIs, but a major side effect is orthostatic hypotension.

Beneficial effects have been claimed, but not proven, with several agents, including statin therapy for lowering serum cholesterol (Scott and Laake 2004); dehydroepian-

drosterone (Huppert and Van Niekerk 2004); estrogen replacement therapy in postmenopausal women (Hogervorst et al. 2004); and ginkgo biloba, an extract of the leaves of the maidenhair tree (Birks et al. 2003a). No evidence has been found for the use of hydergine, an ergoloid mesylate, in DAT (L.S. Schneider and Olin 1994), but it may be appropriately continued for patients who have experienced benefits (American Psychiatric Association 1997). Preventive treatment with antihypertensive drugs is also controversial, but the results of a large international trial with candesartan in mild hypertension are promising (Forette et al. 1998; Lithell et al. 2003). In view of recent findings related to vascular factors influencing the cognitive symptoms of DAT, the management of these factors has become a focus of attention, discussed later in this section in relation to vascular dementia.

Finally, systematic reviews do not support the use of indomethacin, a nonsteroidal anti-inflammatory drug (Tabet and Feldman 2003); piracetam, a nootropic agent with effects on increasing oxygen and glucose utilization and probable platelet antiaggregation properties (Flicker and Grimley Evans 2004); lecithin, a major dietary source of choline (Higgins and Flicker 2004); D-cycloserine, an antibiotic that enhances glutamate function (Jones et al. 2004); and nicotine (López-Arrieta et al. 2003). Future drugs may strategically aim to retard or prevent amyloid deposition and neuronal degeneration and to stimulate neuroprotection (Cutler and Sramek 2001). The development of an experimental vaccine directed against the formation and accumulation of amyloid plaques has shown promise (Bard et al. 2000).

Drug treatment of mild cognitive impairment is controversial because evidence supporting pharmacological strategies remains limited. Efficacy of nicergoline (Fioravanti and Flicker 2004) and the dopamine receptor agonist piribedil (Nagaraja and Jayashree 2001) has been reported, and results of a meta-analysis support the use of acetyl-L-carnitine (Montgomery et al. 2003). Several long-term clinical trials are still ongoing (antioxidants, nootropics, anticholinesterases). Prevention and disease-modifying strategies raise ethical questions because interventions are focused on nondiseased elderly at risk, which means that long-term safety should be given disproportionate emphasis compared with efficacy. At present, treatment strategies for DAT could be extrapolated to mild cognitive impairment (Jelic and Winblad 2003). We recommend follow-up and monitoring of individuals with mild cognitive impairment, especially when neuroimaging suggests a high probability of conversion to DAT (see section "Neuroimaging and Electroencephalography" earlier in this chapter). Early treatment should be considered as soon as the diagnosis of dementia is clear.

**TABLE 7–13. Drug treatments for cognitive and functional losses in dementia of the Alzheimer’s type (DAT): Cochrane System Reviews**

<b>Drug</b>	<b>Effectiveness<sup>a</sup></b>	<b>Cognitive<sup>a</sup></b>	<b>Behavioral<sup>a</sup></b>	<b>ADL<sup>a</sup></b>	<b>Indications in DAT</b>	<b>Dosage</b>	<b>Mechanism of action</b>	<b>Side effects</b>
Donepezil <sup>b</sup>	++	++	++	++	Mild or moderate	5–10 mg once daily	AChE inhibitor	Nausea, vomiting, diarrhea
Rivastigmine <sup>c</sup>	++	++	++	++	Mild or moderate	1.5–6 mg twice a day	AChE, BChE inhibitor	Nausea, vomiting, diarrhea
Galantamine <sup>d</sup>	++	++	++	++	Mild or moderate	4–12 mg twice a day	AChE inhibitor	Nausea, vomiting, diarrhea
Memantine <sup>e</sup>	+	++	+	+	Moderate or severe	10–20 mg twice a day	NMDA antagonist	Agitation, urinary incontinence

<sup>e</sup>Areosa Sastre and Sherriff 2004.

Vascular dementia has no standard treatment (Erkinjuntti 2002), but recently, symptomatic cholinergic treatment has shown promise in both Alzheimer's disease with vascular dementia and vascular dementia alone (Erkinjuntti 2002). Systematic reviews give specific support to memantine (Areosa Sastre and Sherriff 2004), nicergoline (Fioravanti and Flicker 2004), and nimodipine (López-Arrieta and Birks 2004) in both vascular dementia and mixed dementia. Evidence is limited on the primary prevention and secondary prevention of vascular dementia (Roman 2002), but treating associated medical conditions and reducing known cardiovascular and cerebrovascular risk factors seem logical steps. Daily aspirin therapy to inhibit platelet aggregation has been recommended but remains controversial (Hebert et al. 2000) and is not supported by the results of a recent systematic review (Rands et al. 2004). The preventive effects of early treatment of even mild hypertension are also promising for vascular dementia (Forette et al. 1998; Lithell et al. 2003), but no convincing evidence has been found so far relating diabetic treatment to the prevention or management of cognitive impairment in type 2 diabetes (Areosa Sastre and Grimley Evans 2004). More studies are needed of the effectiveness and efficacy of prevention and treatment of mild cognitive impairment of vascular origin. In the meantime, good clinical sense recommends symptomatic treatment and control of other treatable risk factors—namely, cardiac disease, hyperlipidemia, obesity, hyperhomocysteinemia, hyperfibrinogenemia, and other conditions that can cause brain hypoperfusion, such as obstructive sleep apnea and orthostatic hypotension (Frisoni et al. 2002). Psychiatrists can play a prominent role in treating and preventing smoking and alcohol dependence. Genetic counseling may be considered in diseases of genetic basis, such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy.

## Psychological Treatment

Two main goals may be identified in the psychological treatment of dementia: providing support and modifying behavior. Few psychological treatments have been subjected to systematic evaluation, but some research, including single-case studies, along with clinical experience, supports their effectiveness. The supportive techniques are based on the recognition that deterioration of cognitive function and sense of identity has significant psychological meaning for patients with dementia and may be associated with high levels of distress. Patients benefit from specific support and attention to self-esteem issues, as well as assistance in grieving and accepting the extent of their disability. There is some overlap with cognitive-

behavioral techniques because the support is often accompanied by educational measures in which the nature and course of their illness are clearly explained. Psychiatrists also can assist patients and teach other staff to find ways to maximize functioning in preserved areas and to compensate for the defective functions. This includes simple maneuvers, such as taking notes for memory problems or making schedules to help structure activities into a daily routine. In this way, patients with dementia may have a predictable schedule and avoid undue distress, including catastrophic reactions when confronted with unfamiliar activities or environments.

Behavioral treatments are often focused on specific cognitive deficits, and different strategies have been devised. Reality orientation operates through the presentation of orientation-related information (e.g., time-, place-, and person-related), which is thought to provide the person with a greater understanding of his or her surroundings, possibly resulting in an improved sense of control and self-esteem. This technique has been associated with frustration in some patients, but a systematic review found evidence that reality orientation has benefits for both cognition and behavior in dementia (Spector et al. 2004a). Observational studies give some support to other strategies, such as stimulation-oriented treatment, which includes recreational activity, art therapy, dance therapy, and pet therapy. Reminiscence therapy tries to stimulate the patient to talk about the past. Beneficial effects on the patient's mood and/or behavior have been reported with both techniques, but the evidence in systematic reviews is limited (Chung et al. 2004; Spector et al. 2004b). Similarly, evidence is insufficient on the effectiveness of other techniques, such as validation therapy (Neal and Briggs 2004).

## Family Support and Social Care

The fate of dementia patients is determined to a large extent by their social framework (Organization for Economic Cooperation and Development, in press). Psychiatrists and other providers should pay attention to the family and social structures, community supports, and the potential need for residential treatment. Strong evidence suggests that informal (i.e., family) caregivers very frequently have psychiatric morbidity and possibly also medical morbidity related to the burden of caring for patients with dementia (Colvez et al. 2002; DeKosky and Orzogozo 2001; Ory et al. 1999; J. Schneider et al. 1999). However, many caregivers feel that caring for an afflicted loved one, even though an unexpected task, is a meaningful, accepted responsibility of which they wish to be an integral part. Empathic interventions may help them un-

derstand the complex mixture of feelings associated with caring for a loved one with a dementing illness. Formal psychotherapy may be necessary in some cases. Referral to support groups is often indicated, and associations of families of patients with dementia exist in many countries and often provide critical support. The family also should be educated about the disease and helped with information to facilitate planning for financial decisions and end-of-life care issues, including advance directives. Education for family caregivers of DAT patients has been shown to improve the outcomes for both caregivers and patients (Olin and Schneider 2002). Furthermore, comprehensive support and counseling services for spouse-caregivers decrease the likelihood of placing a spouse in a nursing home (Cohen and Pushkar 1999).

### Care Provision

Mental health facilities that specialize in treating dementia are varied. Psychiatrists should participate in supporting access to quality care, but no consensus currently exists about what constitutes quality care and how to assess care provision (Innes 2002). Social service referrals are very helpful to inform the family about available resources. Special care units for patients with dementia may offer models of optimal care, but no empirical evidence indicates that this type of unit achieves better outcomes than do traditional facilities.

The most common facility to care for patients with dementia is the memory clinic (Colvez et al. 2002). Such clinics gain value when attached to a psychosomatic medicine/consultation-liaison service, particularly when liaison is developed with primary care (Lobo and Saz, in press). Community resources include home health services, day care, or nursing homes. Shortage of nursing home beds is reported in most countries, so residential care remains important and in demand (Organization for Economic Cooperation and Development, in press). Geriatric day hospitals provide multidisciplinary rehabilitation in an outpatient setting. A review of studies documented a significant difference in favor of day hospital attendance when compared with no comprehensive elderly care (Forster et al. 2004). However, the general move toward an increased emphasis on community care is also dependent on the availability of informal caregivers. Respite services are considered very important for informal caregivers, although their effectiveness remains inconclusive (Organization for Economic Cooperation and Development, in press).

Long-term care of patients with dementia presents special problems. Delirium, a frequent complication in institutionalized, elderly patients with dementia, is dis-

cussed in Chapter 6, "Delirium." Delirium in patients with dementia is still managed empirically, and no evidence has documented the effectiveness of multidisciplinary team interventions or supported changes in current practice at this time (Britton and Russell 2004). Another complication is wandering, which is very common in long-term dementia patients. They may, at times, put themselves at risk, creating difficult challenges for caregivers and institutional staff. Traditional interventions to prevent wandering include restraint, drugs, and locked doors. Because cognitively impaired patients may respond to environmental stimuli in different ways, new techniques that might reduce wandering include the design of visual and other selective barriers, such as mirrors and grids or stripes of tape. However, a systematic review has found no evidence that these techniques are effective (Price et al. 2004).

The appropriate use of antipsychotic medications and tranquilizers is also an important issue in long-term institutionalized patients. Overuse of medication can lead to worsening of the dementia and to harmful side effects. Available alternatives, such as the search for medical, psychiatric, or environmental factors that may be causing agitation or behavior problems, are discussed in a previous section of this chapter ("Epidemiology, Risk Factors, and Etiology") and should be pursued. However, if a patient's behavior is dangerous, psychotropic medications should be used, and additional measures may be needed if no response occurs. Use of physical restraints should be limited to patients with imminent risk of physical harm to themselves or others and only until more definitive treatment is provided or after other measures have been exhausted (or pose greater risk to the patient). Good clinical practice, and legal regulations in some countries, requires careful consideration and documentation of the indications and available alternatives, monitoring of the response, and reassessment of the need for treatment. Structured educational programs for staff may decrease both the abuse of tranquilizers and the use of physical restraints in the institutionalized elderly.

## Aggression and Violence

Chiadi U. Onyike, M.D., M.H.S.

Constantine G. Lyketsos, M.D., M.H.S.

**AGGRESSION IS UBIQUITOUS** in human societies. As an adaptive behavior, it serves the social expression of drives and feelings that are intimately connected with survival needs. It is a complex socialized behavior associated with motivations such as self-preservation (which includes protection of offspring), retaliation, material advantage, and power. Thus, in some circumstances, aggression represents the expression of appetitive drives, and in others, it represents defensive behaviors. From an “everyday” perspective, aggressive behaviors range from assertiveness to coercion (including the use of force) and from hostile attitudes and verbal abuse to threats, belligerence, and violence.

Generally, psychiatry is concerned with forms of aggression that can be attributed to medical or psychological disorders. Even within this narrower context, aggression still encompasses a broad range of behaviors. In this chapter, we cover those aggressive behaviors that are associated with psychiatric, neurological, and general medical conditions. The focus is on fear-inducing and violent behavior: hostility, verbal abuse, and physically aggressive behavior—actions that threaten or inflict harm on an individual or an object. Definitions of aggression, violence, and related terms used in this chapter are presented in Table 8–1. Although most aggression involves intent to harm, the definition used in this chapter does not require such intent because clinically important aggressive behavior can occur in the absence of demonstrable intent—especially in patients with cognitive impairments, delirium, dementia, or mental retardation. Not included here are behaviors that may be characterized as *agitation*, such as nonthreatening verbal outbursts, oppositional and resistive behaviors, intrusiveness, restlessness, pacing, and other aberrant motor behaviors. We do not deal with community violence (e.g., riots, war, terrorism) or criminality.

**TABLE 8–1. Terms used in this chapter**

<b>Aggression</b>	Hostile, threatening, and violent behaviors directed at another person or objects, often with no (or trivial) provocation
<b>Violence</b>	Overt physical aggression directed at another person or object
<b>Domestic violence</b>	A continuum of behaviors directed against an intimate partner, ranging from verbal abuse, to threats and intimidation, to sexual assault and violence
<b>Agitation</b>	A state of pathologically intense emotional arousal and motor restlessness
<b>Disinhibition</b>	A behavioral state in which ability of the individual to preemptively evaluate and inhibit behavioral responses is decreased or lost
<b>Impulsivity</b>	A behavioral state characterized by a proneness to act without thought or self-restraint; a habitual tendency toward “hair trigger” actions
<b>Irritability</b>	A state of abnormally low tolerance in which the individual is easily provoked to anger and hostility

Psychiatrists primarily encounter aggression and violence when patients present for treatment in acute states. Aggression occurs as a complication of psychiatric states such as delusional psychoses, dementia, agitated delirium, intoxication, personality disorder (especially conduct, antisocial, borderline, and narcissistic types), and even adjustment disorder. Aggression also may complicate many nonpsychiatric illnesses because it can occur when patients feel disregarded, dissatisfied, frustrated, confused, frightened, thwarted, unable to convey concerns, and angry at perceived unfairness or mistreatment or as a “pri-

mary” symptom of the illness. Aggression can manifest in males and females, at any age (except in early infancy), and is seen in all patient care settings—outpatient clinics, inpatient units, rehabilitation programs, residential and custodial care facilities, nursing homes, and emergency departments. Aggressive behavior can result in involuntary confinement (in hospitals and jails), disruption of clinical and custodial care environments, longer hospital stays, and physical injury to patients and their caregivers (family and paid caregivers) and health care professionals. Family, paid caregivers, and health care professionals who are repeatedly exposed to aggression often experience demoralization, which leads to a diminished quality of care for patients.

In this chapter, we focus on aggression and violence in the medically ill, beginning with the epidemiology of aggressive and violent behaviors in diverse clinical settings, including risk factors and the causes and precipitants of aggression; we use the epidemiological causal model of *host*, *agent*, and *environment*. Next, we review the evaluation, formulation, and differential diagnosis of aggression. We conclude with a review of the management of aggressive behavior in the general hospital setting, including the emergency department. The content of this chapter is based on empirical evidence, existing care standards, and clinical experience.

## Epidemiology

---

Violence is common among individuals with psychiatric disorders. In a population-based study from the National Institute of Mental Health Epidemiologic Catchment Area project, 55.5% of the respondents who reported violent behavior in the past year had a psychiatric diagnosis, compared with 19.6% of the nonviolent respondents (Swanson et al. 1990). Only 2.7% of the men and 1.1% of the women without a psychiatric diagnosis reported any violent behavior, compared with 8.9%–21.1% of the men and 3.3%–21.7% of the women with a psychiatric diagnosis; the association was lowest for anxiety disorders and highest for substance use disorders, major affective disorders, and schizophrenia. Having more than one psychiatric diagnosis increased the likelihood of violent behavior in this study; this likelihood increased with each additional diagnosis. However, other data indicate that violence is not the inevitable outcome of mental illness. For example, judging from self-reports by United States community residents, only 4% of the risk for violence can be explained by major mental illness (Swanson 1994).

Most patients with mental illness are not violent, but aggressive and violent subgroups exist. Violent behavior

is associated with specific conditions, such as schizophrenia, major depressive disorders, substance abuse, personality disorders (antisocial and borderline), dementia, and traumatic brain injury, as well as with specific states, such as confusion, intoxication (with alcohol or other substances), akathisia, fearfulness, agitation, *paranoid* delusions, and *command* hallucinations (Eronen et al. 1998; Kalunian et al. 1990; Lyketsos 2000; McNiel et al. 2000; Raja et al. 1997; Sheridan et al. 1990; Soyka 2000; Swanson et al. 1997). The mere presence of delusions does not necessarily increase the risk for violent behavior (Appelbaum et al. 2000); however, psychotic illness concurrent with substance use appears to increase synergistically the risk for violent behavior (Scott et al. 1998; Soyka 2000).

Although men are generally more aggressive than women, the gender gap in the frequency and severity of aggressive behavior narrows among individuals with major mental illness and disappears among psychiatric inpatients and patients recently evaluated in an emergency department (Lam et al. 2000; Newhill et al. 1995). Other psychosocial correlates of aggression include younger age, onset of psychiatric illness at a younger age, previous violence, longer duration of hospitalization, and treatment nonadherence and resistance—particularly among patients with psychotic illness (Binder 1999; Ehmann et al. 2001; Swartz et al. 1998; Torrey 1994). Environmental factors such as overcrowding, rigid limits and rules, and staff attitude (Lancee et al. 1995; Ng et al. 2001; Owen et al. 1998; Palmstierna et al. 1991) may predispose psychiatric inpatients to anger and violence. In addition, the patient’s background contributes powerfully to the development and expression of violent behavior (Volavka 1999). Social maladjustment and impaired functioning also can accentuate the background risk for aggression and violence, particularly in patients with psychotic illness (Swanson et al. 1998).

All health care professionals, regardless of training and specialty, may encounter aggressive, violent patients. Aggression is observed in all ambulatory, hospital, and custodial (or residential) settings, although the frequency generally varies according to the specific population (i.e., diagnostic mix and acuity levels) and the characteristics of the setting (e.g., crowding, staffing levels). Within settings, the frequency of violence may vary by specific diagnosis, mode of presentation of the patient, illness acuity, and stage of illness. For example, aggression may be more frequent in the immediate postoperative period in surgical settings.

In an analysis of data from consecutive medical emergency calls in a 1-month period, emergency medical service (EMS) personnel were reported to have observed aggression in about 8.5% of encounters (Grange and

Corbett 2002). About half of these episodes were directed at these personnel (rather than at other individuals in the setting), with violence constituting 80% of this directed aggression. Patients were responsible for 90% of the directed aggression (relatives and other bystanders were responsible for the remainder). In adjusted analyses, higher relative odds of aggression were observed in encounters that involved males, police presence, street gangs, suspected psychiatric disorder, and abuse of alcohol or other substances. Clearly, EMS personnel may be victims of violence; because they must stabilize and transport these patients to the emergency department, they are at high risk for injury and psychological stress. In a questionnaire survey of a convenience sample of EMS personnel in California (67% response rate, with members of law enforcement excluded from the analysis), 95% reported having to restrain a patient, and 61% reported ever being assaulted (25% of whom were injured by the assault) (Corbett et al. 1998). Other studies have reported similar or higher prevalence estimates of assault and injury (Mock et al. 1998; Pozzi 1998; Tintinalli and McCoy 1993).

The incidence of violence in the EMS setting (as estimated by reviewing call records) was reported to be about 0.8% of all encounters in a 6-month period (Tintinalli and McCoy 1993), but these data were also limited by the use of a convenience sample and reporting biases. Most commentators agree that exposure to aggression among these workers is frequently compounded by their limited formal training on how to manage aggressive patients and lack of counseling in the aftermath of an assault. Fortunately, the relevant training needs of EMS personnel are beginning to be addressed through journals and other media and the development of a comprehensive training curriculum by the U.S. Department of Transportation (1998).

Aggressive and violent episodes are also common in the emergency department. For many patients, their agitation, aggressiveness, or violent behavior may be the reason that they have been brought to the emergency department, whereas for others who were not agitated or aggressive on arrival, threatening and violent behavior may develop as a result of their acute condition or other factors. Although the data are limited, results from several surveys of large emergency departments (with volumes of 40,000 or more cases annually) indicate that several episodes of staff being threatened by patients occur daily, the use of restraints is frequently indicated, and nearly 50% of these facilities experience at least one episode of staff assault each month—up to 25% of the assaults result in staff injury (Blanchard and Curtis 1999). Although health professionals (particularly nurses) are typ-

ically the victims of patient aggression, sometimes a visitor or another patient is assaulted. In some cases, a family member or other visitor, not the patient, is the perpetrator of an aggressive act. Violence in the emergency department is associated with a wide variety of motivations, predisposing factors, and precipitants. These determinants include the following:

- Patient factors, such as intoxication with substances of abuse, presence of psychiatric disorders (including personality disorders), transport to the hospital involuntarily, negative perceptions of hospital staff, and possession of a weapon at presentation
- Staff factors, such as impoliteness, insensitivity, and inadequate training
- Environmental factors, such as high noise levels, overcrowding, and uncomfortable waiting rooms
- System factors, such as high patient volumes, prolonged waiting and throughput times, inadequate security staff, and absent or inadequate formal training in the management of hostile and aggressive patients

Aggression is also common beyond the emergency department and occurs in a variety of inpatient settings. Of the estimated 20% of hospital staff assaulted by patients, up to 90% of violent incidents directed at hospital staff may occur beyond the emergency department (i.e., on inpatient units) (Whittington et al. 1996). In hospitalized patients, aggressive acts may occur as features or complications of confusion associated with the patients' primary conditions (e.g., thyroid storm, head injuries, hypoxia, encephalitis) or administered treatments (e.g., benzodiazepines or corticosteroids) or may result from co-occurring mental illness. On surgical units, aggression may result from confusion occurring in the immediate postoperative period, undiagnosed alcohol withdrawal, or inadequately controlled postoperative pain. Aggression in the general hospital may also evolve from patients' dissatisfaction with care or frustration from unfulfilled wants and expectations or during patient-staff conflicts.

In a recently reported survey of intensive care units (ICUs) in England and Wales, nurses were subjected to verbal hostility by patients in 87% of the ICUs and by patients' relatives in 74% (Lynch et al. 2003). Nurses were physically assaulted by patients in 77% of the ICUs and by relatives in 17%; rates of hostility and assault directed at physicians were moderately lower. Medical illness severity was associated with aggression committed by patients, whereas emotional distress, alcohol abuse, and sociopathic traits were associated with aggression committed by relatives. A similar pattern of aggressive behav-

iors may be seen on general medical and surgical wards, although the frequency of aggressive behaviors (particularly those committed by relatives) is likely to be lower.

Substance abuse and sociopathic traits among inpatients may contribute more to aggressive behaviors expressed in hospital wards (as compared with aggression expressed in ICUs). Substance abusers who have a withdrawal syndrome or intense cravings are frequent perpetrators of in-hospital aggression. Even nicotine can be a factor: smokers are no longer allowed to smoke in hospitals, and although nicotine withdrawal and craving are unlikely to directly cause violence, they can inflame conflict between patient and staff and may become the precipitant of aggression in a patient on the verge because of other factors. Because individuals are more likely to show negative affects and personality traits during times of high stress, including serious medical illness, patients with personality styles high in impulsivity, distrust, and aggressiveness (particularly antisocial or borderline personality disorders) may be more likely to commit violent acts during hospitalization.

Aggression and violence have serious consequences for patients and for those who care for them. These include disruption of the care environment, longer duration of hospitalization, higher treatment costs (Greenfield et al. 1989), and stigmatization of the mentally ill and their caregivers. Patients may sustain injuries—for example, from punching walls or glass, handling dangerous objects, falling, fighting with another patient, or resisting restraint. In addition, inpatients who are prone to impulsive aggressive acts tend to be at higher risk for elopement (Bowers et al. 2000) and for impulsive suicidal acts (Volavka 1999).

Although physicians, nurses, and other personnel are all at risk for injury, by far the hospital staff most likely to be injured by violent patients are nurses and clinical assistants (Binder and McNiel 1994; Hillbrand et al. 1996; Whittington et al. 1996). Assaults and injuries cause demoralization, physical and psychological disability, absenteeism (as a result of sick days and disability), and staff turnover or premature retirement among nurses, as well as increased administrative costs and litigation exposure for the care facility. In addition, violence from patients can cause staff to adopt negative attitudes toward their work and their patients, resulting in impaired job performance, poor patient–staff relationships, and patient dissatisfaction with care (Arnetz and Arnetz 2001). Patient violence has a myriad of negative effects on the treatment environment and the overall quality of patient care and can result in a vicious cycle in which a deteriorating environment promotes yet more violence (Arnetz and Arnetz 2001).

## Mechanisms of Aggression

---

Empirical evidence supports the categorization of aggression and violence as either impulsive or premeditated. This evidence includes the association of impulsive aggression (and not the premeditated form) with cognitive deficits, learning disability, lower verbal skills, brain injury, and abnormal patterns of brain glucose use (Brower and Price 2001; Davidson et al. 2000; Volavka 1999). *Impulsive aggression* is relatively unplanned and spontaneous behavior and is sometimes explosive (such as sometimes occurs in patients with frontal lobe injuries), whereas *premeditated aggression* is deliberate behavior that may be predatory (committed for material gain or power) or pathological (a reaction to misperceptions, hallucinations, or delusions). This simple categorization is clinically useful because 1) most aggressive patients will manifest predominantly impulsive or predominantly premeditated behaviors, and 2) clinically relevant aggressive behaviors are generally impulsive or pathological—although some patients with mental disorders have predatory behaviors. It is important to note that impulsive aggression is not necessarily unintentional. Impulsive aggression occurs on a *continuum of intention*, ranging from entirely unintentional reflexive behaviors (e.g., ill-directed shoving and swinging in a patient with postictal confusion) to resistive behaviors (e.g., thrashing, spitting, and biting during placement of lines or tubes in an agitated patient with delirium) to spur-of-the-moment intentional behaviors (e.g., a patient with borderline personality disorder throwing a telephone at the nurse who is scolding her).

From a pathogenetic perspective, aggression is a heterogeneous behavior associated with background genetic, familial, and social determinants, including unfavorable prenatal, perinatal, and rearing experiences (such as childhood experience of neglect or abuse); genetic endowments and predispositions; poor parental role modeling; poor education; and negative cultural and peer influences (Volavka 1999). These factors, and acquired others such as Axis I conditions, brain injury syndromes, and personality disorders, coalesce in the individual to yield a *host* who has a baseline propensity for aggression that interacts with specific provocations (*agents*) and occurs in environments (*circumstances*) to produce aggressive behaviors. Examples of *agents* include threats by others, misperceptions, conflicts, or physical discomfort. *Circumstances* are contexts, such as intense (or distant) interpersonal relationships, losses, or hospitalization for physical illness, that are generally captured in a narrative that shows the patient's maladaptive interactions with his or her environment given his or her dispositional vulnerabilities. This explanatory approach

describes the setting and sequence of events leading to an episode of aggressive behavior, while simultaneously placing these events in the context of the specific circumstances and the individual's psychological assets and liabilities.

Integration of the host, agent, and circumstance perspectives allows for enhanced understanding of any patient and his or her observed aggressive behavior. In some cases, an aggressive episode is the latest in a pattern of recurring impulsive, predatory, or pathological acts, which may (or may not) be associated with identifiable triggers, in an individual with cognitive or emotional vulnerabilities. In other cases, the act may be a somewhat understandable complication of the patient's primary condition or a not-so-surprising reaction to distressing circumstances.

Consider the following illustrations:

- Aggression and violence in inpatient settings appear to be relatively frequent in the first 48 hours after admission in acutely psychotic patients and in substance users (Barlow et al. 2000; Sheridan et al. 1990). In contrast, a rapid reduction in the risk of aggression in patients with schizophrenia within a few days after admission also has been reported (Binder and McNiel 1990). Both of these observations can be reconciled by considering that agitation and acute psychosis often lead to more intensive treatment efforts.
- Substance users may become aggressive soon after admission as a result of irritability associated with a withdrawal syndrome. When preemptive treatment for the withdrawal syndrome is initiated, the risk for aggression is minimized.
- Patient–staff conflicts—especially those that involve enforcement of rules, denying of privileges or requests (e.g., discharge, change in medications, off-unit smoking breaks), and involuntary admission or transfer—can precipitate aggressive acts and violence (Sheridan et al. 1990).

Psychosomatic medicine specialists often encounter recurrent impulsive aggression, which occurs as an inexplicable event or a “hair-trigger” response to relatively unimportant stimuli. This form of aggression is usually related to dysfunction of the brain areas involved in the modulation (or suppression) of primitive impulses and drives. It often arises as a consequence of physical illness or injury that directly or indirectly affects these brain areas. It is also true that in the general hospital setting, many episodes of impulsive aggression are not related to physical illness or injury per se but rather arise in an individual in whom impulsivity is a dominant (or prominent)

behavioral *trait*—for example, individuals with antisocial and borderline personality disorders. Since Phineas Gage's injury and its sequelae were described about 150 years ago (Harlow 1848, 1868), studies of patients who express acquired antisocial behavior and impulsive aggression following coarse brain injury have yielded important clues about brain mechanisms that modulate the expression of aggression. These case studies have shown that impulsivity, jocularity, tactless talk, aggressive outbursts, and reckless disregard for others frequently follow injury to frontal-subcortical brain circuits in adults. Acquired antisocial behavior and impulsive aggression also have been noted in war veterans with frontal lobe injury and in individuals who had frontal lobe injuries in childhood and subsequently developed coarse adult personality features, including psychological immaturity, impaired executive cognition, and recurring impulsive aggression (Brower and Price 2001).

Abnormalities in tests of executive cognition have been found repeatedly in studies of impulsively aggressive patients with antisocial personality disorder, frontal lobe injuries, and frontotemporal dementias and in children and adolescents with attention-deficit/hyperactivity disorder (ADHD) or conduct disorder (Brower and Price 2001; Coccaro and Siever 2002; Davidson et al. 2000). These abnormalities include deficits in working memory, abstract thinking, moral reasoning, affective regulation, and behavioral inhibition. Even though many of these patients show normal intelligence and executive cognition when tested, their real-life decisions suggest severe impairments in judgment and foresight (Brower and Price 2001).

The orbitofrontal and ventromedial cortices are involved in the restraint of impulsive behavior and thus play a central role in the regulation of impulsive aggression. The limbic system, particularly the amygdala and the cingulate cortex, is also involved in the regulation of aggression, presumably through a role in the generation of defensive aggressive states. Cases of acquired antisocial behavior and impulsive aggression have been associated with traumatic injuries to the orbitofrontal cortex and also to the ventromedial cortex (see reviews by Brower and Price 2001; Coccaro and Siever 2002; Davidson et al. 2000; Lyketsos 2000; Volavka 1999). It has been postulated that impulsive aggression arises as the result of a low threshold in the amygdala for activation of negative affects (fear, anger, and aggressive responses) or a failure of the orbitofrontal cortex to suppress negative affects in conformity to social rules or cues in the environment (Brower and Price 2001; Davidson et al. 2000). This view is supported by data from neuropsychological, neurophysiological, neurochemical, and functional brain imaging studies of impul-

sively aggressive patients and violent offenders (Brower and Price 2001; Coccaro and Siever 2002; Davidson et al. 2000; Lyketsos 2000; Volavka 1999).

The neurotransmitter systems involved in the modulation of aggression are primarily those involving serotonin and the catecholamines (norepinephrine and dopamine). Accumulated evidence indicates that impulsive aggression may result from disruption of serotonin neurotransmission, which putatively leads to the loss of inhibitory control of behavior (Berman and Coccaro 1998; Coccaro and Siever 2002; Davidson et al. 2000; Volavka 1999). These data include lower cerebrospinal fluid (CSF) levels of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in aggressive psychiatric patients, impulsive violent men (including violent offenders), disruptive and aggressive male children and adolescents, victims of violent suicides, and individuals with type 2 alcoholism (which has been associated with familial alcoholism, antisocial behavior, and impulsive aggression). These findings are further supported by pharmacological challenge studies designed to examine whether low CSF levels of 5-HIAA represented low central serotonin activity. These studies have reported a blunted prolactin response to serotonin agonist challenge (with buspirone or fenfluramine) in aggressive, antisocial, and suicidal individuals, indicating deficient serotonergic neurotransmission in patients with impulsive aggression (Coccaro and Siever 2002; Davidson et al. 2000; Volavka 1999).

Irritable aggression has been linked to catecholamine neurotransmission. High noradrenergic activity and low levels of monoamine oxidase (MAO) and catecholamine-*O*-methyltransferase (COMT) are associated with hostility and aggression in adults without psychiatric disorders and patients with psychosis (Volavka 1999). Dopaminergic neurotransmission also has been implicated in the expression of aggressive behavior, putatively because lower activity leads to impaired ability to restrain behavior (Berman and Coccaro 1998). However, only a modest role for noradrenergic and dopaminergic neurotransmission has been shown in impulsive aggression because much of the variance in aggression in these studies is accounted for by CSF levels of 5-HIAA (Coccaro and Siever 2002).

## Evaluation of Aggression

---

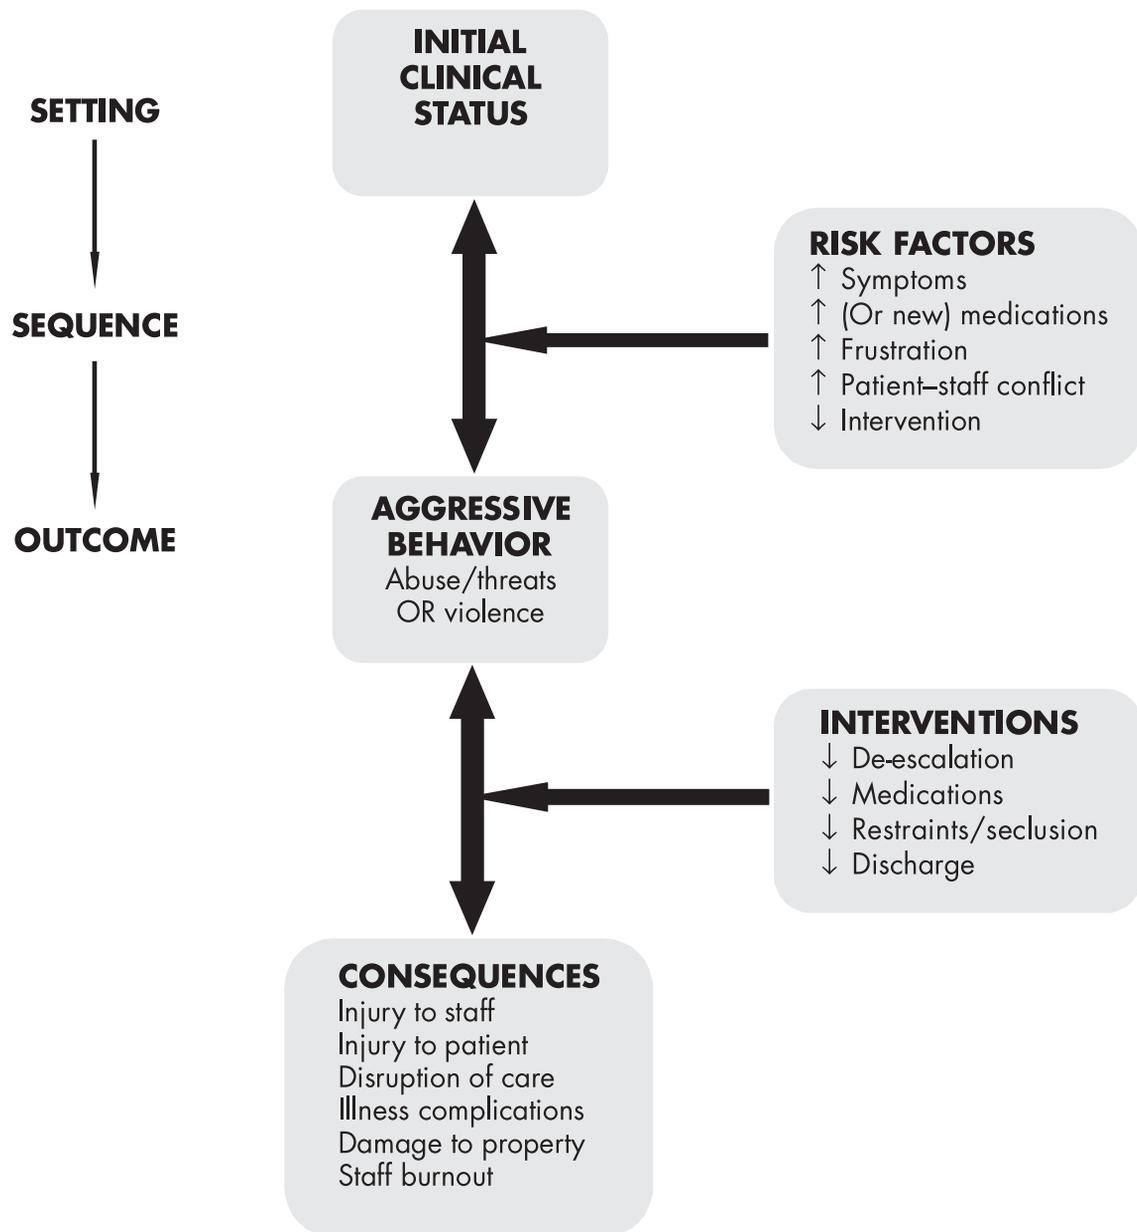

An episode of belligerence and violence in the general hospital setting typically progresses from a specific clinical state—the *setting*—to a *sequence* of events that culminates in the *outcome*—aggressive behavior (see Figure 8–1). Several factors influence the expression of aggression in

the clinic or hospital: aggression may occur if the patient has specific symptoms, mental states, adverse effects of medicines, dissatisfaction with care, or conflicts with staff. However, aggression can be prevented, its intensity reduced, or its consequences avoided or minimized by prompt intervention (the clinical progression of aggressive behavior in the general hospital is depicted in Figure 8–1). The choice of intervention depends on the specific situation as well as the case formulation and the specific diagnosis the patient has received.

The elucidation of the *setting-sequence-outcome* involves describing the specific aggressive behavior, the sequence of events preceding it, and the symptoms and factors that may be influencing its expression. This approach has been referred to as the *define and decode strategy* (Lyketsos 2000). The effects of the patient's behavior also should be noted by inquiring about injury to the patient or others, damage to property, disruption of the milieu, and so on. Precipitants such as staff–patient conflicts, end of visiting hours, or recent administration of a medication should be carefully sought, and the history also should clarify the setting in which the behavior has occurred and the temporal relation of the aggressive behavior to any co-occurring symptoms. It is also helpful to know whether the patient is febrile, confused, in pain, craving cigarettes, cognitively impaired or disabled, anxious or fearful, hallucinating or delusional, or if he or she has epilepsy (especially a recent seizure). All prescribed medicines (e.g., insulin, benzodiazepines, anticholinergics, neuroleptics) should be noted. The psychiatrist should systematically search for symptoms such as acute confusion, restlessness, akathisia, or agitation, which require urgent intervention.

In addition to collecting a careful history of the aggressive episode, the evaluation requires describing concurrent illnesses; the patient's personal, social, and family history (including current psychosocial functioning); any substance abuse; and the patient's personality and psychiatric status. General medical, neurological, cognitive, and mental status examinations are focused on describing systems that have been implicated in the history but also should include important “inspections,” such as the checking of vital signs, airway and cardiovascular status, exclusion of injuries, repeated assessment of alertness, assessment of dangerousness (inquiring about violent or suicidal ideas), and assessment of reality testing.

In the general hospital setting, laboratory data are often essential to accurate differential diagnosis. Blood tests can help to identify infection, anemia, electrolyte disturbances, or biochemical abnormalities that may explain delirium. Likewise, toxicology screens and serum drug concentrations may help to identify acute intoxications and

**FIGURE 8–1.** Clinical progression of aggressive behavior in the general hospital.

chronic substance use. Urinalysis, microbiological cultures (of blood and urine), and chest X ray may be helpful in certain circumstances (e.g., in immunosuppressed patients or patients with dementia). If seizures are a possibility, an electroencephalogram (EEG) should be performed. When obtundation, evidence of recent head trauma, or another reason to suspect an acute intracranial event is present, brain imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) should be obtained. In most circumstances, a brain CT is adequate. A high index of suspicion for intracranial hemorrhage (e.g., subdural hematoma) is appropriate because those

who are violent toward others are at higher risk for being victims of violence themselves.

The integration of the clinical data leads to a case formulation and differential diagnosis, as well as a summary narrative that depicts the *setting-sequence-outcome* of the aggressive episode (and also articulates the contributions of *host*, *agent*, and *circumstance*). The formulation addresses the following questions:

- Does the patient have a mental illness, personality vulnerability, cognitive impairment, delirium, or other condition that predisposes him or her to aggressive behavior?

- Is the aggression linked to specific aspects of illness such as psychomotor agitation, disinhibition, command hallucinations, aphasia, or acute pain?
- Can the aggression be explained by medications causing confusion, akathisia, or intoxication?
- Is the aggression associated with a specific activity or with interpersonal conflicts?
- How is the environment contributing to the behavior?
- Is the environment uncomfortable, noisy, overcrowded, or frightening?

It is also important for psychiatrists to remember that many impulsively aggressive patients have a relatively high risk for suicidal behavior (Volavka 1999). Several psychiatric disorders manifesting aggressive and violent behavior, particularly alcohol dependence and personality disorders, are associated with suicidal behavior. Thus, the evaluation of aggression also must include an assessment of the risk for self-injury and suicide.

## Disorders Associated With Aggressive Behavior

Many disorders can manifest with aggression and violence in the general hospital (Table 8–2). Thus, the psychiatrist's task will include a consideration of these disorders in the differential diagnosis of violent behavior in patients.

### Psychoses and Chronic Serious Mental Illness

As noted earlier in this chapter, several major mental disorders can produce violent behavior. Irritable patients with mania, depression, schizophrenia, or other major psychoses may commit impulsive violent acts. This risk for impulsive violence is greatest during acute presentations and is particularly high when patients have been brought to treatment against their will. Clinicians should therefore maintain high levels of vigilance when evaluating the irritable psychotic patient, especially when the patient is seen in the emergency department or soon after being involuntarily hospitalized.

Deliberate premeditated violence also can arise from psychotic disorders—usually as a response to delusional beliefs—but generally the content of psychotic patients' delusions is focused on familiar individuals (people in the patients' daily life), public figures, or imaginary persecutors rather than on the health professionals caring for them. It also should be noted that many patients with

chronic mental illness have maladaptive coping responses to stress or conflict and thus may react with violence during interpersonal conflicts. Therefore, a crucial aspect of the psychiatrist's role is to educate nonpsychiatric physicians, nurses, and others caring for these patients. When patients with major mental illness are admitted to nonpsychiatric settings, the psychiatrist's role as consultant should include educating the medical team about the illness (its current status and treatment) and the fact that most such patients can communicate their concerns and symptoms, will cooperate with care, and are nonviolent (even when psychotic). Treatment recommendations should include ways of approaching the patient (e.g., approaching the patient from within his or her visual field and calling out a greeting so that he or she is not startled), ensuring that the patient's current psychotropic regimen is prescribed,

and pointing out any known habits or preferences that can be accommodated (e.g., arranging for regular smoking breaks, preferred meals, or a favorite television show). The patient's physicians and nurses should be educated about early signs of agitation, such as pacing, restlessness, staring, and refusal of medications, and contingency plans for managing these symptoms or states should be specified—what behavioral approaches, including positive reinforcers, pacifiers, and tranquilization strategies, should be used and how the psychiatrist can be contacted when his or her expertise is urgently needed.

## Personality Disorders

Violence associated with personality disorders is usually embedded in the individual's behavioral repertoire. Personality disorders that frequently manifest violent behavior are shown in Table 8–2; of these, antisocial personality is the most likely to be associated with habitual aggression. Antisocial individuals usually are thrill-seeking, have low frustration tolerance, and have high rates of substance abuse, criminal behavior, and violence. They often present to the emergency department with injuries resulting from violence (such as stab and gunshot wounds) and with a variety of medical complications of substance abuse (including severe intoxications, wound infections, head injuries, and hepatitis); they often require admission to the medical or surgical ward for treatment of these conditions. Antisocial patients who are intoxicated can become very dangerous because of their mood instability, lowered frustration tolerance, and behavioral disinhibition. While in the hospital, they may become aggressive when their demands—for pain medication, more food, cigarettes, and so on—are not met. In making these demands, they may verbally threaten, intimidate staff with boasts and gestures, or become violent.

Many antisocial patients are repeatedly hospitalized for treatment of problems arising from their lifestyle, especially the medical complications of addictions and risk-taking behaviors. This often arouses resentment and animosity from physicians and nurses, who may believe that their efforts to care for the patient are unwanted and futile. Health care professionals may be provoked into angry verbal (and, rarely, physical) retaliation. Such patients have earned notoriety from their behavior during earlier hospitalizations, which may put them at risk for punitive interventions such as suboptimal care, inadequate pain treatment, and premature discharge. Staff may understandably prefer to focus care on patients who are seen as cooperative, appreciative, and “innocent victims” of disease. This puts the aggressive antisocial patient at higher risk for missed diagnoses and medical errors. Thus, psy-

chiatrists involved in caring for such patients need to know their reputation on the unit and the feelings of the physicians and nurses caring for them. This information is valuable for formulating a plan of care that ensures adequate evaluation and treatment for the patient and appropriate safeguards for the staff. One of the psychiatrist's responsibilities with such patients is to help physicians, nurses, and other staff appropriately handle their anger and frustration, avoiding both overreaction (e.g., yelling at patients, inappropriate precipitous discharge) and underreaction (e.g., failing to set limits, failing to discharge when indicated). Antisocial patients are not immune to other conditions that may explain aggression, including delirium, substance withdrawal, and psychosis. Therefore, psychiatrists should pursue a systematic psychiatric and general medical assessment whenever antisocial patients are encountered in nonpsychiatric settings.

Borderline personality is characterized by intense emotionality, intense relationships, rejection sensitivity, manipulative behaviors, impulsiveness, recklessness, low self-regard, irritability, aggressiveness, and a tendency to extreme reactions. Most patients with borderline personality disorder are women. Their violent acts usually are impulsive and typically occur during interpersonal conflict. They also have a high potential for self-injury and suicidal acts and thus are often seen in the emergency department. Borderline patients can be very difficult to manage because they may demand specific conditions or individuals before submitting to an interview or examination. They are capable of angrily refusing care or of violent temper tantrums. Thus, a major challenge in their care is maintaining limits on behavior and managing the intense negative countertransference feelings that they may stir up. In caring for them, psychiatrists must maintain an empathic stance and assist the staff in doing so, often despite deliberate provocation.

Individuals with borderline personality seen in the emergency department should be screened for depression, substance abuse, and domestic violence because these conditions are highly comorbid. On medical units, borderline patients can become disruptive when their expectations are not met. Psychiatrists should educate their physicians and nurses about the need to define behavior limits, meet expectations agreed on with the patient, and maintain a consistent approach to the patient's care. This is best accomplished in an interdisciplinary care conference, with the psychiatrist assisting the staff in constructing a written treatment contract to be negotiated with, and signed by, the patient.

Other personality disorders are less frequently associated with violent behavior, although narcissistic individuals may threaten or act (e.g., slap a nurse) in retaliation for

perceived slights or to satiate their sense of entitlement, and individuals with paranoid personality may become aggressive in response to perceived mistreatment.

### Intermittent Explosive Disorder, Episodic Dyscontrol Syndrome, and Hypothalamic–Limbic Rage Syndrome

Intermittent explosive disorder, episodic dyscontrol syndrome, and hypothalamic–limbic rage syndrome describe disturbances that are characterized by explosive episodes of aggression and violence. *Intermittent explosive disorder*, as defined by DSM-IV (American Psychiatric Association 1994a) and its text revision, DSM-IV-TR (American Psychiatric Association 2000), refers to a disturbance characterized by recurrent episodes of explosive anger not explained by psychosis or some other mental disorder. *Episodic dyscontrol* is a similar construct, denoting recurring episodes of uncontrollable rage. It has been used as a label for males who have a history of conduct disorder, unstable employment, poverty, domestic violence and other sexual assaults, criminal behavior, and substance abuse (typically alcohol) (Cummings and Mega 2003). Neurological signs such as short attention span, poor coordination, and mild gait abnormalities have been found in some cases, and temporal lobe EEG abnormalities have been found in others. Whereas intermittent explosive disorder denotes a relatively narrow clinical spectrum of explosive aggression, episodic dyscontrol refers to episodic, impulsive violence in a broad, ill-defined group of mostly antisocial individuals. Because episodic dyscontrol syndrome overlaps widely with several psychiatric categories (including intermittent explosive disorder, ADHD, conduct disorder, and antisocial personality disorder), it lacks face validity and is of limited clinical usefulness.

Although rare, rage attacks in association with neoplastic and surgical lesions of the hypothalamus and amygdala have been described (Demaree and Harrison 1996; Tonkonogy and Geller 1992). These attacks, which have been repeatedly reproduced in experimental animals with lesion models and neurophysiological methods, have been termed *hypothalamic rage attacks* or *hypothalamic–limbic rage syndrome*. This disorder is characterized by provoked and unprovoked episodes of uncontrollable rage and may represent an acquired form of intermittent explosive disorder. In addition to rage attacks, patients may have symptoms such as hyperphagia, polydipsia, excessive weight gain, or obesity; clinical findings suggesting thyroid, adrenal, or pituitary disease; a history of recently diagnosed pituitary, midbrain, or temporal lobe tumor; or recent brain surgery. Treatment involves correction of the under-

lying condition (including surgical resection of tumors) and behavioral and pharmacological approaches targeted at aggression.

### Substance Use Disorders

Alcohol is the psychoactive substance most often associated with violence. Alcohol-related violence may result from a severely intoxicated state that produces gross impairment of self-restraint and judgment and/or a blackout. Pathological intoxication, which occurs in vulnerable individuals following the ingestion of only modest amounts of alcohol, may be associated with disorganized behavior, emotional lability, and violent outbursts. In severe cases, pathological intoxication may be accompanied by a delirium with hyperarousal, hallucinations, delusions, and terror, followed by amnesia for the event after recovery. Alcohol withdrawal also can be accompanied by irritability and low frustration tolerance, which predispose to directed aggression, or by seizures that are followed by aggression during a postictal state. Patients who develop delirium tremens may show poorly coordinated, resistive, or pre-emptive violence in response to hyperarousal, hallucinations, and terror.

Intoxication with other substances also can result in violence. Cocaine and amphetamine abuse is common and can produce impulsive, disinhibited intoxicated states during which violence may occur. Patients undergoing opioid, sedative, or cocaine withdrawal may experience anxious tension and irritability, during which interpersonal conflict or frustration may result in violent behavior. Although phencyclidine is not commonly abused, phencyclidine intoxication can manifest with severe impulsively directed violence. Even less common is violence that occurs in individuals who have taken Ecstasy, lysergic acid diethylamide (LSD), or other hallucinogens; as an apparent consequence of severe perceptual disturbances; and in patients who abuse anticholinergic agents, in whom delirium may be accompanied by aggressive behavior.

### Epilepsy

In evaluating episodes of aggression in patients with epilepsy (see also Chapter 32, “Neurology and Neurosurgery”), psychosomatic medicine psychiatrists must carefully consider whether the aggression is directly related to a seizure, a feature of mental state changes associated with seizures, or a complication of other conditions that increase the risk of aggressive behavior. In addition, psychiatrists must be aware that certain seizures can be misinterpreted as intentional violent behavior. Violent behavior

may be observed during complex partial seizures but never during grand mal seizures.

Ictal violence is rare, and most cases are characterized by spontaneous, nondirected, stereotyped aggressive behaviors. Typical characteristics are as follows: 1) the seizure episode occurs suddenly, without provocation, and is of very short duration (usually a few minutes); 2) automatisms and other stereotypic phenomena of the patient's habitual seizures accompany the aggressive act, and the act is associated with these phenomena from one seizure to the next; 3) the patient's consciousness is impaired; 4) the aggressive behavior is poorly directed and involves few skills; and 5) purpose and interpersonal interaction are absent (Marsh and Krauss 2000). In practice, it can be difficult to determine whether a violent behavior should be attributed to a seizure event. This determination requires the integration of findings from interview, clinical history, and video EEG monitoring to make the diagnosis. Abnormal nonseizure EEG phenomena (such as sharp waves) are nonspecific findings and should not be used as evidence that violence is ictal. Widely applicable criteria for attributing a specific violent act to an epileptic seizure have been developed (see Treiman 1986) and are presented in Table 8-3.

Although uncommon, a prodromal state of affective instability preceding a seizure episode by several hours or days may be associated with directed aggression (Marsh and Krauss 2000). The affective symptoms may be specific to the preictal state or an exacerbation of interictal phenomena; these states and their aggressive features usually resolve after the seizure.

Violent behavior in epilepsy is most frequent during postictal confusional states. These states are usually brief but can vary widely in duration because they are influenced by the type and severity of the preceding seizures. Abnormal moods, paranoia, hallucinations, and delirium may occur and result in violence by heightening aggressive propensities or causing misinterpretations of stimuli in the immediate environment. In general, episodes of postictal violence are longer in duration than episodes of ictal violence, are associated with amnesia for the event, and are out of character for the individual. In some males, stereotypic episodes of severe postictal aggression can occur after clusters of seizures (Gerard et al. 1998). Postictal delirium can be detected clinically by assessing the patient's level of consciousness and awareness and performing an EEG—which shows diffuse slowing (and no ictal activity). Typically, the delirium is brief, and a gradual return to normal consciousness follows, but prolonged or repetitive seizures can extend the duration. Violence occurring during postictal delirium is usually relatively undirected; resistive violence is fairly frequent, usually oc-

curing when attempts are made to help or restrain a patient after the seizure.

Many episodes of postictal violence are motivated by a postictal psychosis. The psychosis may emerge from postictal confusion or a lucid state and tends to follow a psychosis-free interval of several hours to a few days after a seizure (or cluster of complex partial seizures) (Marsh and Krauss 2000). Postictal psychosis usually manifests as grandiose affective psychoses (mania or depression with mood-congruent psychotic phenomena) or with thought disorder, hallucinations, and paranoid ideational psychoses reminiscent of schizophrenia. Although usually transient (of no longer than several hours' duration), these states may last up to several weeks. Postictal psychosis has a tendency to recur and may become chronic. Violence in the context of postictal psychosis may be motivated by paranoid delusions and hallucinations, in which case it manifests as well-directed violence. In fact, violence is more likely to occur in individuals with postictal psychosis, compared with those with interictal psychosis or postictal confusion (Kanemoto et al. 1999). Most episodes of postictal psychosis resolve spontaneously or following treatment with low doses of a neuroleptic, and improved control of the epilepsy then becomes the focus of treatment. However, some patients require chronic maintenance treatment with neuroleptics (see also Chapter 11, "Mania, Catatonia, and Psychosis," and Chapter 32, "Neurology and Neurosurgery").

Most violent behaviors in patients with epilepsy have no particular association with ictal or postictal states. For example, studies that report higher prevalence rates of epilepsy in prisoners than in nonprisoners rarely identify connections between criminal acts and specific seizure episodes, and prevalence rates for epilepsy are not higher in violent criminals than in nonviolent criminals (Treiman 1986). Thus, the increased risk for violence in prisoners who have epilepsy can be attributed to other factors

such as cognitive dysfunction and adverse social circumstances (Treiman 1986). The assessment of violence in patients with epilepsy should therefore also elicit a contextualized description (*setting-sequence-outcome*) of the act and other biological and psychosocial factors that may mediate the expression of aggression. These forms of aggression are well directed and are associated with stressors and triggers. They typically occur around other people and are purposeful, nonstereotyped, and highly coordinated. The aggression is “explained” by the situation at hand, is associated with the buildup of negative emotions concerning some circumstance, and may be of relatively prolonged duration.

Brain injury and cognitive impairment are important risk factors for interictal aggressive behavior. In addition, interictal psychiatric phenomena, such as depression, hallucinations, and delusions, and sociopathic personality traits, such as impulsivity, remorselessness, self-absorption, and superficiality, also predispose patients with epilepsy to aggressive behavior. Furthermore, violence can be learned behavior in patients whose educational and social disadvantages are a correlate or result of their epilepsy.

## Delirium

States of heightened arousal often accompany the confusion and fluctuating alertness of delirium and may predispose patients to violent behavior. The presence of hallucinations and delusions also increases the potential for violence in patients with delirium, as it does in patients with epilepsy. The presence of delirium in an aggressive patient should prompt a thorough search for an underlying cause. When ambiguity exists about the presence of delirium, the diagnosis can be established by variable scores on the Mini-Mental State Examination (or other short cognitive battery) in a relatively short period (several hours) or by slowed cerebral activity on the EEG. A more detailed discussion of delirium is presented in Chapter 6, “Delirium.”

## Executive Dysfunction Syndromes

Executive dysfunction syndromes, more commonly called *frontal lobe syndromes*, are manifestations of brain injury characterized by varying combinations of inattention, impulsivity, disinhibition, emotional dysregulation, absence of insight, impairment of judgment, and diminished initiative (Lyketsos et al. 2004). These frontal-subcortical syndromes result from a range of etiologies, including trauma, infection, neoplasm, stroke, and neurodegenerative disease. Explosive violence is often a feature, particularly in patients in whom impulsivity, disinhibition, or

ffective dysregulation predominates. In many individuals with habitual impulsive violence, formal neuropsychological testing indicates deficits in executive cognition (see section “Mechanisms of Aggression” earlier in this chapter); these individuals may be viewed as having occult executive dysfunction syndromes. Further discussion of these syndromes is presented in Chapter 35, “Physical Medicine and Rehabilitation.”

## Dementia

Aggression is common in patients with dementia, with the risk increasing with dementia severity, concurrent medical illness, crowding, noise, poor quality of interpersonal relationships, and sleep disorder (Lyketsos 2000). The presence of motor restlessness, depression, hallucinations, misinterpretations, paranoia, or delusions in patients with dementia also should alert the clinician to the risk for aggressive behavior. Type of dementia appears to have limited influence on the likelihood of aggression, even though patients with vascular dementia and Huntington’s disease may be less cognitively impaired than their counterparts with other forms of dementia.

In elders with dementia, aggression generally manifests as relatively simple behaviors such as throwing objects, pushing, shoving, kicking, pinching, biting, and scratching; destruction of property is uncommon (Cohen-Mansfield and Billig 1986). Sometimes male patients engage in sexually aggressive behaviors, such as grabbing the breasts of women or slapping women on the buttocks (Cohen-Mansfield and Billig 1986). It is unusual for elderly persons with dementia to have well-coordinated and goal-directed physical aggression, but such violence does occur and can be serious, especially when committed by younger patients with dementia.

Aggression in patients with dementia often occurs during routine care activities, such as bathing, morning grooming, and toileting. In these situations, the aggression may result from adversarial interactions with caregivers or from unsophisticated caregiving. Thus, it is important for the physician evaluating violence in the patient with dementia to be cognizant of the circumstances of the act and to search carefully for environmental or caregiver factors that may be triggers for aggression. Careful identification of such “external” factors facilitates their removal or modification (see also Chapter 7, “Dementia”).

## Elder Abuse

Elder mistreatment, in the form of abuse or neglect, also might be a contextual setting for aggression by the mis-

treated elder. Mistreatment begets aggression, but aggressive elders also are more likely to be mistreated by caregivers, whether at home or in an institutional setting. Psychiatrists must be alert to this possibility and screen for mistreatment if an elder presents with an unusual pattern of agitated behavior—for example, if the elder is only aggressive with a particular caregiver or in a particular setting (e.g., while being bathed or dressed) or if he or she presents with physical signs of mistreatment, such as shin bruises or unexplained persistent skin tears. For a comprehensive discussion of elder mistreatment and how to screen for and manage it, the reader is referred to a recent review published by the National Academies of Sciences (2003).

## Domestic Violence

Domestic violence refers to a continuum of behaviors ranging from verbal abuse to threats and intimidation to sexual assault and violence (Golding 2002). The perpetrators do not belong to any particular social class and are often without mental illness, a particular personality type, or a criminal history (Eisenstat and Bancroft 1999). Intimate partners are the usual victims, with more than 90% of the cases involving women being abused by men. Physical intimate partner violence is estimated to occur in 4–6 million relationships in the United States (American Medical Association 1992; Rodriguez et al. 1999). The risk for battery increases (and ongoing battery may worsen) with pregnancy and ill health (Eisenstat and Bancroft 1999; Golding 2002).

Victims of domestic aggression are seen frequently in a variety of ambulatory care settings (Eisenstat and Bancroft 1999): an estimated 25% of women who seek care in the emergency department, 37% of women who are treated for physical injury in the emergency department, 14%–19% of pregnant women (within the past year), 25% of women who are treated for psychiatric symptoms, 25% of those who attempt suicide, and almost 70% of mothers of battered children. Victims of domestic violence experience adverse health outcomes, including risk for serious injury or death, complications of pregnancy and childbirth, sexually transmitted diseases (including human immunodeficiency virus and acquired immunodeficiency syndrome), treatment nonadherence and worse outcomes for existing conditions, somatoform and conversion disorders, eating disorders, substance abuse, anxiety, depression, and suicide (American Medical Association 1992; Coid et al. 2003; Eisenstat and Bancroft 1999). Exposed children sustain emotional injury living in an environment of domestic aggression and may themselves be victims of accidental or intentional violence. Many of these

children will later in life show a wide range of psychopathology and are prone to becoming abusive men and abused women themselves (Eisenstat and Bancroft 1999; Lamberg 2000).

Victims of domestic violence are frequent visitors to clinics and emergency departments, and although some are too afraid to discuss their experiences with a physician, many are willing (Gerbert et al. 1999). Unfortunately, despite this willingness to disclose, most cases remain undetected because few physicians inquire. Several factors account for this lack of inquiry, including inadequate training in the detection and management of domestic violence, physicians' feelings of discomfort and powerlessness, and pressures on physicians to spend less time with patients. Patients' reluctance comes from negative past experiences, fear of retaliation, pessimism, emotional dependency, and low self-confidence.

Vigilant clinicians can recognize patterns suggestive of domestic violence, including repeat visits for vague or minor complaints or chronic pain (especially pelvic), evasive and anxious behavior, inability to recall events, inadequate or baffling explanations for injuries, domineering and obstructionist behavior in a partner, unexplained nonadherence with treatments, and findings of child or elder abuse (Eisenstat and Bancroft 1999). In addition, certain physical findings should raise the possibility of physical abuse: injuries to the head, neck, or mouth; multiple injuries; bruises in various stages of healing; defensive injuries of the forearms; dental trauma; and genital injuries. It is prudent to screen for domestic violence in patients with somatoform, anxiety, and substance abuse disorders and in those with suicidal ideation or attempts.

Routine screening of all women, particularly those seen in emergency departments and in antenatal and gynecology clinics, facilitates early intervention and has been recommended by the American Psychiatric Association (1994b), American Medical Association (1992), and several other professional organizations (American Association of Family Physicians 1994; American College of Emergency Physicians 1995; American College of Obstetrics and Gynecology 1995; Emergency Nurses Association 1998). Women treated for injuries in the emergency department or surgical units and those attending family planning clinics, sexually transmitted disease clinics, and substance abuse programs certainly should be screened for domestic violence. Domestic violence is so common that it is logical to screen all women, regardless of the clinical setting. Mnemonic approaches to screening have been developed and include AVDR (Gerbert et al. 2000):

- Asking about abuse
- Providing Validation and emotional support

- Documenting findings and disclosures
- Referring patients to domestic violence specialists

In Table 8–4, we provide some sample questions that may be used to initiate the screening process. Incorporating screening questions into the routine interview process can minimize physician and patient discomfort.

When ongoing abuse is identified, descriptions of current, recent, and past battery—including dates and circumstances—should be elicited and carefully documented. Legal intervention may rely on this documentation, so all findings should be described in clear and precise language, quoting the specific words spoken by the patient when possible. A complete history and thorough examination should be performed, all injuries should be carefully described (body maps are very useful for this purpose), and photographs should be taken if the patient consents. Strict confidentiality of the disclosure is needed to protect the patient from retaliation; this may require restricted access or sequestration of the disclosure records. On completion of the medical evaluation, a social work evaluation and referral to services such as the National Domestic Violence Hotline (1-800-799-SAFE) and local advocacy organizations should follow (Eisenstat and Bancroft 1999). It is usually best to respect the patient's wishes regarding when to report the violence to legal authorities and when to flee the situation. However, in some states, the physician is required by law to make a report. In the United States, mandatory reporting is the norm whenever evidence of child abuse is found (see also Chapter 3, "Legal Issues").

**TABLE 8–4. Helpful questions for domestic abuse screening by clinicians**

1. Do you and your partner argue a lot? Does it ever get physical? Has either one of you hit the other? Has either one of you injured the other?
2. Do you ever feel unsafe at home?
3. Has anyone hit you or tried to injure you in any way?
4. Has anyone ever threatened you or tried to control you?
5. Have you ever felt afraid of your partner?
6. Is there anything particularly stressful going on now? How are things at home?
7. I see patients in my practice who are being hurt or threatened by someone they love. Is this happening to you? Has this ever happened to you?

## Developmental Disorders

Violent behavior also occurs in patients with neurodevelopmental syndromes such as mental retardation. Few patients with mental retardation are habitually or impulsively aggressive. However, because many patients with mental retardation also have severe communication or language deficiencies, they may be prone to temper tantrums and violence when frustrated or in discomfort (e.g., from pain). They are also at increased risk for psychiatric symptoms, such as irritability, impulsivity, disinhibition, and low frustration tolerance, and affective and psychotic conditions, which may occasionally contribute to aggressive behavior.

## Management of Aggressive Behavior

### Education and Relationship Building

Ideally, the management of aggression in the general hospital setting begins well before a particular patient is seen. These early interventions are part of the liaison role of the psychiatrist and consist primarily of education and relationship-building activities. For example, the psychiatrist may give grand rounds and topical seminars or may seize opportunities provided by collaboration in the care of specific patients to conduct bedside teaching with medical colleagues, nurses, nurse's aides, and other health care professionals. The psychiatrist's goal is to convey basic clinical information about psychiatric disturbances and practical strategies for the management of difficult or problem patients, including aggressive and violent ones. The psychiatrist's teaching should include recognition of the early signs suggesting later aggression (e.g., restlessness, staring, pacing) and behavioral interventions, including verbal de-escalation techniques (nonthreatening approaches such as speaking calmly, using gentle eye contact, adopting a problem-solving stance, and knowing when to disengage) and when and how to use "show of force," pharmacological tranquilization, and physical restraint. This teaching serves to broaden the skill set of the medical team members and to increase their confidence in their ability to manage these patients, which can result in fewer aggressive incidents, less likelihood of patient or staff injury during episodes, more effective treatment of the underlying conditions, and more effective collaboration in their care.

### Safety of the Environment

The safety of the environment should be ensured before any aggressive patient is evaluated. The psychiatrist should

check that actual weapons, such as guns and knives, and potential weapons, such as scissors, belts, and ropes, have been removed. In the emergency department, this is often accomplished by routinely using hand searches and metal detectors and by keeping any discovered items safely locked away. On inpatient units, monitoring and controlling what the patient can keep, conducting periodic room searches, and providing plastic utensils for meals are common interventions. A safe environment also should allow for the examiner's easy escape, as well as observation and easy entry by other health care personnel. The psychiatrist should use what information is available to anticipate what precautions and emergency interventions may be needed before starting the evaluation and should make sure that the medical team is ready to intervene in the event that the patient becomes severely agitated or violent.

## Psychiatric Evaluation

Effective management of the aggressive patient requires a comprehensive psychiatric evaluation, ultimately leading to the identification of potentially modifiable factors at which interventions are targeted. In many instances, formulation of the case results in the diagnosis of a psychiatric disorder, and specific treatment is instituted with the expectation that remission of the disorder will lead to resolution of the aggression. For example, when an acute psychosis is believed to be responsible for the aggressive behavior of a patient who has schizophrenia, an antipsychotic is prescribed. However, in many patients with aggression, the psychiatric diagnosis only partially explains the behavior and does not indicate what the appropriate treatment strategy should be. This situation is often observed in patients with personality disorder, brain injury, or dementia but is frequently also true for patients with major mental disorders such as schizophrenia. In most such situations, careful characterization of the patient's background and careful description and decoding of the aggressive behavior will inform the approach to treatment.

## Positive Therapeutic Alliance

The first step in the management of the aggressive patient is to develop a positive therapeutic alliance (Beauford et al. 1997). In all cases, and particularly in patients who are chronically aggressive or have recurrent violent episodes, it is crucial to actively seek the patient's collaboration in the treatment process. A positive therapeutic alliance facilitates the patient's compliance with behavioral expectations and with prescribed treatments and makes it easier

to mediate patient–staff conflicts and de-escalate aggressive episodes. Also, a positive alliance facilitates the development of a psychotherapeutic relationship that may enable the psychiatrist to eventually reduce the patient's propensity to violent responses when anticipated precipitants occur in the future (O'Connor 2003).

## Behavioral Approaches

Verbal de-escalation techniques (shown in Table 8–5) are often effective for controlling and terminating mild to moderate aggression (threats and belligerence) and are used frequently in the emergency department, psychiatric ICU, and acute psychiatric ward. These techniques can be used in general medical settings by those who have been taught how to use them. Although verbal de-escalation should be conceptualized as a semistructured intervention (see Table 8–5), in practice, it is often deployed as an instinctive, commonsense reaction to the patient's behavior rather than as a systematic intervention. The basic goal of de-escalation is to manage a patient's anger and hostility by conveying empathy and understanding, personalizing the clinician, helping the patient to articulate grievances and frustrations, and actively involving the patient in problem solving and treatment planning (Stevenson 1991). Verbal de-escalation techniques are most use-

---

**TABLE 8–5. Verbal de-escalation techniques**

---

### Communication

#### Nonverbal

- Maintain a safe distance
- Maintain a neutral posture
- Do not stare; eye contact should convey sincerity
- Do not touch the patient
- Stay at the same height as the patient
- Avoid sudden movements

#### Verbal

- Speak in a calm, clear tone
- Personalize yourself
- Avoid confrontation; offer to solve the problem

### Tactics

#### Debunking

- Acknowledge the patient's grievance
- Acknowledge the patient's frustration
- Shift focus to discussion of how to solve the problem

#### Aligning goals

- Emphasize common ground
- Focus on the big picture
- Find ways to make small concessions

#### Monitoring

- Be acutely aware of progress
  - Know when to disengage
  - Do not insist on having the last word
-

ful in situations that involve patient–staff conflict but also can be used to manage pathological aggression and to set the stage for pharmacological interventions.

More sophisticated behavioral approaches have been successfully applied to the management of chronic aggression, particularly in patients with dementia and brain injury. These approaches include behavioral analysis, operant conditioning, differential reinforcement strategies, validation, manipulation of ambient light and/or sound, activity programs, and environmental modification (Lyketos 2000). Evidence for the use of these approaches derives primarily from uncontrolled studies.

## Seclusion and Restraint

It is not unusual for de-escalation and other behavioral techniques to fail to calm the patient who is very agitated, particularly in the emergency department and other acute care settings. Also, in some settings, de-escalation techniques may be impractical because the patient is unable to communicate meaningfully (as a result of confusion, cognitive impairment, or communication disorders), is known to be explosive, is too severely agitated to cooperate, or is already engaging in violent behavior. In such cases, the use of physical restraint, which may involve *manual restraint* (wherein the patient is restrained by several health care workers) and *mechanical restraint* (wherein an appliance is used to restrain the patient), may be needed to terminate dangerous behavior. Sometimes, physical restraint is needed to administer tranquilizers or to protect other medical interventions (e.g., to keep the patient from pulling out intravenous lines, chest tubes, urinary catheters, or other vital lines or tubes). For a brief period immediately after the application of physical restraints (or the administration of tranquilizers), it is prudent to observe the patient in isolation (in his or her own room or a designated safe room) to ensure that the violent episode, its consequences, and identifiable triggers have been successfully managed. Because improper use of restraints can result in injury to the patient or to health care workers, such use should be directed and implemented only by experienced personnel. Training courses in the use of manual and physical restraints are widely supported, and many jurisdictions have developed certification programs.

During the past decade, the use of seclusion and physical restraints has come under intense criticism. As a result, governmental and judicial regulation of restraint use has steadily increased (see also Chapter 3, “Legal Issues”). In response to these trends, the Academy of Psychosomatic Medicine issued guidelines (Bronheim et al. 1998, p. S20) that state the following:

Constant observation and restraints should be implemented for the shortest possible time with the least restrictive, though effective, means available; these interventions must not be made solely for the convenience of medical staff. Assessment and treatment of underlying psychiatric conditions that contribute to the patient's need for these measures should be expeditiously undertaken.

These guidelines are consistent with those developed by other medical associations, with regulatory standards, and with the general opinion of the courts. In general, the standards for the clinical use of restraints are as follows: 1) restraints should be used only when necessary to protect the patient or others from harm; 2) restraints should not be used solely to coerce the patient to accept treatments or remain in the treatment setting; and 3) when restraints are being used, the patient should be closely monitored and his or her condition frequently reassessed. The clinical and regulatory issues involved in the use of restraints are complex; thus, it is often necessary for psychiatrists to help other medical colleagues explore the various options for managing an aggressive patient and to address any staff discomfort with the use of restraints, while keeping in mind the clinical and legal risks involved in using or forgoing restraints.

## Pharmacological Approaches

Data indicating that neurotransmitter systems modulate aggression have stimulated the development of pharmacological approaches for the clinical management of aggression. This pharmacotherapy for aggression is based more on contemporary intuitions of the neurotransmitter effects of medications and how these effects modulate the expression of aggressive behavior and less on evidence from controlled trials. Medications are particularly indicated for impulsive and pathological forms of aggression. In general, treatment of clinically relevant aggression falls into two broad categories: 1) treatment of *syndromic* aggression separate from the diagnostic context and 2) focused treatment of conditions that manifest *symptomatic* aggression, such as schizophrenia, delusional disorders, major depressive disorders, and delirium. The discussion that follows focuses mainly on the treatment of syndromic aggression; treatments for specific conditions are covered in detail in other chapters of this text.

Pharmacological agents are indicated for both acute and chronic aggression. In the treatment of acute aggression, the goal is typically rapid tranquilization (which refers to the use of medications to achieve a rapid termination of agitated or aggressive behavior). A survey of U.S. psychiatrists who specialize in emergency psychiatry found that benzodiazepines (particularly lorazepam) were the preferred

agents for treating acute aggression (Allen et al. 2001) because they are relatively free of adverse effects that are typically associated with neuroleptics, such as the acute dystonias, akathisia, and parkinsonism. However, neuroleptics, especially haloperidol, also were considered first-line agents, particularly for acute aggression associated with psychosis. One controlled trial found the combination of lorazepam and haloperidol to be superior to lorazepam or haloperidol alone for the treatment of acute agitation in patients with psychosis (Battaglia et al. 1997), suggesting that the combination also may be more effective for acute aggression. Newer neuroleptics—the atypical antipsychotics such as risperidone and olanzapine—are also being increasingly used for the management of acute agitation and aggression (Allen et al. 2001). For rapid tranquilization, drugs that can be given parenterally are advantageous. Lorazepam (intramuscular, intravenous) and haloperidol (intramuscular, intravenous) are typically used for this purpose, but other benzodiazepines (e.g., diazepam) and antipsychotics (e.g., fluphenazine, loxapine) are also available. Parenteral formulations of three atypical neuroleptics—ziprasidone, olanzapine, and risperidone—are now available, although the intramuscular formulation of risperidone is a depot injection.

A wider range of pharmacological agents is used for the treatment of chronic aggression (see Table 8–6). Of these agents, neuroleptics are the most widely used. The relative dearth of evidence from placebo-controlled trials and the phenotypic and neurobiological heterogeneity of aggression may explain the diversity of agents used to treat chronic aggression. It is noteworthy that placebo-controlled trials of treatments for agitation and aggression in elderly patients have yielded placebo responses as high as 60% in some studies, underscoring the importance of rigorous methodology in the evaluation of treatments (Lyketsos 2000). However, despite the limited availability of data from controlled trials, considerable empirical support exists for the use of several psychotropic classes in treating aggression.

Neuroleptics are the preferred agents for treating agitation and aggression in the general medical setting, especially when these phenomena arise in a patient with delirium. Neuroleptics are also used to treat aggression in psychotic patients and to tranquilize patients with severe aggression (regardless of cause). Tranquilization may terminate an episode of aggression, but sometimes it does not reduce the frequency or severity of future episodes of impulsive aggression.

In clinical trials of typical neuroleptics for the treatment of impulsive aggression in patients with personality disorders, results have been mixed; however, the atypical agents (which selectively block 5-HT<sub>2</sub> receptors—an ac-

tion associated with reduced aggression in animals) may be more effective in treating chronic impulsive aggression (Coccaro and Siever 2002). Consistent with this, studies have found that clozapine (across a wide range of measures) and perhaps risperidone have superior efficacy for treating aggression in patients with schizophrenia (Buckley et al. 1995, 1997; Czobor et al. 1995; Rabinowitz et al. 1996; Ratey et al. 1993). In a randomized comparative study, clozapine was the most efficacious agent (independent of effectiveness in relieving psychosis); olanzapine, risperidone, and haloperidol were equally effective in treating aggression (Citrome et al. 2001). Although these results would seem to recommend clozapine as a first choice for treating aggression in psychotic patients, in practice, the drug is typically reserved for severe or treatment-resistant cases because of its adverse-effect profile.

Neuroleptics are also used to treat aggression in patients with brain diseases. In multicenter trials enrolling patients with dementia, risperidone and olanzapine were found to be superior to haloperidol for the treatment of aggression (Lyketsos 2000). Haloperidol was superior to placebo in those studies.

Data showing that experimental and pharmacological modulation of serotonin neurotransmission can reduce levels of aggression in nonhuman primates and smaller animals (Walsh and Dinan 2001), and other results showing low CSF levels of serotonin metabolites in impulsively aggressive patients, violent offenders, and suicide attempters (discussed earlier, in the section “Mechanisms of Aggression”), constitute compelling reasons to treat impulsive aggression with selective serotonin reuptake inhibitors (SSRIs), lithium, buspirone, and other drugs that may enhance central serotonin levels. In addition, SSRIs, lithium, and buspirone have been effective, in placebo-controlled trials, in reducing impulsive nonviolent aggression in patients with personality disorders, autism, and depressive disorders (Coccaro and Siever 2002).

Anticonvulsants also have received systematic evaluation for treating aggressive behavior. Divalproex sodium has been evaluated in several open studies. A review of available data concluded that aggression is responsive to divalproex sodium (Lindenmayer and Kotsaftis 2000). However, this review found no blinded, placebo-controlled trials, only three open-label studies, and all other data came from anecdotal reports. In blinded, placebo-controlled trials, carbamazepine reduced aggression in nursing home patients with dementia (Tariot et al. 1998) and in patients with personality disorder (Cowdry and Gardner 1988; Gardner and Cowdry 1986). Phenytoin also may be useful for the treatment of aggression because limited data from controlled trials suggest that some cases of impulsive aggression may respond to the medication (Barratt et

**TABLE 8-6. Medications used in the treatment of chronic aggression**

Medication	Starting dosage	Usual target dosage
<b>SSRIs</b>		
Sertraline	25 mg/day	150–200 mg/day
Fluoxetine	10 mg/day	60–80 mg/day
Paroxetine	10 mg/day (or bedtime)	20–60 mg/day
Citalopram	10 mg/day	20–40 mg/day
<b>TCAs</b>		
Nortriptyline	10–25 mg at bedtime	Serum level: 50–150 ng/dL
Clomipramine	25 mg at bedtime	Serum level: 150–200 ng/dL
<b>SNRIs</b>		
Venlafaxine XR	37.5 mg/day (or twice daily)	225–300 mg/day
Trazodone	25–50 mg at bedtime	300–500 mg/day
Nefazodone	50 mg at bedtime	500–600 mg/day
Mirtazapine	7.5–15.0 mg at bedtime	15–45 mg/day
<b>Neuroleptics</b>		
Haloperidol	2.5 mg/day (or twice daily)	15–20 mg/day
Fluphenazine	2.5 mg/day (or twice daily)	15–20 mg/day
Loxapine	5–10 mg twice daily	50 mg/day
Thioridazine	50 mg/day	200 mg/day
Risperidone	0.5–1.0 mg/day	4–8 mg/day
Olanzapine	2.5–5.0 mg at bedtime	10–20 mg/day
Clozapine	12.5–25.0 mg/day	150–300 mg/day
Quetiapine	25 mg twice daily	100–250 mg/day
<b>Anticonvulsants</b>		
Divalproex sodium	250 mg twice daily	Serum level: 50–100 ng/dL
Carbamazepine	100 mg twice daily	Serum level: 4–12 ng/dL
Gabapentin	300 mg twice daily	1,800–2,400 mg/day
Phenytoin	100 mg twice daily	300 mg/day
<b>Others</b>		
Lithium	300 mg/day	Serum level: 0.6–1.2 mEq/dL
Bupirone	5.0–7.5 mg twice daily	20–30 mg/day
Propranolol	20–40 mg twice daily	80–160 mg/day
Amantadine	50–100 mg twice daily	200–300 mg/day
Progesterone	10 mg/day	20 mg/day
Leuprolide	2.5–5.0 mg intramuscularly every 2 weeks	10 mg intramuscularly every 2 weeks

*Note.* SNRIs=serotonin-norepinephrine reuptake inhibitors; SSRIs=selective serotonin reuptake inhibitors; TCAs=tricyclic antidepressants. Initial and target doses are up to 50% lower when the patient is an elder, is mentally retarded, is taking many medications, has a severe systemic or metabolic illness, or has a dementia.

al. 1997). However, psychiatric experience with phenytoin is very limited. On the contrary, gabapentin is frequently prescribed for impulsive aggression, but no empirical evidence yet supports this practice.

Because overactivity in the noradrenergic system has been implicated in expression of aggression, noradrenergic blockade has emerged as another therapeutic strategy. The typically used agents are propranolol and nadolol, both beta-adrenergic blockers. Clinical trials have found them to be effective in patients with traumatic brain injury, dementia, and psychosis (Allan et al. 1996; Ratey et al. 1992; Shankle et al. 1995; Sorgi et al. 1986). Beta-

blockers may cause hypotension and bradycardia and therefore should be used with caution. In fact, low-dose treatment may be effective for certain patients; one study found that low-dose propranolol (10–80 mg/day) reduced aggression in patients with dementia (Shankle et al. 1995).

Table 8-6 provides a summary of other medications that may be helpful for treating aggression. Progesterone and leuprolide are used for some patients with aggressive sexual behavior (see Chapter 17, “Sexual Disorders”). In routine practice, psychiatrists often use combinations of medications from different classes because the response to single-agent therapy is usually modest.

## Conclusion

---

Aggression is a major clinical and public health problem. In clinical settings, it represents a difficult, disruptive, and dangerous problem for psychiatrists, nonpsychiatric physicians, nurses, and other health care workers. Fortunately, strategies exist to manage this problem. A careful description of the aggressive episode, in the context of a comprehensive psychiatric examination, informs clinical management. Out of the clinical examination comes an appreciation of the fundamental nature of the problem (for instance, whether the aggression is impulsive or premeditated), the factors that have produced and/or sustained it, and the approaches to treatment.

The treatment of aggression requires awareness that psychiatric diagnosis alone is often not enough to inform the treatment—and, therefore, an individualized approach. For most patients, aggression is managed empirically with a combination of approaches—behavioral, environmental, and pharmacological. In the general hospital, the management of aggressive patients involves active collaboration among psychiatrists, nonpsychiatric physicians, nurses, and other health care workers. This collaboration works best when the ground has been prepared beforehand through the teaching efforts of the psychiatrist and will maximize the effectiveness of interventions while minimizing the risk of injury to patients and medical staff.

Finally, it is also important to keep in mind that many aggressive patients, particularly those with impulsive aggression, are also at risk for suicidal behavior and require a careful suicide risk assessment and appropriate interventions. Recent research has yielded much insight into the neurobiology of aggression and violence, but more work is needed to develop predictive methods and more effective preventive and treatment modalities.

# 9 Depression

---

Gary M. Rodin, M.D., F.R.C.P.C.

Robert P. Nolan, Ph.D., R.Psych.

Mark R. Katz, M.D., F.R.C.P.C.

**MEDICAL AND DEPRESSIVE** illnesses are common conditions that frequently coexist in the general population. This association is to be expected both because of coincidence and because the risk of depressive disorders is increased in most medical conditions. This elevated risk is due, in part, to the association of most, or all, serious medical illnesses with a variety of nonspecific risk factors for depression. There also has been much speculation about whether specific biological mechanisms may account for the comorbidity of depression with particular medical conditions.

Depression is frequently undiagnosed and untreated in medical and primary care populations, despite its frequency, negative effect on health, and treatability. Such underdiagnosis may occur for several reasons. One reason is that many of the symptoms of depression are similar to those of medical illness. As a result, it may be problematic to determine whether such symptoms are manifestations of a physical disease or of a comorbid depressive disorder. Furthermore, in the context of a serious medical illness, it can be difficult to differentiate normal, adaptive psychological reactions from dysfunctional psychological states and overt psychiatric illness. For example, distinguishing to what extent passive suicidal ideation in individuals with advanced disease reflects depression and to what extent it reflects the wish to escape from unbearable suffering or from a rational wish to end life may be problematic. False positive diagnoses of depressive disorders also may occur when physical symptoms of medical illness, such as apathy, fatigue, sleep disturbance, and realistic feelings of sadness, are mistakenly attributed to a depressive disorder. Hypoactive delirium associated with apathy and psychomotor retardation also may be mislabeled as depres-

sion. However, it is clearly established that depressive disorders occur with increased frequency in the medically ill, have an adverse effect on quality of life, and increase morbidity and mortality in many medical disorders.

In this chapter, we review the prevalence, clinical features, screening and diagnostic issues, and etiological mechanisms related to depressive disorders in specific medical populations and consider approaches to treatment. In addition, we address some of the potential mechanisms to account for the links between depression and specific medical illnesses affecting the course and outcome.

## **The Continuum of Depression: From Experience to Disorder**

---

The experience of sadness is a normal, expectable response to the multiple adverse effects of a serious medical illness. These effects include changes in bodily appearance and functioning; pain and physical distress; limitations in the capacity to work and to engage in pleasurable activities; a perceived alteration in the anticipated life trajectory; fears of disability and dependency; alterations in intimate relationships, family life, social relationships, and activities; and neurobiological and hormonal abnormalities.

Initial grief reactions and a subsequent mourning process are common following the onset of a serious or terminal illness (reviewed in detail in Chapter 40, "Palliative Care"). Individuals who have difficulty resolving this process and who have other risk factors are more likely to develop major depressive disorder (MDD). Factors that affect the likelihood of a comorbid depressive disorder include the personal coping style of the individual, the

Many medical illnesses have been shown to be associated with an increased risk for MDD. In the Epidemiologic Catchment Area program, the prevalence of affective disorders was 9.4%–12.9% in medically ill patients but only 5.8%–8.4% in a matched control group of healthy individuals (Wells et al. 1988). In another study (Ormel et al. 1993), the decline in functioning secondary to a medical illness was shown to be associated with an increased subsequent risk for the development of major depression. The prevalence of MDD in medical populations varies, to some extent, with the severity of the medical condition. In that regard, the prevalence of MDD has been found to increase progressively from community samples (2%–4%), to primary care settings (5%–10%), to medical inpatient settings (6%–14%) (Burvill 1995). Furthermore, the number of comorbid medical diseases has been shown to be associated with the onset of a depressive episode in both primary care (Barkow et al. 2002) and community samples (Lindeman et al. 2000; Wilhelm et al. 1999). Similar to MDD, minor depressive disorders have been reported in up to 16% of medical outpatients (D.A. Beck and Koenig 1996), a rate several times higher than that in the general population (Burvill 1995). The prevalence of depressive disorders in specific medical conditions is discussed in subsequent sections of this chapter.

## Clinical Features and Diagnosis

---

The four major categories of depressive disorders specified in DSM-IV-TR (American Psychiatric Association 2000) are 1) MDD, 2) dysthymic disorder, 3) adjustment disorder with depressed mood, and 4) mood disorder due to a (specified) general medical condition. The last category refers to mood disorders judged to be the direct physiological consequence of a specific general medical condition. In that regard, medical conditions such as stroke, Parkinson's disease, multiple sclerosis, pancreatic cancer, and diabetes all have been postulated to be a direct cause of depression. However, this category is problematic because the specificity of these relationships is most often difficult or impossible to confirm. A depressed mood in this context has not been shown to be due to the linear effect of any one psychological, biological, or social factor; usually, these interact with one another in the etiology of depression. DSM-IV-TR also delineates the condition of dementia with depressed mood, which is addressed in Chapter 7 ("Dementia") of this text.

The diagnosis of depressive disorders in medical populations is fraught with difficulty for a variety of reasons, including the following:

1. Many symptoms of medical illness (e.g., fatigue, anorexia, weight loss, insomnia, psychomotor retardation, and diminished concentration) resemble those of depression. Following a stroke, a variety of emotional disturbances, such as "emotionalism," pathological crying, apathy, or fatigue, can be mistaken for depression (Bogousslavsky 2003).
2. Thoughts of death and the desire for death may be reported by patients with advanced medical disease in the absence of a depressed mood. A subtle form of suicidality, the desire for hastened death, has been reported by 4% of hospitalized cancer patients (Jones et al. 2003) and by 17% of cancer patients in the last few weeks of life (Breitbart et al. 2000). The desire for hastened death in cancer patients is associated with depressive symptoms but also may be linked to hopelessness and unrelieved pain. Interestingly, with more advanced disease, the desire for hastened death may occur in the absence of self-reported depression (Jones et al. 2003). These findings suggest that loss of the will to live may be a less reliable sign of a depressive disorder in those with advanced medical disease than in nonmedical populations.
3. Physical suffering and disability may diminish the capacity to experience pleasure in many activities, in the absence of comorbid depression. Whereas the loss of interest and pleasure in activities is usually a characteristic symptom of depression, the multiple physical symptoms associated with many serious medical conditions may interfere with pleasure in such activities, independent of a depressed mood. It may not be until pain and other physical symptoms have been adequately treated that the interest, or capacity, to engage in valued activities can resume. A depressed mood or withdrawal from social or physical activities that is disproportionate to physical disability increases the likelihood that depression is present.
4. In medical populations, depressive symptoms may manifest in atypical or masked forms, including the amplification of somatic symptoms and noncompliance with or refusal of medical treatment (Starace et al. 2002). These factors may contribute to both the underdiagnosis and the overdiagnosis of MDD in medical populations.
5. The onset of a serious medical illness may be associated with a profound sense of loss, which may be similar to that observed with bereavement and grief. The boundary between nonpathological grief reactions and clinical depression is frequently difficult to establish, and the 2-week duration of symptoms specified in DSM-IV-TR may be too short to make this distinction. Whether the usual criteria for depression should

apply in this context is unclear, although it has been recommended that when depressive symptoms persist after 2 months, antidepressant treatment should be considered (Whooley and Simon 2000).

Various approaches have been proposed to diminish the effect of confounding medical symptoms in the diagnosis of MDD. DSM-IV-TR suggests an “exclusive” and an “etiological” approach, which specifies that symptoms that are judged by the clinician to be etiologically related to a general medical condition should be excluded from the diagnostic criteria for MDD. An exclusive approach is one in which symptoms are removed from the diagnostic criteria if they are not found to be more frequent in depressed than in nondepressed patients (Bukberg et al. 1984). This approach is intended to avoid attributing symptoms of physical illness to a depressive syndrome. However, the wording in DSM-IV-TR leaves unclear whether this exclusion applies only to the physiological consequences of the medical condition or extends to psychological reactions to the condition (Koenig 1997). In any case, the criteria for determining which symptoms are due to a medical illness and which are due to other factors unrelated to the medical illness are unclear (Rifkin et al. 1985).

Another approach to the diagnosis of MDD in the medically ill is “substitutive” (Endicott 1984). In this approach, symptoms most likely confused with medical illness, such as loss of energy, weight loss, and impaired concentration, are substituted with symptoms that are more likely to be affective in origin, such as irritability, tearfulness, social withdrawal, and feeling punished (Cavanaugh et al. 1983). This substitution eliminates the need to distinguish symptoms of medical illness from those of depression; however, it also excludes some somatic symptoms that are core manifestations of more severe forms of depression. Furthermore, the criteria to determine which symptoms should be substituted are not clearly established, and this approach has not been widely adopted.

Koenig et al. (1997) evaluated the rates of depression in hospitalized elderly medical patients according to six different diagnostic schemes. They found that the prevalence of MDD varied from 10% to 20%, depending on the diagnostic scheme used, and that of minor depression varied from 14% to 25%. However, they concluded that there was no overall single advantage of one diagnostic scheme compared with the others. The exclusive-etiological approach identified the most severe persistent depressions, but an inclusive approach, in which all symptoms are included without making a judgment as to whether they may be related to a comorbid medical disorder, was the most sensitive and reliable approach. In cases that continue to be confusing, a trial of treatment may be in-

dicated to help resolve the uncertainty and to reduce the risk of failing to treat a potentially reversible depressive disorder.

## Health Outcomes

---

It was estimated in the Global Burden of Disease Study (C.J. Murray and Lopez 1997) that MDD was the fourth leading cause of disability in 1990 and that, within two decades, it would be the second leading cause, surpassed only by heart disease. Depressed patients show substantial and long-lasting impairment in multiple domains of functioning (Hays et al. 1995). Depression is also associated with a significant economic burden due, in part, to work-related disability (Druss et al. 2000) and to increased medical costs both in primary care (S.D. Pearson et al. 1999; Simon et al. 1995) and in hospital settings (Druss et al. 1999). After a review of cross-sectional, longitudinal, and treatment studies of patients with and without arthritis, chronic obstructive pulmonary disease, diabetes, or heart disease, Simon (2003) concluded that depression significantly increases the burden of functional impairment in medical illness and that treatment of depression reduces both disability and health service costs.

Medical illness with comorbid MDD is associated with worse medical outcomes and with an increased mortality rate because of several different factors. An increased risk of suicide has been reported in carefully conducted studies of several medical conditions, including cancer (Breitbart and Krivo 1998), multiple sclerosis (Stenager et al. 1996), and Huntington's chorea (Almqvist et al. 1999). In addition to an increased suicide rate (Wulsin 2000), MDD has been associated with increased mortality from other medical disorders (Musselman et al. 1998; Penninx et al. 1998). Mortality in the medically ill has been related to the triad of current MDD, a history of depression, and the severity of the medical illness. The increased mortality rate with MDD persists even when the contribution of factors such as smoking, physical health, and alcohol consumption is controlled (Schulz et al. 2000). Studies of specific medical conditions have found that depression is associated with a more rapid progression of HIV disease (Leserman et al. 1997; Page-Shafer et al. 1996) and with increased mortality in cardiovascular disease (Frasure-Smith et al. 1995; Lesperance et al. 1996; Morris et al. 1993), including poorer 6-month survival rates after myocardial infarction (Frasure-Smith et al. 1993).

Depression may affect health outcomes via several different mechanisms. Biological aspects of depression may increase cardiac mortality through its effects on the autonomic nervous system. Some of these postulated effects

are outlined later in this chapter (see subsection “Depression and Coronary Artery Disease”). Noncompliance with medical treatment also may contribute to the increased morbidity and mortality in depressed medical patients. A meta-analysis (DiMatteo et al. 2000) suggested that the odds are three times greater that depressed patients will be noncompliant with medical treatment recommendations compared with nondepressed patients. Depression also has been associated with poor treatment compliance in patients with end-stage renal disease and patients with HIV disease (Starace et al. 2002) and with more impaired metabolic control in patients with type 1 diabetes (Lustman et al. 2000a). Such noncompliance may include not taking treatments that are prescribed, not following diet or lifestyle recommendations, and not attending medical appointments (Wing et al. 2002).

Depression may be associated with a variety of other health risk behaviors such as cigarette smoking, as well as overeating and physical inactivity, both of which may be associated with obesity. These factors may not only increase the risk of depression but also contribute to poorer health outcomes in those who are depressed. Current depressive symptoms are associated with smoking (Breslau et al. 1993), and smokers who are depressed more often tend to fail smoking cessation programs (Anda et al. 1990). Mechanisms that have been postulated to account for the association of depression and smoking include the hypotheses that smoking is used to self-medicate to prevent or to reduce depressive symptoms and that the propensity to smoke and the tendency to become depressed share a common genetic or emotional basis (Dilsaver et al. 1990; Hughes 1985).

The relationships among depression, overeating, inactivity, and obesity are difficult to unravel, partly because many of the studies of obesity are based on selected samples of those who seek treatment (Stunkard et al. 2003). However, current evidence suggests that a childhood history of obesity is associated with depression in adult life (Pine et al. 2001) and that depression is associated with obesity in women but not in men (Istvan et al. 1992). Both binge-eating disorder (Marcus et al. 1995) and night-eating syndrome (Gluck et al. 2001) have been associated with increased rates of MDD, as has physical inactivity (Paluska and Schwenk 2000).

## Screening for and Detection of Depression in the Medically Ill

---

### Obstacles to Diagnosis in the Clinic Setting

Depression and other forms of distress are often underdiagnosed and undertreated in medical settings (Newport

and Nemeroff 1998; Rodin et al. 1991). This is of concern because missing the diagnosis of MDD, or of a minor depressive disorder, may result in the lost opportunity to improve quality of life, decrease the risk of suicide, shorten hospital stay, and improve treatment compliance in the medically ill (D.A. Beck and Koenig 1996; Hall and Wise 1995; Koenig 1997; Strain 1998).

There are many potential explanations for the poor detection of clinical depression in clinic settings. Most medical visits last less than 15 minutes, and many issues must be addressed in this brief time (Kroenke et al. 1997). Such time constraints and the lack of privacy in the medical setting may limit disclosure or elaboration of symptoms. It is, therefore, not surprising that medical specialists are frequently unaware of which of their patients are emotionally distressed and in need of further evaluation and intervention (Sollner et al. 2001). Some clinicians may fear that they lack sufficient time or skill to manage the emotionality that may be triggered when they inquire about their patients' emotional reaction to the illness experience. Some patients may be reluctant to disclose depressive symptoms because of perceived stigma or perceived lack of interest by their medical caregivers. However, most patients are comfortable discussing psychosocial problems and welcome questions about such issues (Kroenke et al. 1997). Some patients may not recognize depressive symptoms that are present or may attribute such symptoms to the effects of their medical condition. Indeed, both patients and clinicians may have difficulty in differentiating the somatic symptoms of depression from the manifestations of medical disease. In addition, both may normalize or rationalize the depression as an appropriate, understandable reaction to the multiple stresses of medical illness. Unfortunately, the “understandability” of such depressive states may lead to the mistaken belief that treatment is unnecessary or ineffective. Finally, the patient or the clinician may be skeptical about the efficacy and tolerability of antidepressant treatment.

### Screening for Depression: General Considerations

An obvious need exists for accurate and rapid methods of screening for depression in medical settings, where assessment might otherwise not be conducted. A screening program allows for standardization in identifying distress and can facilitate psychosocial resource planning and referral of patients for psychosocial and psychiatric treatment. The ideal screening instrument would be easy to administer and score, acceptable to patients, and, most important, accurate (Zabora 1998). The utility of screening for depression also depends on whether it leads to

timely and effective intervention. Recent critical reviews of depression screening suggest that such efforts have resulted in increased recognition of depression but not necessarily in better management of depression or in improved outcomes (Schade et al. 1998).

## Description of Screening Instruments

The three instruments that have been most widely used to screen for depression in the medically ill are (Bottomley 1998) 1) the Center for Epidemiologic Studies Depression Scale (CES-D) (Radloff 1977), 2) the Hospital Anxiety and Depression Scale (HADS) (Zigmond and Snaith 1983), and 3) the Beck Depression Inventory-II (BDI-II) (A. T. Beck et al. 1996). The Patient Health Questionnaire (PHQ) (Kroenke et al. 2001) is new, and its use is rapidly spreading. A brief discussion of each of these instruments follows.

The CES-D Scale (Radloff 1977) is a 20-item self-report measure of depressive symptoms, in which only 4 of the 20 items are somatic. Originally designed as a measure of depressive distress in nonpsychiatric community samples, it may be the most widely used screening instrument in North America. It also has been extensively used in medically ill samples with evidence of good psychometric properties (Beeber et al. 1998; Devins et al. 1988). A cutoff score of 17 was originally recommended to identify subjects with clinically significant depressive distress (Radloff 1977). However, the sensitivity and specificity of various cutoff scores have been evaluated in a variety of medical populations. Kuptniratsaikul et al. (2002) found that the CES-D was an accurate instrument in screening for depression in spinal cord injury patients. A cutoff score of 21 provided a sensitivity of 80% and a specificity of 70%, with a positive predictive value of 46%. One study in cancer patients found acceptable levels of sensitivity (70%) and specificity (80%) but a low positive predictive value (26%) when a cutoff score of 16 was used (Pasacreta 1997). Another study (Katz et al. 2004) found the CES-D to be accurate in screening for depression in head and neck cancer patients, with a cutoff score of 17 yielding a sensitivity of 100%, a specificity of 85%, and a positive predictive value of 63%. These studies support the value of the CES-D to screen for depression in the medically ill, although the positive predictive value has been relatively low in some studies, and a lack of consensus remains about the optimal cutoff score.

The HADS (Zigmond and Snaith 1983) is a 14-item self-report scale with separate 7-item subscales for anxiety and depression. It was specifically designed for use in the medically ill and has been most widely used in Europe. The Depression subscale places emphasis on anhe-

donia and does not include somatic items; it is brief and highly acceptable to patients (Herrmann 1997) and has been extensively used in the medically ill (Herrmann 1997). The HADS has been shown to have good concurrent and discriminant validity (Bramley et al. 1988; Clark et al. 1998; Flint and Rifat 1996; Snaith and Taylor 1985) and acceptable sensitivity to change (Flint and Rifat 1996). However, it has not been extensively validated as a screening instrument, for which conflicting data exist regarding its accuracy (Herrmann 1997). Some (Berard et al. 1998; Chaturvedi et al. 1996; Kugaya et al. 2000; Razavi et al. 1990) have reported acceptable sensitivity and specificity for the HADS. Katz et al. (2004) found that the HADS was highly accurate in screening for depression in head and neck cancer patients, although their optimal cutoff score was lower than that in other reports in the literature. Others found that the HADS performed very poorly as a screening instrument, with unacceptably low levels of sensitivity, specificity, or positive predictive value (Clarke et al. 1993; Lloyd-Williams et al. 2001; Silverstone 1994). Investigators also disagree about whether the total score (HADS-T) or the depressive subscale (HADS-D) should be used to screen for depression. Although the HADS-D seems more appropriate, according to theory and factor-analytic data (Flint and Rifat 1996; Herrmann 1997), some empirical studies have found that the total score predicts more accurately the presence of MDD or minor depression (Chaturvedi et al. 1996; Razavi et al. 1990).

A lack of consensus exists about the utility of the HADS and about the optimal cutoff scores to screen for MDD and minor depression. Cutoff scores recommended in the literature for the HADS-D have ranged from 7 (Razavi et al. 1990) to 11 (Clarke et al. 1993), with a cutoff score of 8 being the most widely recommended (Berard et al. 1998; Chaturvedi et al. 1996; Silverstone 1994). For the HADS-T, recommended total scores have ranged from 13 (Razavi et al. 1990) to 21 (Clarke et al. 1993), with Chaturvedi et al. (1996) and Kugaya et al. (2000) recommending midrange scores of 16 and 15, respectively.

The BDI-II (A. T. Beck et al. 1996) is the most widely accepted measure of depressive distress. Originally developed for use as a measure of symptom severity in psychiatric patients, this 21-item self-report scale has been used in numerous studies of depression in the medically ill. Concerns have been raised about its validity in patients with medical illness because of the preponderance of somatic items, and about its acceptability to patients because of its forced-choice format and complex response alternatives (Koenig et al. 1992). However, several studies have evaluated the accuracy of the BDI-II as a screening instrument in medically ill samples and found it to be

an accurate self-report measure of depressive symptoms (Berard et al. 1998; Clarke et al. 1993; Craven et al. 1988).

A. T. Beck et al. (1996) recommended a BDI-II cutoff score of 10 when screening for mild depression, 16 for mild to moderate depression, 20 for moderate to severe depression, and 30 for severe depression. Studies in the medically ill have recommended cutoff scores ranging from a low of 10 (Nielsen and Williams 1980) to a high of 16 (Berard et al. 1998), with several recommending scores between 13 and 15 (Clarke et al. 1993; Craven et al. 1988; Meakin 1992). Berard et al. (1998) found in a sample of 100 mixed cancer outpatients that an optimal cutoff score of 16 yielded a sensitivity of 86%, specificity of 95%, and positive predictive value of 82%. Katz et al. (2004) found the BDI-II to be an accurate tool in screening for depression in head and neck cancer patients. The optimal cutoff score in this sample was 13, which corresponds to the midlevel cutoff score recommended in the literature. This score yielded a sensitivity of 92%, a specificity of 90%, and a positive predictive value of 69%. As with the CES-D Scale and the HADS, the preponderance of evidence suggests that the BDI-II can be used effectively to screen for depression in the medically ill.

The PHQ-9 is the nine-item depression module of the PHQ, a self-administered version of the PRIME-MD diagnostic instrument for common mental disorders that is specifically designed for primary care settings (Kroenke et al. 2001). The PHQ as a whole has been studied in thousands of primary care and medical specialty outpatients in the United States, Europe, and China. A Spanish language version has been validated as well (Diez-Quevedo et al. 2001). The PHQ-9 scores each of the nine DSM-IV-TR criteria for major depressive episode from 0 (not at all) to 3 (nearly every day). Assessed against an independent structured interview by a mental health professional, in a sample of 6,000 medical outpatients, a PHQ-9 score of 10 or greater had a sensitivity of 88% and a specificity of 88% for major depression. PHQ-9 scores of 5, 10, 15, and 20 represented mild, moderate, moderately severe, and severe depression, respectively. In a large sample of obstetrics-gynecology patients, the PHQ identified 13% as having mood disorders, 80% of which had been unrecognized by their physicians (Spitzer et al. 2000). The PHQ also yields an index of depressive severity, which also highly correlates with mental health professional assessment (Spitzer et al. 1999).

Any of these instruments may be acceptable to screen for depression in the medically ill, although the evidence for the utility of the HADS is less strong than for the BDI-II and the CES-D Scale. The PHQ has better sensitivity and specificity than the HADS (Lowe et al. 2004). The cutoff score used on any of the measures should de-

pend, to some extent, on the purpose of screening and the resources available for follow-up. If the intent is to avoid missing cases of depression, then less stringent cutoff scores should be used, at the risk of capturing more false positive results. If there is concern about limited resources to follow up on the results of the screening, then more stringent cutoff scores should be used, which will result in fewer false positive results.

## Single-Item and Very Brief Screening Scales

In addition to the use of depression rating scales in the medical setting, some evidence indicates that single-item screening for depression may have some utility. In a study conducted by Chochinov et al. (1997) with terminally ill patients, single-item screening from the Schedule for Affective Disorders and Schizophrenia (SADS) (Endicott and Spitzer 1978) diagnostic interview correctly identified the eventual diagnostic outcome of MDD, minor depression, or no depression. It should be noted that the single item "Are you depressed?" was not administered on its own but as part of a series of the following questions: "How have you been feeling? Describe your mood.... Have you felt depressed (sad, blue, moody, down, empty, as if you didn't care)? Have you cried or been tearful? (How often? Does it come and go?) . . . (How long does it last?) . . . (How bad is the feeling? Can you stand it?) . . . (What about during the last week?)." This approach is not actually single-item screening, but the publication of these findings nevertheless stimulated interest in single-item or very brief screening measures for depression in the medically ill.

C. Watkins et al. (2001) explored the accuracy of a single question assessing depression from the Yale-Brown Obsessive Compulsive Scale (Goodman et al. 1989) and compared it with clinician-derived diagnoses of depression with the Montgomery-Åsberg Rating Scale for Depression (Montgomery and Åsberg 1979). The specific item used was "Do you often feel sad or depressed?" Stroke patients were asked to simply reply "yes" or "no." They found that this single item had a sensitivity of 86%, a specificity of 78%, and a positive predictive value of 82% in screening for depression. In contrast, Lloyd-Williams et al. (2003) found that asking patients in a palliative care unit the single question "Are you depressed?" with a response choice of "yes" or "no" yielded a sensitivity of only 55% and a specificity of 74% for the diagnosis of MDD. Pomeroy et al. (2001) compared very short screening scales for depression with longer, more widely used scales in elderly medical patients, including the 30-item, 15-item, and 4-item Geriatric Depression Scales (Yesavage et al.

1983) and the 1-item Mental Health Index (Berwick et al. 1991). They found that the 4-item Geriatric Depression Scale and 1-item Mental Health Index were as effective as the longer scales in screening for depression in this population.

Kroenke et al. (2002) recently evaluated the two-item version of the PHQ (PHQ-2), which was itself derived from the nine-item PHQ module for depression (Kroenke et al. 2001). The PHQ-2 includes the first two items of the PHQ-9: "Over the last two weeks, how often have you been bothered by...little interest or pleasure in doing things" and "feeling down, depressed or hopeless?" Using an independent, structured, mental health interview for comparison, Kroenke et al. (2002) found that a PHQ-2 score of 3 or greater had a sensitivity of 83% and a specificity of 92% for MDD in a sample of primary care and obstetrics-gynecology clinic patients.

These studies suggest that very brief structured assessments of depression that focus on the core features of depression and/or anhedonia may be useful in the medically ill and that further study to compare these assessments with the longer, more established scales is warranted. Furthermore, it would appear that the major shortcoming in the detection of depression is not in the nature of the instrument used or in the question posed in the clinical setting but rather in the failure to screen for depression using any method.

## Depression in Specific Medical Conditions

---

Depressive symptoms and depressive disorders have been found to occur at increased rates in virtually all medical conditions in which they have been studied. There have been claims and hypotheses that specific biological mechanisms may cause depression in specific medical populations, including patients with stroke, Parkinson's disease, type 1 diabetes, and some types of cancer. However, such specificity has not been substantiated in any of these conditions, although each has multiple nonspecific risk factors associated with it that may increase the prevalence of depression.

There are a variety of reasons for interest in the association of depressive disorders with specific medical diseases. There has been particular concern about depression in individuals with coronary artery disease (CAD) because of its reported association with increased mortality (see also Chapter 19, "Heart Disease"). In other conditions, such as diabetes mellitus or HIV disease, depression has been of particular interest because of the risk that

it will adversely affect treatment adherence. We do not attempt to review depression in all medical conditions; the reader may refer to the chapters on specific medical conditions in this book for more information. We selectively focus on several representative medical disorders that have been more extensively investigated in relation to depression.

## Depression and Coronary Artery Disease

Approximately 27%–35% of patients with CAD present with dysphoric mood, and MDD has been diagnosed in 16%–23% of this population (R.M. Carney et al. 1987; Forrester et al. 1992; Lauzon et al. 2003; Schleifer et al. 1989). Elevated symptoms of depression and MDD are common following the spectrum of CAD events and interventions, including myocardial infarction (MI) (Frasure-Smith et al. 1999), percutaneous transluminal coronary angioplasty (R.M. Carney et al. 1987; Mendes de Leon et al. 1996), coronary artery bypass graft surgery (Connerney et al. 2001), and coronary catheterization (Hance et al. 1996). Depressed mood is also prevalent among patients with congestive heart failure, who represent an older population that is more vulnerable to medical and psychosocial comorbidities (Jiang et al. 2001; Vaccarino et al. 2001).

Depressed mood has been identified as an independent predictor of morbidity and mortality following the onset of CAD (Hemingway and Marmot 1999; Rozanski et al. 1999). A few studies have reported a significantly increased relative risk for coronary events when depressive symptoms that meet DSM-IV-TR criteria for MDD are present (e.g., Lesperance et al. 2002). However, it is also noteworthy that even mild to moderate depression is associated with secondary coronary events (Hemingway and Marmot 1999; Rozanski et al. 1999). The American College of Cardiology regards depression as a secondary risk factor for CAD because of its independent association with CAD but not as a Category I risk factor, which would require evidence that a decrease in symptoms of depression leads to a decrease in morbidity or mortality among patients with CAD (Grundy 1999; T.A. Pearson and Fuster 1996).

The prognostic importance of mild to moderate symptoms of depression raises the possibility that a specific symptom cluster within the MDD profile, rather than the full syndrome, may account for the association between depression and coronary events. For example, vital exhaustion has been observed to predict recurrent coronary events, including MI, following percutaneous transluminal coronary angioplasty (Appels and Mulder 1988; Mendes de Leon et al. 1996). This symptom con-

struct, which overlaps with depression, includes excessive fatigue, low energy, feelings of demoralization, and irritability. It remains to be established whether other depressive symptoms, such as anhedonia, psychomotor retardation, and diminished attention and concentration, are associated with greater disease severity and prolonged disability in CAD patients. Depressive symptoms may increase medical risk because they may adversely affect motivation to initiate and sustain heart-healthy lifestyle changes, such as smoking cessation, modification of diet, and an exercise program.

A subgroup of depressogenic symptoms may trigger a psychophysiological pathway to secondary coronary events by increasing sympathetic tone. CAD patients who are depressed have greater sympathetic and neuroendocrine response to stress, as well as decreased heart rate variability, diminished baroreflex sensitivity, and higher resting heart rate (R.M. Carney et al. 1988; Krantz et al. 2000; Krittayaphong et al. 1997; L.L. Watkins and Grossman 1999). These sympathoexcitatory states lower the threshold for hypertension and progression of the atherosclerotic process (C.B. Eaton et al. 1999) and for clinically significant cardiac events (Dambrink et al. 1994; Huikuri et al. 1999; Lanza et al. 1997; Shusterman et al. 1998; Sroka et al. 1997; Valkama et al. 1995; van den Berg et al. 1997), including sudden cardiac death (Meredith et al. 1991; Wallis et al. 2000).

Two large randomized, controlled trials have assessed the efficacy of antidepressant therapies in reducing morbidity and mortality in a CAD population. The Sertraline Antidepressant Heart Attack Trial (SADHART) assessed the efficacy of sertraline compared with placebo in alleviating depression and reducing recurrent coronary events among 369 patients with CAD whose symptoms met the criteria for MDD (Glassman et al. 2002). Results from SADHART were quite modest, with sertraline failing to significantly enhance left ventricular ejection fraction, ventricular premature complex runs, or other indices of cardiovascular functioning. Fewer severe cardiovascular events were noted in the group that received sertraline rather than placebo, but this reduction did not reach statistical significance. In addition, symptoms of depression were significantly alleviated with sertraline. The Enhancing Recovery in Coronary Heart Disease (ENRICHHD) trial was designed to assess the efficacy of interventions for depression and low social support in decreasing morbidity and mortality following MI (Berkman et al. 2003). In this study, 2,841 patients with MI were randomized to receive cognitive-behavioral therapy (CBT) or usual medical care. Antidepressant pharmacotherapy (i.e., selective serotonin reuptake inhibitors [SSRIs]) was prescribed for patients presenting with severe symptoms of

depression. The ENRICHHD trial failed to significantly lower the prevalence of recurrent MI or mortality over a 4-year interval. However, the intervention group did show a modest but statistically significant improvement in social support and reduced symptoms of depression over the short-term interval of this trial.

## Depression and Cancer

Prevalence rates for MDD in cancer have varied widely in the literature, with reported rates ranging from 1.5% to 50% (Raison and Miller 2003). The reasons for such variability include the heterogeneity of cancer and the higher rates of depression associated with some cancer types (e.g., lung, pancreas, brain, and oropharynx tumors) (McDaniel et al. 1995; Zabora et al. 2001). Pancreatic cancer has been considered to have a specific association with depression (Passik and Roth 1999), but one study suggested that this association may have been overestimated and that depressive symptoms in this context are closely linked to pain (Kelsen et al. 1995). Certain chemotherapeutic treatment modalities for cancer, including the cytokines (e.g., interleukin-2, interferon- $\alpha$ ), corticosteroids (e.g., prednisone, dexamethasone), and *Vinca* alkaloids (e.g., vincristine, vinblastine), are also associated with higher rates of depression (Capuron et al. 2001). It has been suggested that the prevalence rates for depression associated with cancer may be declining as a result of recent improvements in cancer treatments and more frequent provision of psychosocial support for cancer patients (Spiegel and Giese-Davis 2003). However, recent reviews suggest that the overall prevalence rate for MDD and minor depression in cancer patients is still between 10% and 30% (Hotopf et al. 2002). The prevalence rates tend to be higher in cancer patients who have more advanced disease, who are hospitalized, or who have lower performance status (Ciaramella and Poli 2001).

Depression in cancer is associated with many adverse health outcomes. Several recent studies have suggested that depression is an independent predictor of mortality (Herrmann et al. 1998; Loberiza et al. 2002; Stommel et al. 2002; Watson et al. 1999), although others have failed to find such an association (Teno et al. 2000; Tross et al. 1996). Other reported adverse sequelae of depression in cancer patients include decreased compliance with medical treatment, increased length of hospital stays, impaired quality of life, and reduced capacity to cope with pain and other physical symptoms (Massie and Popkin 1998; Pelletier et al. 2002; Pirl and Roth 1999). The emergence of MDD is associated with significantly higher rates of treatment discontinuation in patients with malignant melanoma receiving interferon- $\alpha$  (Musselman et al. 2001) and with

a heightened desire for hastened death in hospitalized cancer patients (Jones et al. 2003) and terminally ill patients (Chochinov et al. 1995, 1999).

As with other medical illnesses, the diagnosis of depression may be difficult to make in the context of cancer. Fatigue and anorexia are almost universal concomitants of advanced cancer, and the side effects of many chemotherapeutic agents and radiation therapy protocols may be difficult to distinguish from depression-related symptoms. This may be the case with cytokine-induced sickness syndrome, a condition resulting from tissue damage secondary to cytokines such as interferon, which are used in cancer treatments (see Raison and Miller 2003). Despite this symptom overlap, an inclusive approach to diagnosing depression in cancer has been recommended (Chochinov et al. 1997).

## Depression and Neurological Disease

The relation between neurological disorders and depression has been of particular interest both because of the frequent comorbidity of these conditions and because of what it might indicate about the neurobiology of depression. High rates of depression have been documented in many neurological illnesses with both cortical and subcortical pathology, including Parkinson's disease, post-stroke syndromes, various forms of dementia, epilepsy, Huntington's disease, and multiple sclerosis (see also Chapter 7, "Dementia"). Understanding the interface between depression and disorders of the central nervous system (CNS) provides a potential opportunity to clarify the neuroanatomic pathways involved in depression. Sheline (2003) recently noted that the sites of damage to brain structures, including the frontal cortex, hippocampus, thalamus, amygdala, and basal ganglia, identified in a variety of neurological disorders overlap with some areas implicated in early-onset recurrent MDD. A specific neuroanatomic circuit, the limbic-cortical-striatal-pallidal-thalamic tract, is now thought to be particularly important in the neurobiological mediation of depression. This tract is intimately involved in emotional regulation and has been associated with structural brain abnormalities, particularly volume loss, in computed tomography (CT) and magnetic resonance imaging (MRI) studies of patients with primary unipolar depression. Mechanisms that have been postulated to account for this volume loss in early-onset recurrent depression include chronic stress-induced hypercortisolemic states of glucocorticoid-mediated neurotoxicity, inhibition of neurogenesis, decreased brain-derived growth factor, and loss of neuroplasticity (Sheline 2003).

## *Parkinson's Disease*

Clinically significant depressive symptoms are thought to occur in approximately 50% of the patients with Parkinson's disease (Dooneief et al. 1992), and, indeed, melancholia was described as a feature of the disorder in the original description by James Parkinson in 1817. Most depressed patients with Parkinson's disease do not have MDD but rather dysthymic disorder, minor depression, and nonpsychiatric states of sadness (McDonald et al. 2003). Such depression may be caused by the psychosocial stress of this progressive incurable disorder, its effect on quality of life, and the implications for future functioning. However, other factors, including neurobiological ones, also may play an etiological role. Neurodegeneration of subcortical nuclei and disturbances in the structure and metabolic activity of the circuit connecting basal ganglia to thalamus and frontal cortex have been correlated with clinical symptoms of depression in patients with Parkinson's disease (McDonald et al. 2003). It also has been postulated that degeneration of dopamine-, serotonin-, and norepinephrine-containing neurons in the ventral tegmental area and in the substantia nigra, which project to mesocortical and mesolimbic and striatal areas, may explain some of the depression seen in these patients (McDonald et al. 2003). Finally, treatment of Parkinson's disease with levodopa and other agents may be associated with mood disturbances (Cummings 1992).

The assessment of depression in patients with Parkinson's disease presents many challenging issues. These include differentiating depressive symptoms, such as psychomotor retardation, affective restriction, fatigue, and disturbances in sleep and concentration, from the core features of Parkinson's disease. The akinesia and restricted facial expression that are characteristic of Parkinson's disease also may lead to the overdiagnosis of depression. Also, the dementia that commonly coexists with Parkinson's disease may be associated with apathy and cognitive impairment, which can be mistaken for depression. However, evidence indicates that screening instruments such as the BDI are useful to assess depression in Parkinson's disease, despite the overlap of somatic items with symptoms of Parkinson's disease (Leentjens et al. 2000).

Depressive disorders in patients with Parkinson's disease are one of the most important reversible factors that affect functioning and quality of life. Depressive disorders in Parkinson's disease have been associated with increased impairment of fine motor performance, cognitive function, and perceived quality of life (McDonald et al. 2003). In a randomized, multisite treatment study, depressive symptoms were the single most important determinant of

patient quality-of-life ratings, exceeding the effects of both disease severity and medication (Global Parkinson's Disease Survey Steering Committee 2002).

### ***Poststroke Depression***

Strokes are the third leading cause of mortality and the most common serious neurological disorder, accounting for 50% of all acute hospitalizations for neurological disease (R.G. Robinson 2003). Pooled data from prevalence studies in the worldwide literature indicate that mean prevalence rates of major depression are 19.3% among hospitalized and 23.3% among ambulatory samples of stroke patients (R.G. Robinson 2003). Depression in these patients affects functional rehabilitation and cognitive functioning in the poststroke period (Herrmann et al. 1998; Kauhanen et al. 1999; Paolucci et al. 1999; Spalletta et al. 2002). Furthermore, poststroke depression may be associated with a heightened risk of mortality 1 year (House et al. 2001) and 10 years (Morris et al. 1993) later, even after medical and other background variables are controlled.

It has been suggested that poststroke depression is associated with lesions in the left anterior and left basal ganglia regions (R.G. Robinson 2003). However, a recent meta-analysis failed to show any association between poststroke depression and left anterior or left hemisphere lesions (Carson et al. 2000). Bogousslavsky (2003) suggested that poststroke depression in the chronic phase tends to be associated with lesions in the subcortical white matter, thalamus, and basal ganglia and brain stem. In a recent review, Whyte and Mulsant (2002) concluded that the available data support the hypothesis that poststroke depression is multifactorial in origin, which is consistent with the biopsychosocial model of illness (Whyte and Mulsant 2002).

Good evidence now shows that tricyclic antidepressants (TCAs), such as nortriptyline, and serotonin reuptake inhibitors, such as citalopram, are effective in treating poststroke depression (Andersen et al. 1994; R.G. Robinson et al. 2000). Preliminary evidence also suggests that cognitive impairment associated with poststroke depression may be improved by treating the depression (Kimura et al. 2000). Finally, two of three randomized, controlled antidepressant trials (Narushima et al. 2002; Rasmussen et al. 2003) suggested that cardiovascular morbidity and mortality may be reduced in stroke patients who receive antidepressant medication, particularly SSRIs.

### ***Dementing Disorders***

Depression is one of the most common neuropsychiatric, noncognitive symptoms of Alzheimer's dementia (Lee

and Lyketsos 2003). The prevalence of MDD ranges from 20% to 32% in Alzheimer's dementia (Burns et al. 1990; Lyketsos et al. 2002; Migliorelli et al. 1995), with minor depression occurring in an additional 25% (Migliorelli et al. 1995). Symptoms of Alzheimer's dementia, such as emotional lability, may be easily mistaken for depression. Other symptoms, such as apathy, may arise additively from both conditions. Apathy has been found in 27% of Alzheimer's dementia patients and in 56% of Alzheimer's dementia patients with comorbid MDD (Lyketsos et al. 2001). These diagnoses may be even more difficult to distinguish in cognitively impaired patients because of the associated difficulty in communication (Lee and Lyketsos 2003).

The occurrence of late-onset depression and reversible cognitive impairment associated with depression (i.e., pseudodementia) also has been shown to be highly correlated with the eventual diagnosis of Alzheimer's dementia (Alexopoulos et al. 1993). It has been postulated that noradrenergic neuronal loss in the locus coeruleus, and serotonergic cell loss in the dorsal raphe nucleus in Alzheimer's dementia, may contribute to these high rates of reported depression (Forstl et al. 1992). Depression is also thought to be common in other dementing disorders, such as vascular dementia. Subcortical white matter infarcts are thought to be associated with depression in vascular dementia and, to some degree, in Alzheimer's dementia (Alexopoulos et al. 1997).

In Alzheimer's dementia, depression is associated with more adverse outcomes, such as nursing home placement, diminished activities of daily living, more rapid cognitive decline, and increased mortality (Bassuk et al. 1998; Kopetz et al. 2000; Lyketsos et al. 1997). However, the findings regarding the treatment of depression in Alzheimer's dementia have been equivocal. Some studies have found antidepressants to be efficacious in this population, whereas others have reported minimal treatment effects (see Lee and Lyketsos 2003).

### ***Epilepsy***

Depression is the most common psychiatric condition found in patients with epilepsy, with prevalence rates linked to the degree of seizure control. MDD has been found in 20%–55% of those with recurrent seizures but in only 3%–9% of those whose seizures are well controlled (Kanner 2003). The relation between depression and epilepsy appears to be bidirectional. Depression may be caused by the seizure disorder, particularly with complex partial seizures (Kanner 2003). It also has been suggested that monoamine depletion, which may occur with depression, may contribute to seizure activity (Jobe et al.

1999). In support of this interrelationship, a history of depression was found to be 17 times more common in patients with complex partial seizures than in control subjects (Forsgren and Nystrom 1990). This increased rate of depression could be partially caused by the effects of certain antiepileptic drugs, such as phenobarbital. Although antidepressants may lower the seizure threshold, this risk is small and more common with TCAs than with SSRIs or venlafaxine (Kanner 2003). Bupropion, maprotiline, and amoxapine are the most likely antidepressants to trigger seizures and should be avoided in this population (Pisani et al. 2002).

### ***Other Neurological Disorders***

Depressive disorders may occur in up to 50% of patients with multiple sclerosis, typically during acute exacerbations or as part of a chronic progressive course (Minden and Schiffer 1990). Some evidence indicates that depressed patients with multiple sclerosis are more likely to have white matter demyelinating plaques involving the arcuate fasciculus (Pujol et al. 1997). Interferon-beta-1b, used to treat multiple sclerosis, is associated with depression in up to 40% of patients with multiple sclerosis (Mohr et al. 1996).

Huntington's disease is an autosomal dominant disorder affecting the basal ganglia and is characterized by involuntary movements and cognitive impairment. Huntington's disease has been associated with MDD in up to 32% and with bipolar disorder in 9% of patients (Folstein et al. 1983). These and other neurological disorders are discussed more fully in Chapter 7, "Dementia."

## **Depression and Type 1 Diabetes**

Type 1 diabetes mellitus is a chronic medical condition associated with considerable treatment demands, including multiple daily insulin injections, adherence to a diet that is restrictive, and monitoring of serum glucose levels. Individuals with diabetes must live with this illness and with its risks of multiple medical complications, including blindness, renal failure, amputations, neuropathy, and cardiovascular disease. The burden of this disease and its frequent medical comorbidity might be expected to increase the risk for depression. However, it also has been suggested that the neurochemical changes associated with the metabolic impairment in type 1 diabetes mellitus may contribute to mood disturbances via neurobiological mechanisms (Jacobson et al. 2002).

It is well documented that depressive disorders are at least twice as common in those with type 1 or type 2 diabetes mellitus as in the general population (Anderson et al. 2001; W. W. Eaton 2002; Egede et al. 2002). Further-

more, some studies suggest that depression in individuals with diabetes mellitus is characterized by longer episodes (Peyrot and Rubin 1999), higher recurrence rates, and lower recovery rates (Kovacs et al. 1997). Depression in individuals with diabetes mellitus is an important risk factor because it is associated with poorer adherence to the diabetes mellitus dietary and medication regimen and with poorer quality of life (Ciechanowski et al. 2000; Gary et al. 2000; Hanninen et al. 1999).

Some studies have indicated that MDD is associated with poorer glycemic control (Lustman et al. 1986, 1997, 2000a), whereas others have not confirmed the relationship of hyperglycemia to MDD (N. Robinson et al. 1988) or to depressive symptoms (Jacobson et al. 1990; Peyrot and Rubin 1997, 1999). Both biological and psychological mechanisms have been postulated to account for the potential relationship between depression and metabolic control in diabetes mellitus. The relationship between depression and poor compliance with the diabetes treatment regimen may be reciprocal, with depression leading to lower self-efficacy and to self-neglect. Van Tilburg et al. (2001) found that variations in glycemic control in type 1 diabetes mellitus were associated with clinically meaningful differences in depressive symptoms, which appeared to be at least partly mediated through decreased self-care behavior. It also has been postulated that the metabolic abnormalities associated with diabetes mellitus lead to changes in brain structure and function, which then render individuals more susceptible to develop a depressive disorder (Jacobson et al. 1990).

Whatever the mechanism that accounts for the comorbidity of depression and diabetes, this association clearly has serious health implications. Depression has been associated with an increased risk of diabetes-related medical complications, including sexual dysfunction, retinopathy, nephropathy, heart disease, and stroke (de Groot et al. 2001; Kinder et al. 2002). Because of the reciprocal relationship between depression and metabolic control, attention to both mood disturbances and measures to enhance diabetes management is necessary to prevent or delay the progression of such complications.

## **Depression Caused by Medications**

Depression has been reported as an adverse effect of many different drugs (see Table 9-1). In some cases (e.g., anticonvulsants), depression occurs primarily at high serum levels, whereas other drugs (e.g., interferon) may cause depression frequently at normal doses. Some reports in the literature have been uncritical, either misinterpreting drug-induced symptoms as indicative of de-

**TABLE 9–1. Selected drugs reported to cause depression**

---

Angiotensin-converting enzyme inhibitors
Anticonvulsants
Antihypertensives (especially clonidine, methyldopa, thiazides)
Antimicrobials (amphotericin, ethionamide, metronidazole)
Antineoplastic drugs (procarbazine, vincristine, vinblastine, asparaginase)
Beta-blockers
Calcium channel blockers
Corticosteroids
Estrogens
Interferon
Isotretinoin
Metoclopramide
Nonsteroidal anti-inflammatory drugs (especially indomethacin)
Sedative-hypnotics
Statins

---

pression (e.g., weakness, sedation, bradykinesia, fatigue, anorexia, insomnia) or misattributing preexisting depression to the drug. Consequently, controversy surrounds the question of whether some of these drugs do cause depression (e.g., beta-blockers) or how serious a threat is posed (e.g., isotretinoin). Most of these drugs and their psychiatric side effects are discussed in other chapters of this textbook.

## Treatment

---

Both pharmacotherapy and structured forms of psychotherapy have been shown to be effective in the treatment of MDD (Schulberg et al. 1998) and dysthymic disorder or minor depression (Thase 1997; Williams et al. 2000). Some carefully designed studies have shown that the combination of pharmacotherapy and psychotherapy is more effective in the treatment of chronic and more severe forms of depression than either modality alone (Keller 2000; Thase 1997). Psychotherapeutic modalities such as interpersonal therapy (IPT), CBT, and problem-solving interventions also have been shown to be as effective as pharmacotherapy for the treatment of milder depressions (Barrett et al. 2001; Thase 1997). Remission of depressive symptoms in this setting has been associated with improved social and occupational functioning (Ormel et al. 1993; Von Korff et al. 1992). However, despite the evidence for the effectiveness of treatment and for the elevated rates of depression found in medical populations, the rates of treatment for depression are not

higher than those of individuals with depression in the absence of comorbid medical conditions (Koike et al. 2002). In fact, it has been estimated that more than 60% of primary care patients with depression do not receive adequate care for this condition (Kessler et al. 2003).

Most antidepressant treatment studies have been conducted in primary care or psychiatric samples, typically with individuals who do not have a serious medical illness. However, several recent studies have reported that both pharmacological and psychotherapeutic interventions are effective for the treatment of depression associated with medical disorders such as type 1 diabetes mellitus (Lustman et al. 1998), post-MI (Frasure-Smith and Lesperance 2003), chronic obstructive pulmonary disease (Borson et al. 1992), cancer (van Heeringen and Zivkov 1996), and HIV infection and AIDS (Elliot et al. 1998). Evidence to support the effectiveness of psychotherapeutic and psychopharmacological treatment of depression in the medically ill is discussed in the following subsections.

## Psychopharmacological Management of Depression in the Medically Ill

SSRIs, heterocyclic antidepressants and TCAs, novel antidepressants, and psychostimulants have been used in the treatment of depression comorbid with medical illness. A recent meta-analysis of the Cochrane database of treatment outcomes provided evidence that SSRIs, TCAs, and other antidepressants improve depressive symptoms in patients with a wide range of physical illnesses significantly more often than does either placebo or no treatment (Gill and Hatcher 2003). All antidepressants are discussed more fully in Chapter 37 (“Psychopharmacology”); we summarize some key points here.

### SSRIs

SSRIs are generally regarded as first-line treatment in the management of depression in the medically ill because of their tolerability and relative safety. Randomized, controlled trials have shown various SSRIs to be effective in patients with cardiac disease (Glassman et al. 2002; Strik et al. 2000), stroke (Andersen et al. 1994; Wiart et al. 2000), cancer (Holland et al. 1998; Pezzella et al. 2001), HIV infection (Elliot et al. 1998; Rabkin et al. 1999; Zisook et al. 1998), Alzheimer’s disease (Karlsson et al. 2000; Lyketsos et al. 2000), multiple sclerosis (Mohr et al. 2001), and diabetes (Lustman et al. 2000b). Results of open trials indicate that SSRIs may improve depressive symptoms in patients with Parkinson’s disease (Hauser and Zesiewicz 1997; Tesei et al. 2000) and in those with renal failure (Levy et al. 1996).

An innovative study reported by Musselman et al. (2001) showed that paroxetine was very effective in preventing depression in melanoma patients receiving high-dose interferon- $\alpha$  therapy. Subjects were randomized to paroxetine or placebo at the start of their interferon therapy. MDD subsequently developed in 45% of the placebo group but in only 11% of the paroxetine group. This difference significantly affected health outcomes because 35% of the placebo group, compared with only 5% of the paroxetine group, discontinued interferon- $\alpha$  because of severe depressive distress. This study raises important questions about the potential benefit of prophylactic antidepressant treatment in other high-risk populations.

With medically ill patients, SSRIs may provide benefits beyond their antidepressant effect. Some evidence suggests that fluoxetine may improve motor function (Dam et al. 1996) and cognitive performance (González-Torrecillas et al. 1995) in stroke patients and may help improve glycemic control in patients with diabetes mellitus (Lustman et al. 2000b). Paroxetine and citalopram may possess analgesic properties in the treatment of diabetic neuropathy (Sindrup et al. 1990, 1992), and fluoxetine and sertraline may be useful as analgesics for chronic pain syndromes (Breitbart 1992; Hynes et al. 1985). Sertraline also was effective in reducing hot flashes in men requiring hormone replacement therapy for advanced prostate cancer (A.J. Roth and Scher 1998). It also has been shown to reduce hot flash frequency and intensity in women with breast cancer who develop chemical menopause associated with tamoxifen use (Loprinzi et al. 2000b; Stearns et al. 2000). Fluoxetine may ameliorate severe refractory or orthostatic hypotension (Grubb et al. 1994).

SSRIs have been regarded generally as safer and less toxic than TCAs. However, significant side effects still may occur with SSRIs in the medically ill (Jansen Steur 1993; Richard et al. 1999). All SSRIs can cause nausea, headache, sexual dysfunction, and tremor. Other frequent side effects include nervousness, insomnia, sedation, diarrhea, constipation, and dry mouth. Rare but potentially serious side effects of SSRIs include the syndrome of inappropriate antidiuretic hormone secretion and platelet dysfunction leading to bleeding (van Walraven et al. 2001). Some reports indicate that SSRIs may worsen motor symptoms in some patients with Parkinson's disease (Richard et al. 1999).

Drug interactions or the presence of hepatic disease may affect SSRI metabolism and excretion and alter antidepressant pharmacokinetics (Beliles and Stoudemire 1998). A reduced initial dose with slow titration of the shorter half-life SSRIs is recommended for patients with

hepatic disease because the metabolism of SSRIs is decreased by significant hepatic disease (Beliles and Stoudemire 1998; Joffe et al. 1998). Fluvoxamine should be avoided because of its propensity for drug interactions (Beliles and Stoudemire 1998). Sertraline and citalopram appear to present the lowest risk for drug interactions (Beliles and Stoudemire 1998). Drug interactions are reviewed in detail in Chapter 37 ("Psychopharmacology") and in the specialty and subspecialty chapters.

### *Novel Antidepressants*

Novel antidepressants include venlafaxine, bupropion, mirtazapine, nefazodone, and moclobemide. Venlafaxine, bupropion, and mirtazapine have become increasingly popular as alternatives to SSRIs in the medically ill, although a paucity of empirical evidence exists regarding their use in this population. Evidence shows that moclobemide is efficacious in reducing depressive symptoms in patients with Alzheimer's disease (M. Roth et al. 1996). Results of open trials point to the effectiveness of other novel antidepressants in patients with stroke (venlafaxine) (Dahmen et al. 1999), cancer (mirtazapine) (Theobald et al. 2002), and HIV infection (nefazodone) (Elliot et al. 1999).

Extended-release venlafaxine is a serotonin-norepinephrine reuptake inhibitor that is well tolerated, having side effects similar to those of the SSRIs, but it may be associated with increased blood pressure at higher doses. In depressed patients, this dual-action agent may achieve greater remission rates compared with the SSRIs (Smith et al. 2002; Thase et al. 2001). Extended-release venlafaxine has a wide dose range with few drug interactions and is minimally protein bound. A recent randomized, controlled trial showed efficacy in breast cancer patients with hot flashes (Loprinzi et al. 2000a), and it has been found to be useful for neuropathic pain in cancer and in other populations (Davis and Smith 1999; Dwight et al. 1998).

Mirtazapine increases norepinephrine and serotonin concentrations through blockade of inhibitory receptors. Unlike the SSRIs, mirtazapine does not appear to cause nausea, insomnia, anxiety, or sexual dysfunction (De Boer 1996). Mirtazapine, as a result of its serotonin<sub>3</sub> receptor-blocking anti-emetic effects, may be useful in treating medically ill patients who are experiencing nausea. It may rapidly improve insomnia and anorexia, which are commonly seen with depressive disorders in the medically ill. The main side effects of mirtazapine are sedation and weight gain, which may be useful in some cachectic patients (Stimmel et al. 1997). Mirtazapine is also associated with very minimal drug interactions (De Boer 1996).

Bupropion is a norepinephrine and dopamine modulator. It is not sedating, does not cause sexual dysfunction,

and has little cardiotoxicity (Golden et al. 1998). It may be particularly useful in treating patients with prominent fatigue. Side effects may include agitation, insomnia, and seizures at higher doses. Because of this latter concern, it is generally recommended that single doses greater than 150 mg and daily doses greater than 300 mg be avoided in patients with brain tumors and a history of seizures (Golden et al. 1998).

### TCA<sub>s</sub>

TCA<sub>s</sub> have been shown to be efficacious in poststroke depression, cancer, HIV infection, Parkinson's disease, Alzheimer's disease, multiple sclerosis, diabetes, and renal failure (Gill and Hatcher 2003). TCA<sub>s</sub> have proven to be effective as analgesics in the treatment of chronic pain syndromes, including pain related to cancer (reviewed in Magni et al. 1987). With their analgesic and sedating effects, TCA<sub>s</sub> may be particularly useful in depressed patients with significant pain and/or insomnia.

TCA<sub>s</sub> are variably noradrenergic and/or serotonergic. Their side effects are related to their central and peripheral anticholinergic effects, their central antihistaminic properties, and their effects on the cardiac conduction system and the peripheral autonomic nervous system. TCA<sub>s</sub> should be avoided in patients with cardiac disease because they are associated with hypotension and the potential for arrhythmias (Glassman et al. 1993; Jackson et al. 1987). TCA<sub>s</sub> should be used with caution in diabetic patients because their anticholinergic, orthostatic hypotensive, and cardiovascular adverse effects can exacerbate complications of diabetes mellitus (C. Carney 1998). Anticholinergic side effects of TCA<sub>s</sub> may exacerbate cognitive impairment and cause delirium in patients with CNS disorders, especially dementia (Reynolds 1992). TCA<sub>s</sub> that are more anticholinergic generally are not recommended for the treatment of depression in patients with HIV or AIDS because they promote thrush (Rabkin et al. 1994). TCA<sub>s</sub> may not be suitable for patients at increased risk for bone fractures, cancer, or skeletal weakness because orthostatic hypotension may cause falls (Shuster et al. 1992). TCA<sub>s</sub> have been associated with seizures, mainly in overdoses or at high plasma levels (Preskorn and Fast 1992).

Many patients are unable to tolerate tricyclics, and they can be lethal in overdose. For insomnia or pain, lower doses of TCA<sub>s</sub> may be needed than those required for an antidepressant effect (Potter et al. 1998). If a TCA is desired for medically ill patients, the secondary amines such as nortriptyline or desipramine are preferred because they are better tolerated (Potter et al. 1998). Nortriptyline has reliable serum levels and a defined therapeutic window that may guide clinical management, par-

ticularly in patients with liver disease or malabsorption (Potter et al. 1998).

### Psychostimulants

Methylphenidate has been shown to alleviate depressive symptoms in a range of medical conditions, including stroke (Grade et al. 1998), HIV disease (Fernandez et al. 1995), and cancer (Grade et al. 1998). Psychostimulants are generally well tolerated and, in relatively low doses, can elevate mood rapidly, increase appetite, diminish fatigue (Homsí et al. 2001; Masand et al. 1991), serve as adjuvant analgesics (Bruera et al. 1987; Forrest et al. 1977), improve attention and concentration, and reduce sedation caused by opiates or other drugs (Homsí et al. 2001). Many would consider psychostimulants to be the antidepressants of choice in the palliative care setting because of their rapid onset of action (Wilson et al. 2000). Side effects are typically mild and dose-related and include agitation, nausea, and insomnia. Rarely, psychotic symptoms or tachycardia and hypertension may occur (Masand et al. 1991). Methylphenidate is typically given in divided doses (2.5–10 mg) in the morning and afternoon.

### Electroconvulsive Therapy in the Medically Ill

Electroconvulsive therapy (ECT) is sometimes used in the medically ill as an alternative to antidepressants in the treatment of severe or refractory depression (Beale et al. 1997). ECT has been shown to be an effective treatment of depression in Parkinson's disease and also may improve the symptoms of the Parkinson's disease itself (Poewe and Seppi 2001). It has been shown to improve depression following stroke (Currier et al. 1992; G.B. Murray et al. 1986) and in patients with multiple sclerosis, endocrine disorders, and renal failure (Weiner and Coffey 1993). ECT has been associated with improvements in cognition and mood in patients with dementia (Rao and Lyketsos 2000). ECT is considered safe for epilepsy patients with severe or refractory depression (Lambert and Robertson 1999). ECT should be considered early in the course of psychotic depression and depression associated with severe suicidal ideation or failure to maintain adequate nutritional status (Kaplan and Sadock 1998). ECT and its risks are reviewed in detail in Chapter 39 ("Electroconvulsive Therapy").

### Psychotherapeutic Treatment of Depression in the Medically Ill

The relationship with the primary medical caregiver may be the most important psychotherapeutic tool for many patients with a serious medical illness. Patient groups and

self-help and other support groups also may protect the patient from depression by diminishing stigma and promoting self-efficacy and a sense of mastery. A referral for specific psychotherapeutic intervention should take into account the severity of the patient's distress, the available support network, the patient's motivation for psychological assistance, and the patient's capacity to learn new coping strategies and to engage in a process that involves introspection and the expression of feelings.

Psychotherapeutic approaches to treatment of depression in medical populations may include the promotion of active coping strategies and the implementation of specific interventions, including CBT, IPT, and supportive-expressive therapy on an individual or a group basis. The need to refer to a mental health professional will depend on the severity of the depression and on the skill, interest, and availability of primary care practitioners. Many psychosocial interventions have been shown to improve psychological well-being and to reduce depressive symptoms in medically ill patients. Some of the studies in which a specific intervention was targeted toward depressive symptoms or toward the diagnosis of MDD or dysthymic disorder are reviewed here.

Barrett et al. (2001) compared the effectiveness of a problem-solving approach to support active coping strategies with that of paroxetine for the treatment of minor depression or dysthymic disorder in a primary care sample. In this randomized, controlled study, both treatment approaches were equally effective for the treatment of dysthymic disorder but were no more effective than watchful waiting for the treatment of minor depression. Teri et al. (1997) found that patients with Alzheimer's disease and depressive symptoms showed significant improvement in depressive symptoms with a behavioral intervention for patient-caregiver dyads focused on either pleasant events or caregiver problem solving.

Some positive results have been found with CBT or IPT for the treatment of depression in the medically ill. Mohr et al. (2000) found that a telephone-administered cognitive-behavioral intervention to assist patients in coping with cancer was associated with a greater reduction in depressive symptoms compared with usual care. Lustman et al. (1998) showed in patients with type 2 diabetes that an intervention that included CBT and diabetes education produced more than a threefold higher remission rate from depression compared with a control condition. This treatment was associated with a significant improvement in glycosylated hemoglobin 6 months after the end of treatment. A randomized trial of CBT plus group therapy when feasible, together with SSRIs, for cardiac patients who had elevated and/or persistent depressive symptoms resulted in an improvement in the

treatment group that was greater than in the usual care group. However, this intervention did not result in increased rates of cardiac event-free survival in the treatment group (Berkman et al. 2003). Kelley et al. (1993) found that both cognitive-behavioral and support group brief therapies equally reduced depressive symptoms in depressed HIV-infected individuals. Mohr et al. (2001) found that individuals with multiple sclerosis and MDD had a greater reduction in depressive symptoms when CBT or sertraline was used than did those who received supportive-expressive therapy. In contrast, a randomized trial of CBT for depression following stroke failed to find any significant difference between the treatment group and the control group (Lincoln and Flannaghan 2003). Furthermore, in a recent review of 15 trials of at least fair quality in which the effects of interventions such as CBT, relaxation therapy, and education on depressive symptoms in cancer patients were examined, Newell et al. (2002) identified no significant reduction in depressive symptoms following any of the interventions. However, Markowitz et al. (1998) found that depressed HIV-positive patients had greater improvement in depressive symptoms with IPT or supportive psychotherapy plus imipramine than did subjects who received supportive therapy or CBT alone.

These studies of psychotherapeutic interventions to treat depression indicate some degree of effectiveness in a variety of medical populations, although their effectiveness is often improved when combined with antidepressant medication. Numerous other nonspecific psychotherapeutic and educational interventions also may be effective in reducing depressive symptoms and in protecting individuals from their emergence. However, the range of psychosocial interventions designed to improve adjustment in medical populations is beyond the scope of this chapter.

## Conclusion

---

Clinical depression, particularly MDD and dysthymic disorder, is common in the medically ill and is associated with impaired quality of life, decreased compliance with medical treatment, and increased medical morbidity and mortality. The diagnosis of depressive disorders in medical patients is complicated by the frequent overlap between symptoms of depression and those of medical illness. This overlap may contribute to underdiagnosis, when symptoms of depression are assumed to be features of the medical condition, or to overdiagnosis, when symptoms of a medical illness are attributed to a depressed mood. However, the failure to simply inquire about the symptoms of

depression may be the most common reason that the diagnosis of depression is overlooked in a medical population. Screening tests may be useful for drawing the attention of clinicians to these symptoms and identifying patients in medical clinics who are most likely to have depressive disorders.

The increased prevalence of depression in the medically ill is most often the result of multiple nonspecific risk factors, although there has been continued speculation that specific biological mechanisms operate in certain medical conditions.

Psychopharmacological and psychotherapeutic approaches are both effective in the treatment of depressive disorders in the medically ill and can be used together. Medical patients may be more sensitive to the side effects of pharmacological treatments, and careful attention must be paid to the dosage, to the potential for drug interactions, and to impairment in hepatic or renal function, which can affect drug metabolism.

# 10 Suicidality

---

John Michael Bostwick, M.D.

James L. Levenson, M.D.

**ONE OF THE** most common questions posed to any psychiatrist, including psychosomatic medicine specialists, is whether a patient is suicidal. Suicidal ideation, frequent and ubiquitous in medical settings, challenges the psychiatrist to discern what drives the patient's suicidal statement. Compared with suicidal ideation, completed suicide is rare in psychiatric patients and rarer still in medically ill patients.

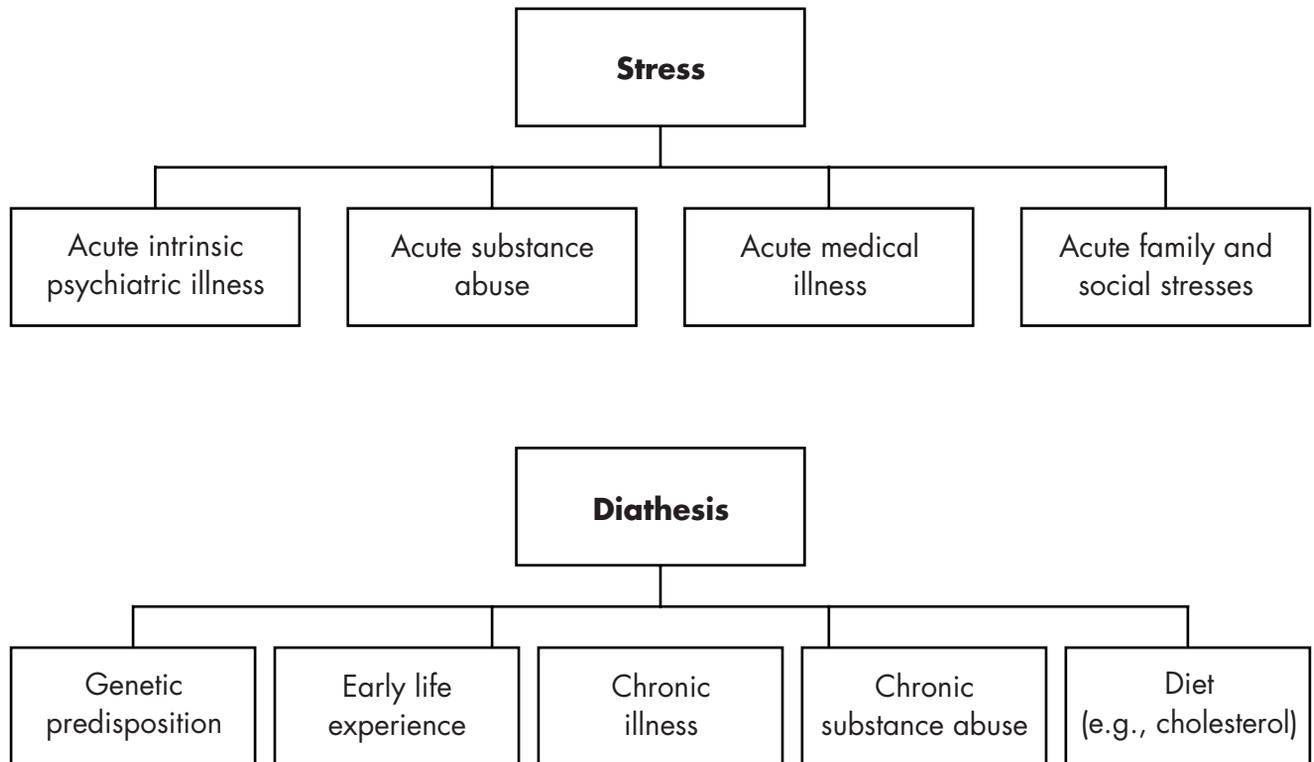

Completed suicides are statistically rare events. Many risk factors are recognized, but none has a high positive predictive value (Mann 1987). As a low-base-rate phenomenon, screening for suicide risk has a high rate of false-positive results. Demographic risk factors alone will identify many more subjects potentially at risk than imminently in danger of dying (Goldberg 1987).

Despite hundreds of studies over decades that made dozens of epidemiological correlations between suicide and particular descriptors, no effective screening paradigm has been identified. This situation is no different with suicidality in medical illness. Many medical illnesses have been associated with increased suicide attempts—for example, in one study, lung disease (odds ratio [OR]=1.8) and peptic ulcer (OR=2.1) (Goodwin et al. 2003). A Canadian study showed elevated ORs for completed suicide in cancer (1.73), prostate disease (1.70), and chronic pulmonary disease (1.86) (Quan et al. 2002). In a Swedish study, visual impairment (OR=7.00), neurological disorders (OR=3.8), and malignancy (OR=3.4) were independently associated with suicide (Waern et al. 2002). Nevertheless, these increased rates are still too low to use the medical diagnosis to predict suicide. Moreover, no epidemiological risk factor represents an individual's suicide intent—the essential, highly personal variable in suicide prediction (Davidson 1993). Fortunately, the field of suicidology has shifted from trying to predict individual suicides

to a more realistic goal of estimating probabilities of risk for particular subpopulations (Hughes and Kleespies 2001). Such data can then be used to inform the psychiatrist's assessment of an individual patient's suicide threat while also considering the personal meaning of the patient's communication.

A focus on probabilities of risk and general categories of psychiatric symptoms rather than individual diagnoses lends itself well to understanding suicidality in the medically ill. Medical illness by itself is rarely a sole determinant of suicide potential. Comorbid factors drive what is best understood as a multidetermined act (Hughes and Kleespies 2001). Shneidman (1989), the father of American suicidology, conceptualized a cubic model of suicidal states, incorporating *perturbation* (the state of being stirred up or upset), *pain* (psychological pain resulting from frustrated psychological needs), and *press* (genetic and developmental susceptibility to particular events). Moscicki (1995) envisioned two distinct but interactive groups of risk factors, with recent events—"proximal risk factors"—unfolding on a substrate of underlying "distal" conditions. According to both models, the assessment of a medically ill person—as with any suicidal person—demands attention to what past characterological, temperamental, or experiential features push someone toward suicide.

In Mann's (1998) diathesis-stress model of suicidal behavior, *stresses* resemble Moscicki's proximal factors, and *diatheses* resemble her distal ones (Figure 10-1). Noting that two groups of patients, each with the same severity of depressive illness, attempt suicide at different rates, Mann proposed suicide diathesis components, including genetic predisposition, early life experience, chronic illness, chronic substance abuse, and certain dietary factors. Extreme stress alone, which Mann defined as acute psychiatric illness, intoxication, medical illness, or family and

**FIGURE 10-1. Diathesis–stress model of suicidal behavior: components of stress and diathesis.**

social stresses, is not typically enough to invoke suicidal behavior. A suicidal individual already has the predisposition, or diathesis, on which the stress is superimposed, resulting in the suicide attempt (Mann 1998).

Mann’s subcategories adapt readily to the medically ill. Acute intrinsic psychiatric illness is represented by dementia, depression, delirium, and anxiety in the context of a general medical illness. Acute substance abuse appears in the form of intoxication or withdrawal syndromes. Acute medical illness includes not only the disease itself but also the effects of treatments. Acute family and social stresses could include fears of becoming a burden, financial consequences such as expense of treatment and lost income, and disruption in the family members’ lives. These state phenomena occur against the background of trait characteristics, which Mann labels as *diathesis*. Diatheses include genetic predisposition to illness, coping styles and personality characteristics (e.g., pain tolerance), and the long-term effects of chronic physical illness or substance abuse.

The Mann model, though comprehensive, does not inform the psychiatrist whether a patient is at immediate risk for suicide. Litman (1989) noted that the 95% prevalence of psychiatric illness among individuals who com-

mit suicide is derived from psychological autopsies and retrospective studies, the scientific equivalent of Monday-morning quarterbacking. At any moment, very few of those who are “at risk” will die by suicide. Identifying the medical patient at high risk is just a first step in evaluation. The search for possible biological markers for suicide has focused on the midbrain dorsal and median raphe nuclei, with their serotonergic inputs to the ventral prefrontal cortex. Responsible for dampening aggressive or impulsive behavior, the ventral prefrontal cortex exerts its inhibitory effects on suicidal behavior less effectively when serotonergic hypofunction occurs (Kamali et al. 2001). A history of child abuse, a familial depression history, substance abuse, head injury, genetic variants, and low cholesterol levels are all associated with both lower serotonergic activity and greater suicide risk (Mann 1998). No practical test based on these psychobiological research advances currently exists. If a test were available, it would likely provide only one more risk factor in a complex biopsychosocial formulation.

Kishi and Kathol (2002) identified four “pragmatic reasons” for suicidality: 1) psychosis, 2) depression, 3) poor impulse control, and 4) philosophical reasons. White and colleagues (1995) subdivided the suicidal med-

ically ill into three general categories: 1) patients admitted to a medical–surgical bed after a suicide attempt, 2) patients with delirium and resultant agitation and impulsivity, and 3) patients with chronic medical illness causing frustration or hopelessness.

In this chapter, we integrate these two approaches first by reviewing the general epidemiology of suicide and suicide attempts and then by discussing psychodynamic factors. The next section concerns the management of the medical and surgical consequences of a suicide attempt and the care of high-risk patients on medical inpatient units. Suicide in the medically ill is reviewed next, exemplified by a focus on cancer, end-stage renal disease, and AIDS. Finally, we address physician-assisted suicide.

## Epidemiology

---

Suicide assessment begins with demographic clues to the patient's relative risk of suicide. Both descriptive and dynamic risk factors are important. In this section, we review descriptive risk factors—comparatively static characteristics of the individual. As the subsequent sections make clear, however, changes in psychiatric status coupled with recent life events are crucial in understanding suicidality in the medically ill.

### Completed Suicide

Reported suicide was the eleventh leading cause of death in the United States in 2001, equal to 1.3% of all deaths (McIntosh 2003). The known suicide rate is nearly identical to what it was in 1900 (Monk 1987), but the epidemiology of suicide has been shifting over the last decade. Between 1990 and 2001, suicide rates have decreased in every age category, with the overall annual rate in the United States declining from 12.4 to 10.8 per 100,000. In 2001, annual suicide rates per 100,000 individuals increased throughout life—from 0.7 in 5- to 14-year-olds and 9.9 in 15- to 24-year-olds to 17.5 in those ages 85 years and older. In 15- to 24-year-olds, suicide ranks behind only accidents and homicide as a leading cause of death (McIntosh 2003). The suicide rate among men is three times higher than among women. Nonwhite Americans killed themselves in 2001 at less than half the rate of white Americans.

Over the course of the life cycle, men and women show different patterns of suicide. For men, suicide rates gradually rise during adolescence, increase sharply in early adulthood, and then decrease before starting an upward trajectory in midlife, increasing into the 75- to 84-year age bracket and beyond (Shneidman 1989). Suicide

rates for women peak in midlife and then decrease, in contrast to the bimodal peaks for men. Men's suicide methods tend to be more violent and lethal; men are more likely to die by hanging, drowning, and shooting. Women are less likely to die in suicide attempts because they are more likely to choose the less lethal methods of wrist cutting and overdose (Kaplan and Klein 1989; A. Morgan 1989). Traditionally, epidemiological studies have shown that suicide attempters are more likely to be younger, female, and married and to use pills, whereas completers are more likely to be older, male, and single and to use violent means (Fawcett and Shaughnessy 1988). However, anyone at any age may contemplate or execute suicide.

History of a suicide attempt is an important predictor of future suicide risk (Pokorny 1983). One of every 100 suicide attempt survivors will die by suicide within 1 year of the index attempt, a suicide risk approximately 100 times that for the general population (Hawton 1992). Twenty-five percent of chronically self-destructive or suicidal patients will eventually kill themselves (Litman 1989). Of those who complete suicide, 25%–50% have tried before (Patterson et al. 1983). A Danish study of patients admitted to a psychiatric unit after a suicide attempt reported that 12% successfully completed suicide within the next 5 years, 75% within 6 months of their last admission (Nielsen et al. 1990). Bostwick and Pankratz (2000) found that depressed patients who had suicidal ideation or who had just made a suicide attempt had a lifetime prevalence of suicide of 8.6%. Palmer et al. (in press) found that three-fourths of suicides in schizophrenic patients occur within 10 years of the first admission or first diagnosis.

It has been repeatedly shown in general population American and European retrospective psychological autopsy studies over the last half-century that psychiatric illness—particularly depression and alcoholism—is associated with the vast majority of completed suicides (Barraclough et al. 1974; Dorpat and Ripley 1960; Robins et al. 1959; Roy 1989). Most patients had not been identified before death as being psychiatrically ill and had not received treatment.

Many suicides are committed by patients with active alcohol use disorders. In one study, 43% of the suicide attempters were using alcohol at the time of the attempts (Hall et al. 1999). In another study, nearly 20% of the subjects completing suicide were legally intoxicated at their deaths (Buzan and Weissberg 1992). Although alcohol abusers may kill themselves at any age, especially when acute intoxication clouds their judgment and disinhibits them, those with chronic alcoholism tend to commit suicide after their relationships, work performance, and health are all in decay. Murphy and Weitzel (1990) estimated that 3.4% of alcoholic patients kill themselves,

a rate that is nearly three times the lifetime risk in the general population (Murphy and Weitzel 1990). Most of the higher suicide rates among men may be accounted for by the higher rates of alcoholism among men (Klerman 1987).

Alcoholic patients often commit suicide in response to crises in their personal lives. One-third of alcoholic patients who kill themselves have lost a close relationship within the previous 6 weeks, and another one-third anticipate such a loss (Murphy 1992). Alcoholic patients frequently have numerous other suicide risk factors, many resulting from their substance abuse, including comorbid major depression, estrangement from family and social supports, unemployment, and serious medical illness. People who abuse other psychoactive substances also have high suicide rates. For example, opiate-dependent patients kill themselves at 20 times the expected rate (Miles 1977), although inadvertent overdoses may constitute part of this number.

## Attempted Suicide

An estimated 735,000 suicide attempts occurred in the United States in 2001, 25 times more than completed suicides. Although there are important differences, attempted suicides are not a discrete category from completed ones, particularly in the medically ill. Suicide attempts occur across spectra of lethality of intent and lethality of effect, which may or may not coincide. Some patients deliberately plan death but naively choose a nonlethal method (e.g., benzodiazepine overdose), whereas others only intend gestures but unwittingly select a fatal method (e.g., acetaminophen overdose). At the more severe end of the spectrum, suicide attempters resemble completers. In a New Zealand study, Beautrais (2001) compared individuals who died by suicide with those who made very serious attempts. She found that they shared the same predictors, including current psychiatric disorder, history of suicide attempts, previous psychiatric care and contact, social disadvantage, and exposure to recent stressful life events.

Nonetheless, some characteristics distinguish surviving attempters from those who die. In the study by Hall et al. (1999) of serious suicide attempters, the patients, by and large, did not have long-standing mental illness or carefully considered plans. They did not have command hallucinations and were not particularly ruminative about their suicidal intent. Whereas 80% had symptoms of an anxiety or a depressive disorder, few had chronic symptoms. Patients who overdose are more likely to survive because they have time after the act to reconsider (or be found) and undergo medical treatment, infrequent options after a jump or a gunshot wound. As with completed

suicides, demographics change over the life cycle. The ratio of attempts to death in the young is 100–200:1, but by old age, it narrows precipitously to 4:1.

Hackett and Stern (1991) reported that 1%–2% of all patients evaluated in the Massachusetts General Hospital emergency department had overdosed, and 47% of these required admission—one-half to medical–surgical wards and one-half to psychiatric units. Of the patients, 85% had overdosed on benzodiazepines, alcohol, nonnarcotic analgesics, antidepressants, barbiturates, or antihistamines/anticholinergics.

Medical illness is a common factor in suicide attempters admitted to general psychiatry units. In a 1-year sample of admissions to a Danish psychiatry unit, 52% of the individuals had a somatic disease, and 21% took daily analgesic medications for pain. The somatic group was older, and most had neurological or musculoskeletal conditions in conjunction with depression that was more severe than in the nonsomatic group (Stenager et al. 1994). In the study by Hall et al. (1999) of 100 serious suicide attempters, 41% had a chronic, deteriorating medical illness, and 9% had recently received a diagnosis of a life-threatening illness.

## Psychodynamic Factors

---

Litman (1989) described a *presuicidal syndrome*, a change in cognitive set, that characterizes lethal attempts and completed suicides. The presuicidal patient in crisis has constricted choices and perception, a tunnel vision of life as hopeless, physical tension, and emotional perturbation. The tension and distress may be relieved by a fantasy of death. The hopelessness is combined with help rejection and distrust. Often the patient has a long-term disposition toward impulsive action, an all-or-nothing approach to problems, and the characterological attitude “my way or no way.”

Klerman (1987) framed the presuicidal crisis in terms of a medical model—as the result of an underlying condition, the patient has lost the capacity for rational thought. The hopelessness and helplessness of severe depression may have reached irrational proportions. Hallucinations may be commanding self-harm. Clouded sensorium, impaired judgment, and the disinhibition and misperceptions of delirium, intoxication, or substance withdrawal all may be causing the patient to act in self-destructive or dangerous ways that he or she would be unlikely to resort to when his or her mind was clear.

Gardner and Cowdry (1985) divided suicidal behavior into four categories, each with its own affective state, motivation, and outcome:

1. *True suicidal acts* are characterized by intense melancholia and despair, a wish for release from emotional pain, and the highest risk of completed suicide, given the likelihood of careful planning and a high-risk to low-rescue ratio.
2. *Retributive rage* is characterized by impulsiveness, vengefulness, and a nihilistic, constricted capacity to see other immediate options.
3. *Parasuicidal gesturing*, often repetitive and tinged with strong dependency needs, appears to be a form of communication, designed to extract a response from a significant other.
4. *Self-mutilation* serves the purpose of relieving dysphoria, a form of “indirect self-destructive behaviors” (N. Farberow 2000).

Only the first category includes the *intent* to die, but any of the four can be lethal.

An early study of personality factors and suicide among medically ill patients identified a “dependent-dissatisfied” behavior pattern among the patients who committed suicide (L. Farberow et al. 1966). Many subsequent investigators have added to the picture of the types of personality structure or cognitive styles that lend themselves to suicidal ideation or behavior. Berger (1995) observed that rational-seeming suicides were unusual in his study of the medically ill and instead were correlated with maladaptive emotional reactions. Describing the role of hopelessness in the thinking of terminally ill cancer patients who wished for hastened death, Breitbart et al. (2000) found the hopelessness to represent a pessimistic cognitive style rather a patient’s assessment of a poor prognosis. That is, patients wished to speed death not because they were mortally ill but because they were chronically pessimistic. A similar finding came from Goodwin and Olfson’s study (2002) of suicidal ideation in nearly 2,600 patients with physical illness diagnoses. Perception of poor health was a significant predictor of suicidal ideation, even after controlling for psychiatric disorders, physical conditions, and other factors.

The tendency of patient and medical provider alike to attribute the hopelessness to the disease—the proximal factor—has resulted in a failure to recognize the mental disorder or personality type—the distal condition—that is actually speaking. “There has been a tendency to regard the suicide of a victim of severe medical illness, such as cancer, as a rational alternative to the distress caused by the disease,” concluded Suominen and colleagues (2002) after analyzing a year’s worth of suicides in Finland. “On the other hand, most suicide victims with physical illness have suffered from concurrent mental disorder....Mental disorders may thus have a mediating role between medical disorder and suicide” (p. 412).

Suicide is often a response to a loss, real or imagined. To help assess the meaning of suicidal ideation or behavior, psychiatrists must inquire about recent or anticipated losses and coping strategies that the patient has used with past losses (Davidson 1993). Fantasies of revenge, punishment, reconciliation with a rejecting object, relief from the pain of loss, or reunion with a dead loved one may be evident (Furst and Ostow 1979).

A patient’s degree of autonomy and extent of dependency on external sources of emotional support can shed light on the level of psychic resilience (Buie and Maltsberger 1989). A recent loss of a loved one or a parental loss during childhood increases suicide risk. Holidays and anniversaries of important days in the life and death of the deceased person, when the loved one’s absence is experienced more intensely, also increase the risk for suicide. In medical settings, what may be lost is a part of one’s self. It may be tangible—an organ, a limb, sexual potency—or intangible—a sense of youthfulness, health, or invincibility. Glickman (1980) believed that a suicidal patient cannot be judged safe until he or she has either regained the lost object, accepted its loss, or replaced it with a new object.

Psychiatrists must monitor themselves for reactions and countertransference feelings toward suicidal patients. In medical settings, consulting psychiatrists help other health care professionals identify and overcome their countertransference reactions as well. These include the classic reactions of “countertransference hate” (Maltsberger and Buie 1974), in which aversion to the suicidal patient (conscious or unconscious) leads to acting angrily toward the patient or withdrawing to an aloof passivity, both of which increase the risk for suicide. Overidentification with seriously medically ill patients may lead to other countertransference reactions. For example, in response to a hopeless patient, the psychiatrist may become overly pessimistic or too reassuring.

## Management in Medical Inpatient Settings

---

For a patient who survives a recent suicide attempt, the emergency department usually is the first stop for assessment and triage. If the patient is medically cleared, ideally a psychiatrist, but sometimes another mental health professional, evaluates the patient and decides whether psychiatric inpatient or outpatient management is the appropriate disposition. It is important for psychiatrists to form their own judgment about whether patients are truly medically stable enough for transfer out of the medical

setting because countertransference to suicidal states frequently causes nonpsychiatric physicians to minimize the role of medical contributions and prematurely “clear” patients. For a patient with self-induced injuries severe enough to require additional medical or surgical care, admission follows, and a psychiatrist is consulted. Patients who are admitted to medical–surgical beds after suicide attempts represent a particularly dangerous subset of suicidal patients. Considering data from all of New Zealand’s public hospitals, Conner et al. (2003) showed that individuals hospitalized with self-induced injuries have a relative risk of 105.4 for suicide within the next year and a relative risk of 175.7 for additional self-injury hospitalizations, compared with the New Zealand general population.

Divergent conditions such as delirium, psychosis, personality disorder, and intoxication and withdrawal syndromes have in common the impulsivity that must be anticipated and managed in medical settings. Withdrawal—particularly from alcohol or sedative-hypnotics—epitomizes impulsivity syndromes that can be deadly and must be recognized and aggressively managed with detoxification protocols. In the absence of a suitably equipped psychiatric unit, the psychiatrist will need to arrange medical admission.

In addition to trying to make the environment safe, egress must be controlled. In the general medical hospital, patients should be prevented access to open stairwells, roofs, and balconies, and all windows should be secured (Berger 1995). In a classic study of the dangers of hospitalizing impulsive patients in an unsecured environment, Reich and Kelly (1976) described 17 medical inpatients who attempted suicide while on the medical and surgical wards at Peter Bent Brigham Hospital between 1967 and 1973 and survived. They judged 15 of the 17 patients to have mental disorders, but the cardinal characteristics of depression and hopelessness were not present in this sample. “All...were impulsive acts, none of the patients gave warnings, left notes, expressed suicidal thoughts or appeared to be seriously depressed” (Reich and Kelly 1976, p. 300). The investigators considered most of these 17 attempts to be reactions motivated by anger at perceived loss of emotional support, usually from staff. They attributed this underlying impaired impulse control to personality disorders in 8 of the patients, to psychosis in 7, and to delirium in 3.

When a suicidal or an impulsive patient is too medically ill to be cared for on a locked general psychiatry unit, a medical–psychiatry unit—if a hospital has one—is the ideal disposition for such a patient. In the absence of such a specialty unit, medical intensive care units are more likely to provide one-to-one nursing care, although criti-

cal care physicians may argue that such observation in the absence of need for critical care is an inappropriate use of their service.

Ms. C, a 22-year-old woman addicted to crack cocaine, developed severe cardiomyopathy after the birth of her third child. Four months later, no longer able to climb the two flights of stairs to her apartment without becoming short of breath, she was admitted to the hospital with congestive heart failure. A toxicology screen was positive for alcohol and cocaine.

After she arrived on the medical floor, Ms. C curled up in a fetal position and refused to speak to her nurse until she was found lighting a cigarette while receiving oxygen. When the nurse attempted to stop her, Ms. C began cursing and shrieked that if she were not allowed to smoke, she would overdose on digitalis she had hidden in the room.

Ms. C refused to submit to a room search. The psychiatric consultant recommended that security be called so that Ms. C could not leave before he could perform an emergency evaluation. Ms. C had to be placed in leather restraints when she assaulted the officers. After speaking with the psychiatrist, Ms. C agreed to take medication (5 mg of haloperidol and 1 mg of lorazepam). She then consented to a search of her belongings. A bottle of 50 digitalis tablets was found in her suitcase. Because of her threats and impulsivity, the psychiatrist recommended constant observation with sitters.

As Ms. C’s case shows, the first task in the medical setting is ensuring the patient’s safety (Gutheil and Appelbaum 2000). A safe environment must be created and maintained until the patient is stable enough for psychiatric transfer.

Patients who are most intent on suicide, as well as those who are most impulsive and unpredictable, may attempt suicide in the hospital. The patient’s room must be secured—that is, anything that patients could potentially use to injure themselves must be removed. Luggage and possessions should be searched with a suspicious eye and a morbid imagination. Staff must ferret out sharp objects, lighters, belts, caches of pills—anything that could inflict damage in either an impulsive or a carefully planned way. Objects that are being brought into the room must be regarded as potential hazards (e.g., the phlebotomist’s needles, the pop-tops from soft drink cans, the custodian’s disinfectants). The rooms of the general medical hospital lack many of the safeguards that are routine on inpatient psychiatric units, such as locked unit entrances and collapsible shower heads, curtain rods, and light fixtures. Normally, in the former, scissors and a variety of paraphernalia that can be “creatively” used for self-harm are easily accessible. The culture on medical inpatient units also differs from that on psychiatric units. On medical units, staff do not usually consider elopement a risk; they

assume that patients are fundamentally compliant and that they will press their call buttons when they need help (Kelly et al. 1999).

Early reports focused on jumping as a means of suicide in medically hospitalized patients (N. Farberow and Litman 1970; Glickman 1980; Pollack 1957), a usually lethal method regardless of whether the patient actually intends to die. In the most recent study, White and colleagues (1995) identified impulsivity and agitation in many of the 12 patients who jumped from an Australian general hospital during a 12-year period. Five had been noted to be delirious on the day of the jump, 7 were dyspneic, and 10 were in pain. Ten of the 12 had two of these factors, and 1 had all three factors.

Modern hospitals are deliberately built without open stairwells and without windows that open or break easily; however, many older buildings remain in service, indicating the persistent need for corrective precautions. The inpatient suicide rate in a New York hospital dropped five-fold during the first 11 years after the hospital secured the windows and implemented educational programs encouraging staff members to pay closer attention to disruption in the doctor–patient relationship (Pisetsky and Brown 1979; Sanders 1988).

Shah and Ganesvaran (1997) found that one-third of 103 suicides committed by psychiatric inpatients at their hospital involved patients away on pass, and another one-third involved patients away from the hospital without permission. Methods readily available near the hospital include jumping in front of vehicles, leaping from buildings or bridges, and drowning in nearby bodies of water (H. Morgan and Priest 1991). Although these authors studied psychiatric inpatients, the same dangers exist with patients on medical units. Passes are rarely given from contemporary medical units, but elopements are all too common, with resultant ready access to potentially lethal means of suicide.

Constant observation by a one-to-one sitter is indicated for patients judged at high risk for impulsive self-harm. This may require compromising patients' privacy. Patients permitted to use the bathroom unobserved have been known to hang or cut themselves behind the closed door. A moment of privacy granted to the patient out of misplaced civility, or a few minutes of inattention or absence by the sitter, may be all the time a suicidal person needs to execute a suicide plan. All staff guarding suicidal patients should know how to summon security personnel as reinforcements when they perceive that they have lost control of the patient or the situation. In an era of cost cutting, the consultant may feel pressure to limit the use of constant observation. Economizing on sitters could mean the life of a suicidal patient. On the other hand, staff

anxiety may lead to overuse, initiating one-to-one sitters for every patient who has expressed any suicidal thoughts. In addition to wasting resources, overuse of sitters may desensitize them to the constant awareness needed for their role. The decision to use constant observation should be made on clinical grounds. Prudent risk management supports avoiding under- and overuse of one-to-one sitters.

After the environment is secured, the medical psychiatrist should search for reversible contributors to the impulsive state, including delirium (see Chapter 6, "Delirium"), medical illness or medications that may be contributing to mood (see Chapter 9, "Depression"), anxiety (see Chapter 12, "Anxiety Disorders"), and psychotic disorders (see Chapter 11, "Mania, Catatonia, and Psychosis").

Agitation and active suicide attempts in the hospital often require chemical restraints and, rarely, physical restraints. Neuroleptics should be used in patients with delirium or psychosis, and neuroleptics and/or benzodiazepines should be given to other agitated, anxious patients. Physical restraints may be required if other measures prove inadequate. In some cases, emergent electroconvulsive therapy may be necessary (see Chapter 39, "Electroconvulsive Therapy").

## Suicide in the Medically Ill

---

Physical disease is present in a high proportion of people who commit suicide. A recent review cited several large studies that reported that medical illness was present in 30%–40% of the patients who committed suicide (Hughes and Kleespies 2001). However, most of these suicides do not occur during medical hospitalization. About 2% of Finnish suicides occurred in medical or surgical inpatients (Suominen et al. 2002). In Montreal, Quebec, about 3% of the suicides were in general hospital inpatients, of which one-third (1%) were medical–surgical patients (Proulx et al. 1997). During a 10-year period in a 3,000-bed Chinese medical hospital, there were 75 self-destructive acts, only 15 of which proved fatal (Hung et al. 2000).

Sanders (1988) reviewed six studies of inpatients at a general hospital who committed suicide. Most had one or more chronic or terminal illnesses or sequelae that were painful, debilitating, or both, including dyspnea, ostomies, or disfiguring surgery. Harris and Barraclough (1994) compiled a list of 63 medical disorders noted in the medical literature as potentially having elevated suicide risk. In their meta-analysis, they concluded that the only disorders that actually elevated suicide risk were HIV and

AIDS, Huntington's disease, cancer (particularly head and neck), multiple sclerosis, peptic ulcer disease, end-stage renal disease, spinal cord injuries, and systemic lupus erythematosus. More recent studies confirm or add to a seemingly arbitrary list of medical conditions associated with risk for suicide. In a Canadian study, cancer, prostate disease, and chronic pulmonary disease were associated with suicide ORs of 1.70–1.86 among adults older than 55 years with versus without the diseases (Quan et al. 2002). In the previously cited Chinese study of patients who committed suicide in a general hospital, 40% had cancer, 13% had neurological disease, 13% had cardiovascular disease, and 7% had liver failure (Hung et al. 2000). In the Montreal study, associated diagnoses included cardiovascular disease, abdominal pain, cerebrovascular disease, Parkinson's disease, and rheumatoid arthritis (Proulx et al. 1997). Of 12 patients who jumped from an Australian hospital between 1980 and 1991, 4 had delirium, 4 had terminal cancer, 2 had advanced lung disease, and 1 had irreversible cardiac failure (White et al. 1995). However, these studies were small and did not capture suicides in the medically ill attempted or completed outside the hospital, so they cannot be used to construct a list of "most suicidal" medical disorders.

A recent study drawing on the U.S. National Comorbidity Survey identified a dozen general medical diagnostic categories with statistically significantly elevated ORs for suicide attempts, most ranging from 1.1 to 3.2, except for AIDS (133.9) and hernia (10.4) (Goodwin et al. 2003). Clinically, however, use of a diagnosis alone in estimating suicide risk is not helpful. Even though the OR in each of the 12 categories achieved statistical significance, substituting a rate only slightly higher than the very low base rate offers little to guide clinical decision making, particularly if this is the only indicator being used to predict suicide.

What does appear useful is that suicides in the medically ill—as in the general population—appear to be related to frequently unrecognized comorbid psychiatric illnesses, including depression, substance-related disorders, delirium, dementia, and personality disorder (Davidson 1993; Kellner et al. 1985). In their study of the role of physical disease in 416 Swedish suicides, Stensman and Sundqvist-Stensman (1988) concluded that somatic disease was one important factor in the complexity of the suicidal act, but psychiatric conditions such as depression and alcohol abuse were more significant. Rather than focus on particular medical diagnoses, it will be more fruitful for the medical psychiatrist to determine whether a suicide-prone psychiatric condition is present in a medically ill patient, whether the patient is at a particularly emotionally difficult time in his or her illness course, and whether secondary

effects of the medical illness—pain, physical disfigurement, cognitive dysfunction, and disinhibition—are present that add to the risk.

It must be emphasized that no matter how horrific the medical condition, significant suicide risk is not the rule. According to Brown et al. (1986), most terminally ill patients do not develop severe depression, and suicidality is closely associated with the presence of a depressive disorder. In the study of terminally ill cancer patients by Breitbart et al. (2000), only 17% had a high desire for hastened death, for which depression and hopelessness were the strongest predictors. An important empirical finding in a Canadian study was that the will to live in the terminally ill fluctuates, mostly predicted by depression, anxiety, shortness of breath, and sense of well-being (Chochinov et al. 1999).

Three diagnoses—cancer, end-stage renal disease, and AIDS—are discussed here to illustrate these points further. These comparatively common conditions underscore principles that can be extrapolated to the breadth of diagnoses and situations encountered in medical settings.

## Cancer

Three large studies have found an increased suicide rate among patients with cancer. Luohivuori and Hakama (1979) studied 63 suicides among 28,857 Finnish cancer patients and found relative risks (compared with the general population) of 1.3 for women and 1.9 for men, with the highest excess mortality associated with gastrointestinal tumors. Fox et al. (1982) studied 192 suicides between 1940 and 1973 among 144,530 patients in the Connecticut Tumor Registry and calculated no increased suicide risk for women but a 2.3 relative risk for men. In the largest study of the relation between cancer and suicide, Allebeck and colleagues (1985) gathered statistics on 963 suicides between 1962 and 1979 among 424,127 Swedes with a diagnosis of cancer and found an overall 1.9 relative risk for men and a 1.6 relative risk for women. Gastrointestinal tumors (excluding colorectal cancers) in men (relative risk=3.1) and lung tumors in either sex (relative risk=3.1 for men and 3.5 for women) were associated with the highest rate of death due to suicide.

Cancer patients who die by suicide are psychiatrically similar to noncancer patients, particularly when the cancer is in remission. In a case-control study of 60 suicides in individuals with cancer and 60 age- and sex-matched comparison suicides in individuals without a cancer history, Henriksson et al. (1995) found that most of the patients with cancer who committed suicide—as well as the control subjects without cancer—had a diagnosable psychiatric disorder. Terminally ill cancer patients had lower

rates of depression and alcohol dependence than did patients in remission (72% vs. 96%), but nearly three-quarters still met criteria for a depressive disorder. As a group, cancer patients had fewer psychotic disorders than did control subjects. Allebeck et al. (1985) observed that the longer the time from diagnosis of cancer, the lower the relative risk for suicide in a Swedish cohort. In the first year after diagnosis, the relative risk was 16.0 for men and 15.4 for women. From 1 to 2 years, the ratio decreased to 6.5 for men and 7.0 for women. By 3–6 years, the ratio was 2.1 for men and 3.2 for women. By 10 years after diagnosis, the rate, at 0.4, was actually less than one-half that in the general population. A study of Japanese cancer patients found the highest risk of suicide soon after patients had been discharged from the hospital, with an elevated relative risk the first 5 years after diagnosis compared with the general population and disappearing thereafter (Tanaka et al. 1999).

The fear of pain, disfigurement, and loss of function that cancer evokes in the patients' imagination can precipitate suicide, especially early in the patients' courses. In a large cohort of Italians with cancer, suicide accounted for only 0.2% of the deaths, but the relative risk during the first 6 months after diagnosis was 27.7 (Crogetti et al. 1998). The high relative risk of suicide just after diagnosis comes at a time of overwhelming fear and cognitive overload. In individual patients, important contributing factors (Filiberti et al. 2001) can include overly pessimistic prognosis, exaggerated impressions of anticipated suffering, a physician unintentionally undermining hope, fear of loss of control, or nihilism about treatment. Patients may fear or experience inadequate pain control, lost dignity, compromised privacy, or guilt at having habits that caused the disease. Surgical treatments may be disfiguring, chemotherapy debilitating, and side effects defeminizing or emasculating. As cancer patients live longer with their disease, most become less frightened and less susceptible to suicide.

## End-Stage Renal Disease

More formidable than the suicide risk among cancer patients was the purported increase in relative risk of suicide among patients with end-stage renal disease. Abrams and colleagues (1971) reported very high rates of suicide and suicidal behavior among 3,478 renal dialysis patients studied at 127 dialysis centers. In their sample, 20 deaths were the result of suicide; 17 suicide attempts were unsuccessful; 22 patients withdrew from the program, knowing that doing so would hasten their deaths; and 117 deaths were attributed to noncompliance with treatment. The authors' calculated suicide rate of 400 times that in the

general population has been widely quoted but is misleading. In arriving at a 5% figure for suicidal behavior in dialysis patients, they used an extremely broad definition of suicide that encompassed death caused by a wide range of causes, from willful acts of self-destruction to noncompliance.

Most of the cases that Abrams and colleagues called suicide would never come to the attention of psychiatry today. Although their report has been widely cited, no other subsequent study (there have been nearly 20) has defined suicide so broadly (Bostwick and Pankratz 2000). In extreme cases, noncompliance is better understood as a function of personality-disordered behavior; in less dramatic examples, it can be an understandable human response to a burdensome treatment. Deciding to forgo dialysis is not equivalent to suicide (see also Chapter 22, "Renal Disease"). A recent United States study concluded that "most patients who decide to stop dialysis do not seem to be influenced by major depression or ordinary suicidal ideation" (Cohen et al. 2002, p. 889). Treatment withdrawal, negotiated among the patient, significant others, and the treatment team, has become routine as quality of life during dialysis fades.

In 1,766 Minnesota dialysis patients followed up for 17 years, for example, only 3 killed themselves by frank suicide, representing only 2% of the 155 cases in which dialysis was discontinued (Neu and Kjellstrand 1986). The suicide rate in this sample of dialysis patients was only about 15 times that in the general population, which is a considerable rate but much lower than Abrams and colleagues' figure. Haenel et al. (1980) also found less dramatic suicide rates among European patients undergoing chronic dialysis between 1965 and 1978. In Switzerland, dialysis patients killed themselves at about 10 times the rate in the general population. When patients who refused therapy and died as a result were included in the suicide group, the rate was 25 times higher. They also found no statistically significant difference between suicide rates among patients with functioning cadaveric renal transplants and patients undergoing maintenance dialysis, suggesting that transplantation may not in and of itself be associated with decreased suicide risk. Overall, among dialysis patients pooled from all countries belonging to the European Dialysis and Transplant Association, the suicide rate was 108 per 100,000 per year (Haenel et al. 1980). Whether compared with the general population suicide rate of 4–5 per 100,000 in Mediterranean countries or 20–25 per 100,000 in central European or Scandinavian countries, the figure of 108 per 100,000 represents a higher suicide rate, although not orders of magnitude greater than that in the general population.

## AIDS

AIDS patients also have a higher relative risk of suicide, even though the risk appears to have decreased since the disease emerged. The existing data are primarily based on men who had sex with men in the United States in the 1980s. Extrapolation to the present is problematic because of many changes, including the demographics and geographic distribution of AIDS, advances in treatment, availability of mental health services, public education, and reduction in stigma and social hysteria. The perspective of suicide has changed as AIDS has evolved from a terminal illness to a chronic one. Another caveat in interpreting studies of suicidality in persons with HIV is that results will be confounded because the study populations (e.g., men who have sex with men, injection drug abusers, and poor minority heterosexual women) all differ in their sociodemographics and psychiatric epidemiology.

Marzuk et al. (1988) found a suicide rate in persons with AIDS 36 times that in an age-matched sample of men without AIDS and 66 times that in the general population in New York City in 1985. Marzuk and colleagues (1997) reexamined this question based on all suicides in New York City in 1991–1993 and concluded that positive HIV serostatus was associated, at most, with a modest elevation in suicide risk. In California, in 1986, the rate was 21 times higher than that in the general population (Kizer et al. 1988). In the largest study to date, Cote et al. (1991) charted a continuous decrease in suicide rates over 3 years among AIDS patients in 45 states and the District of Columbia. From 1987 to 1989, a total of 165 suicides among AIDS patients were reported to the National Center for Health Statistics. Of these, 164 were committed by men. The relative suicide risk calculated for AIDS patients was 10.5 in 1987, 7.4 in 1988, and 6.0 in 1989. The authors attributed the decrease to advances in medical care, diminishing social stigma, and improved psychiatric services, while noting probable underreporting of deaths due to both AIDS and suicide (Cote et al. 1991). In a review of 100 publications with information about suicide and HIV, Palmer et al. (in press) concluded that there has been a distinctive downward trend in HIV-related suicidality in the United States since the beginning of the epidemic.

Frierson and Lippman (1988) suggested that suicide risk also may be increased among HIV-positive but asymptomatic people who fear the eventual illness, HIV-negative people who are worried about contracting the disease, and people who enter suicide pacts with dying loved ones. Rundell and colleagues (1992) compared 15 HIV-infected active-duty members of the air force who attempted suicide with 15 who did not and identified several risk factors equivalent to risk factors for suicide in

general, including social isolation, perceived lack of social support, adjustment disorder, personality disorder, alcohol abuse, interpersonal or occupational problems, and history of depression.

Recent studies reflect both the changing demographics of HIV and AIDS and the stable classic risk factors for suicidality. Roy (2003) found that almost half of a cohort of HIV-positive substance-dependent patients had attempted suicide. Those who had attempted suicide were younger; were more likely to be female; and were more likely to have more childhood trauma, more depression, more family history of suicidal behavior, and higher neuroticism. A survey in HIV-infected Americans living in rural areas found that 38% had thoughts of suicide during the past week, associated with greater depression and more stigma-related stress and less coping self-efficacy (Heckman et al. 2002).

Finally, two recent studies, one in Italy (Grassi et al. 2001) and one in Brazil (Malbergier and de Andrade 2001), found that although psychiatric morbidity and suicidal ideation or attempts are common in HIV-positive intravenous drug abusers, they are equally common in those who are HIV-negative. A Swiss study of men having sex with men found a high rate of suicide attempts in both HIV-negative and HIV-positive individuals, with moderately more suicidal ideation in those who were HIV-positive (Cochand and Bovet 1998). Dannenberg et al. (1996) compared 4,147 HIV-positive United States military service applicants and 12,437 HIV-negative applicants disqualified from military service because of other medical conditions (matched on age, race, sex, and screening date and location) with the matched general population; the relative risk for suicide was similar for each group: 2.08 in the HIV-positive and 1.67 in the HIV-negative applicants. These studies reinforce the point that psychopathology is implicated more potently than any specific medical diagnosis in suicidality.

## Prevention and Treatment

The first priority in preventing suicide in the medically ill is the early detection and treatment of the comorbid psychiatric disorders covered throughout this book. Patient and family education about the medical disease course and its treatment can help prevent excessive fear and pessimism. Direct questions and frank discussion about suicidal thoughts, ideally part of every primary physician's care for any patient with a serious disease, can reduce suicidal pressures. One important role for psychiatrists is to restrain other physicians from automatically prescribing antidepressants for every medically ill patient who expresses a wish to die. Overdiagnosis of depression can

lead to inappropriate pharmacotherapy, pathologization of normal feelings, or neglect of relevant personality traits potentially amenable to psychotherapeutic intervention. Soliciting patients' wishes and preferences regarding pain management and end-of-life care early on may reduce the fear of having no control of their dying that lures some patients toward suicide.

Palliative care for the terminally ill is essential in offering relief to those for whom life has become (or is feared) unbearable (see Chapter 40, "Palliative Care"). Psychiatrists can help elicit fears, guilt, impulses, and history that patients may be reluctant to share with their primary physicians. In addition to treating psychiatric symptoms, psychiatrists can monitor for illicit drug use, medication side effects, and emergent neuropsychiatric complications of the underlying medical illness. Psychotherapy can facilitate the exploration and expression of grief and restore a sense of meaning in life (Chochin 2002; Frierson and Lippman 1988; see also Chapter 38, "Psychotherapy," and Chapter 40, "Palliative Care"). Psychotherapy also may be psychoeducational, reinforcing patients' and family members' accurate knowledge about the disease. Attention to patients' spiritual needs is very important as well; spiritual well-being offers some protection against end-of-life despair (McClain et al. 2003). Finally, for both patients and family, support groups and other community resources may be critical in making the difference between feeling life is worth living and giving up.

## Physician-Assisted Suicide

---

In an editorial in *Medicine*, McHugh (1994) argued that assisted suicides and "naturalistic" ones occurred in different groups of people. Conceptually, physician-assisted suicide follows a rational request from a competent, hopelessly ill patient whose decision is not driven by psychiatric illness. It is legal in very few jurisdictions, where there are practice guidelines and legal safeguards.

In a pair of unanimous 1997 decisions, the U.S. Supreme Court ruled that there is no constitutional right to physician-assisted suicide and that states can prohibit physician conduct in which the primary purpose is to hasten death (Burt 1997). Only one state, Oregon, has legalized physician-assisted suicide; its Death With Dignity Act was passed in 1994 and enacted in 1997. Terminally ill Oregonians can ask their primary care physicians to prescribe lethal doses of medication, but the patients must be able to administer the killing doses themselves.

The safeguards built into the Oregon process closely resemble criteria in place in the Netherlands since 1973,

outside the law for nearly three decades, until the Dutch Parliament passed the Termination of Life on Request and Assistance With Suicide Act in 2001 (Cohen-Almagor 2002). To meet the guidelines of the act, the patient must experience his or her situation as intolerable and voluntarily and repeatedly ask the physician for assistance with suicide. The request must be informed, uncoerced, and consistent with the patient's values, and all treatment options must have been exhausted or refused. Finally, the initial physician must seek a second opinion to confirm the diagnosis and prognosis and report the death to the designated municipal authorities (Cohen-Almagor 2002; de Wachter 1989; Singer and Siegler 1990). Quill and colleagues (1992) suggested an addition to these more legalistic safeguards—that physician-assisted suicide should be carried out only in the context of a meaningful doctor-patient relationship.

The Oregon law is both more conservative and more specific than its Dutch counterpart. It requires applicants to have the capacity to make their own health care decisions. They must have an illness expected to lead to death within 6 months and must make their requests to the physician in the form of one written and two oral statements separated by 15 days from each other. The primary physician and the consultant giving a second opinion not only must agree on capacity, diagnosis, and terminal prognosis but also have the option of referring the patient for a mental health evaluation if either suspects that depression or another psychiatric disorder is affecting the patient's judgment. The primary physician is required to inform the patient of all feasible options, such as comfort care, hospice care, and pain management; only then can the patient be given a lethal prescription (Chin et al. 1999). The law specifically forbids active euthanasia, which is distinguished from physician-assisted suicide by the physician actively performing the killing act. Physician-assisted suicide is thus denied to patients who lack motor capacity (e.g., patients with amyotrophic lateral sclerosis) (Rowland 1998). Such individuals may still wish for physician-assisted suicide; Ganzini et al. (2002) reported that one-third of amyotrophic lateral sclerosis patients discussed wanting assisted suicide in the last month of life, particularly those with greater distress at being a burden and those with more insomnia, pain, and other discomfort.

Although he postulated that a request for suicide could be rational, Muskin (1998) advocated a psychodynamic approach to a dialogue between the patient and the physician, a dialogue he believed any such request demands. He saw the query as "an opportunity for patient and physician to more fully understand and know one another" (p. 327) and asserted that "every request to die

should be subjected to careful scrutiny of its multiple potential meanings” (p. 323). For example, is the patient asking the physician to provide a reason to live? Does the patient harbor revenge fantasies? Is the patient driven by inadequately treated pain or depression, by guilt or hopelessness, or by feelings of already being dead?

In contrast to Muskin’s fundamentally intrapsychic approach, Hackett and Stern (1991) outlined diverse interpersonal factors to be considered in evaluating a patient requesting physician-assisted suicide, potentially life-threatening analgesics, or withdrawal of life support. The attending physician and consulting psychiatrist each must take sufficient time to understand the wishes of the patient. What has the patient pictured his or her clinical course to be? What are his or her values? What notions exist about the end of life? Is the patient clinically depressed? Where does the family stand? Does the family understand the patient’s request, and how do they affect it? At what point does the patient specify that the potential for meaning in his or her life has been exhausted? Does the patient fear that he or she will become a financial burden, a caregiving burden, or both? Has any of this been discussed with the family? If the patient considers life devoid of value and meaning for himself or herself, does it have meaning for significant others? Does that affect the patient’s thinking? Has the patient made any effort to achieve family consensus so that death can actually be a meaningful shared family experience?

The psychiatrist’s role in physician-assisted suicide is to be available for consultation. In that psychiatrists are almost never primary care providers for terminally ill patients other than dementia patients, who—by definition—lack capacity and are thus not eligible for physician-assisted suicide, Oregon psychiatrists have not been writing lethal prescriptions (Linda Ganzini, personal communication, 2003). Moreover, mental health evaluation is not among the mandatory safeguards in the Oregon law. Despite numerous investigators who have opined that primary care physicians are usually ill-equipped to tease out factors confounding a truly informed decision to take an active role in the timing of one’s death (Billings and Block 1996; Conwell and Caine 1991; Hendin and Klerman 1993), only 20% of potential Oregon physician-assisted suicide patients have a mental health evaluation (Ganzini et al. 2000).

Block and Billings (1995) outlined five key clinical questions for psychiatrists to explore in clarifying decision-making capacity in terminally ill patients requesting euthanasia or assisted suicide:

1. Does the patient have physical pain that is under-treated or uncontrolled?

2. Does the patient have psychological distress driven by inadequately managed psychiatric symptoms?
3. Does the patient have social disruption resulting from interpersonal relationships strained by fears of burdening others, losing independence, or exacting revenge?
4. Does the patient have spiritual despair in the face of taking the measure of a life nearing its end while coming to terms with personal beliefs about the presence or absence of God?
5. Does the patient have iatrogenic anxiety about the dying process itself and the physician’s availability as death encroaches?

Regardless of the status of the law, Block and Billings argued that requests to hasten death will come, and they explicitly acknowledged in a case example—as others have done in notorious publications (“A Piece of My Mind: It’s Over, Debbie” 1988; Quill 1991)—that some physicians participate in extralegal physician-assisted suicide. They enjoin the psychiatrist to perform several functions for a nonpsychiatric colleague wrestling with such a request, including “offering a second opinion on the patient’s psychological status, providing a sophisticated evaluation of the patient’s decision-making capacity, validating that nothing treatable is being missed, and helping create a setting in which the primary physician and team can formulate a thoughtful decision about how to respond” (Block and Billings 1995, pp. 454–455).

Making time and space for a comprehensive mental health evaluation for the presence of a treatable psychiatric disorder can result in a patient deciding to live longer and withdraw the physician-assisted suicide request (Hendin and Klerman 1993), particularly if “the demoralizing triad” of depression, anxiety, and preoccupation with death is confronted and dispelled. The Oregon experience has shown that intervening in any or all of Block and Billings’s five realms can forestall a physician-assisted suicide request actually being carried to completion. Only 1 in 6 requests resulted in the physician issuing a prescription, and only 1 in 10 of those initially requesting physician-assisted suicide ultimately used the medication to hasten death (Ganzini et al. 2001).

Although the U.S. Supreme Court in its 1997 decision specifically denied that physician-assisted suicide was a constitutional right, it endorsed making palliative care more available and acknowledged the legal acceptability of providing pain relief, even if it hastened death (Burt 1997; Quill et al. 1997). Terminal sedation (in which a patient is given narcotics, even to the point of unconsciousness) accompanied by withdrawal or withholding life-prolonging therapies such as ventilatory support (see

Chapter 20, “Lung Disease”), antibiotics, food, and water has become normative end-of-life management (see Chapter 40, “Palliative Care”).

The distinctions among, and propriety of, physician-assisted suicide, active euthanasia, and passive euthanasia remain controversial and beyond the scope of this chapter, but some clarifications should be noted. At present, all 50 states in the United States continue to outlaw active euthanasia, and since the 1997 Supreme Court ruling, no state is required to permit physician-assisted suicide within its borders. Some have worried that making physician-assisted suicide legal would undermine the availability of appropriate care, partly driven by financial exigencies such as strained health care resources. In the Netherlands, the availability of euthanasia appears to have stunted the evolution of palliative care (Cohen-Almagor 2002), but in Oregon, the reverse appears to have happened. The availability of physician-assisted suicide has coincided there with a dramatic increase in the use of hospice. In 1994, when voters approved physician-assisted suicide, 22% of Oregonians died in hospice care. By 1999, that figure had risen to 35% without any appreciable increase in the geographic distribution or number of hospice beds in the state (Ganzini et al. 2001). The fear that physician-assisted suicide would become a ubiquitous and convenient way of prematurely disposing of Oregon’s dying patients also appears not to have been borne out: in 1999, fewer than 1 in 1,000 Oregon deaths resulted from physician-assisted suicide (Ganzini et al. 2001). Another concern among the public is whether allowing patients to decide to die through refusal of fluids and nutrition will cause undue suffering. The evidence clearly shows that this is not the case (Ganzini et al. 2003).

Psychiatrists will continue to be consulted frequently when patients request withdrawal of treatment or assisted suicide. Evaluation of the patient’s capacity for decision making follows the same principles as for other medical decisions (see Chapter 3, “Legal Issues,” and Chapter 4, “Ethical Issues”), but psychiatrists should strive to distinguish those who wish to die despite remediable contributors to their despair from those who primarily find the burdens of treatment outweighing the offered benefits. As with any “competency consultation,” the psychiatrist should always broaden the scope of examination to a full understanding of the patient and his or her predicament.

## Conclusion

---

Compared with suicidal ideation, completed suicide is rare in psychiatric patients and rarer still in the medically ill. Although there are identifiable demographic factors

associated with increased risk for suicide, by themselves these factors will identify many more persons potentially at risk than imminently in danger of dying. Many medical illnesses have been associated with increased suicide attempts, but medical illness by itself is rarely the sole determinant of suicide potential. The assessment of a suicidal medically ill person—as with any suicidal person—demands attention to the role played by characterological, temperamental, or experiential features in the individual’s immediate push toward suicide. Management begins with a search for reversible contributors to impulsivity, such as delirium, psychosis, and intoxication. A priority in preventing suicide in the medically ill is the early detection and treatment of comorbid psychiatric disorders.

One of the most frequent reasons for psychiatric consultation in medical hospitals is for evaluation for transfer of care of patients who have made suicide attempts. Because countertransference issues not infrequently lead nonpsychiatric physicians to prematurely “clear” patients, it is critical for psychiatrists to form their own judgments about whether patients are truly medically stable enough for transfer out of the medical setting. If a suicidal patient must remain on a medical floor, the psychiatric consultant should keep in mind that rooms in the general medical hospital may lack safeguards routinely found on inpatient psychiatric units. Constant observation by a one-on-one sitter is indicated for patients judged to be at high risk.

Suicide is not synonymous with refusal of lifesaving treatment or with requests to hasten death in terminal illness. Psychiatrists are frequently consulted when patients request withdrawal of treatment or assisted suicide; in these situations, the clinician should evaluate the patient’s capacity for decision making, the adequacy of pain management, and the role that treatable psychiatric illness may be playing in the request. Psychological distress, social disruption of interpersonal relationships, and spiritual despair must also be explored and addressed. Responding to these issues with concern and comfort may transform a desire for hastened death into a graceful and timely exit from life.

## Mania, Catatonia, and Psychosis

---

Prakash S. Masand, M.D.

Eric J. Christopher, M.D.

Greg L. Clary, M.D.

Rajnish Mago, M.D.

James L. Levenson, M.D.

Ashwin A. Patkar, M.D.

**IN THIS CHAPTER**, we review the impact of mania, catatonia, and psychosis on medical care and treatment in patients with serious medical illness. The etiology and differential diagnosis of secondary mania, catatonia, and psychosis are also reviewed. Mania, catatonia, and psychosis attributed to a medical condition or substance use are termed secondary disorders. Although the terms *primary* and *secondary* are not formally used in DSM-IV and DSM-IV-TR (American Psychiatric Association 1994, 2000), many clinicians prefer to use them to distinguish between syndromes that result from psychiatric disorders such as schizophrenia and affective disorders and those that are due to general medical conditions, psychoactive substances, or medications.

### Mania in the Medically Ill

---

Bipolar illness is common in the general population, with a lifetime prevalence rate between 1% and 3% (Kessler et al. 1997; Regier et al. 1990). It is often underrecognized; it also is often misdiagnosed as major depression, anxiety disorder, or schizophrenia, and in medical inpatients it may be mistaken for delirium. While evaluating patients for secondary causes of mania, clinicians should always consider

the possibility that the patient may have a primary bipolar disorder. In general, the treatment of primary mania in the medically ill should follow established guidelines, except when the medical condition (e.g., impaired hepatic metabolism) requires modifications in the medications used (see Chapter 37, “Psychopharmacology”).

### Diagnosis

A classification system of six subtypes of bipolar disorder published in 1978 included type IV, defined as manic symptoms with etiology related to general medical illness or the use or abuse of prescription or illicit drugs (Krauthammer and Klerman 1978). In DSM-III, this condition was referred to as “organic mania” (American Psychiatric Association 1980). In current DSM-IV-TR terminology, secondary mania, or manic symptoms attributed to an organic etiology, is referred to as mood disorder secondary to a general medical condition (American Psychiatric Association 2000). The diagnosis of secondary mania requires a prominent and persistent elevated, expansive, or irritable mood and evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.

An overlap of the clinical presentation of secondary mania with delirium can complicate diagnosis and treatment. Both can present with abrupt onset, inattention, agitation, disordered sleep, and psychosis. Delirium differs from secondary mania in its waxing and waning course, clouding of consciousness, and visual hallucinations and illusions, whereas secondary mania is suggested by manic affect, hypersexuality, and pressured speech.

The course of secondary mania has not been well defined, nor are its prevalence and incidence known. With primary bipolar illness, the course is usually chronic and recurrent, but in secondary mania, the episode may begin within hours or days of the organic or toxic insult. The differentiation between primary mania and secondary mania is often based primarily on a temporal correlation between an organic factor and the manic behavior. In determining whether such a correlation is substantive, it is important to obtain a careful history of psychiatric symptoms before what is believed to be the initiating event, looking for previously unrecognized cyclical episodes of affective illness. Age at presentation can be a significant factor in determining the difference between secondary mania and primary bipolar disorder (see subsection "Mania in the Elderly" later in chapter). Bipolar illness most commonly has onset during the first three decades of life (Goodwin and Jamison 1990). Initial bipolar episodes rarely occur after age 50 years, although there is a growing literature describing late-life bipolar illness (Krishnan 2002).

In contrast to patients with primary mania, patients with secondary mania may have some cognitive dysfunction (American Psychiatric Association 1994). The likelihood that mania is secondary is greater when there is no prior personal or family history of bipolar disorder, when cognitive dysfunction or focal neurological signs are present, or when affective symptoms fail to respond to treatment. The distinction between primary and secondary mania may not be possible in some patients who have a preexisting vulnerability to bipolar disorder and in whom the medical illness or drug appears to have precipitated mania. The presence of a family history of affective disorder suggests but does not prove that a patient's mania is primary (Jorge et al. 1993). For example, approximately 30% of brain-injured patients with mania have at least one relative with unipolar depression (Shukla et al. 1987; Snowden 1991; Starkstein et al. 1987). A personal or family history of affective illness could indicate either that the mania is primary or that the patient was more vulnerable to developing secondary mania after brain injury. Postpartum mania is another example in which the primary–secondary distinction is often ambiguous, because precipitous hormonal change and preexisting bipolar vulnerability

may both play a role (see Chapter 33, "Obstetrics and Gynecology")

## Etiology

The etiology of secondary mania is heterogeneous, and it is likely that several different distinct mechanisms contribute to its pathophysiology. Secondary mania unrelated to primary bipolar illness has been attributed to various conditions, including drug use, central nervous system (CNS) trauma, neoplasms, vascular and degenerative diseases, epilepsy, infections, and metabolic conditions (Table 11–1) (Clayton 1981; Krauthammer and Klerman 1978; Stasiek and Zetin 1985). In cases of secondary mania caused by medications such as psychostimulants or dopamine agonists, behavioral changes are typically totally reversible. However, symptoms may persist in patients with mania secondary to CNS injury (from either traumatic injury or stroke), neoplasm, infection, or underlying neurodegenerative diseases such as Huntington's disease or multiple sclerosis (Evans et al. 1995; Rundell and Wise 1989).

### *Mania in the Elderly*

It is particularly appropriate to consider secondary mania in elderly patients with new-onset mania; they have been reported to be twice as likely to have a neurological disorder as patients with prior episodes of mania (Shulman and Post 1980; Shulman et al. 1987, 1992).

The relationships between bipolar disorder, old age, and dementia are not well defined (Shulman and Post 1980; Shulman et al. 1987, 1992). Bipolar patients above age 65 are not necessarily only those who have had bipolar disorder since they were much younger. A bimodal distribution of bipolar disorder for women has been noted, with the greatest peak before age 30 and a second peak in the late 40s (Goodwin and Jamison 1990). In men there is an increased incidence of mania in old age, with a peak in the eighth or ninth decade (Sibisi 1990; Spicer et al. 1973). There is increasing evidence of subtle vascular disease in elderly patients with mania (McDonald et al. 1991). It has been reported that a high prevalence of deep subcortical ischemic changes occurs in patients with late-life bipolar disorder. There is some evidence for genetic loading in elderly patients with bipolar disorder, but the number of affectively ill relatives is greater in the group with early-onset illness than in those with late-onset bipolar illness (Krishnan 2002).

Neurological impairment appears to create a diathesis for the development of late-onset mania. In a retrospective review of 50 patients age 65 or older admitted for an episode of mania (Shulman et al. 1992), the rate of con-

**TABLE 11–1. Selected causes of secondary mania**

<b>Neurological conditions</b>
Cryptococcal meningoencephalitis
Human immunodeficiency virus (HIV) encephalopathy
Huntington's disease
Kleine-Levin syndrome
Klinefelter's syndrome
Multiple sclerosis
Neurosyphilis
Psychomotor seizures
Strokes (temporal, right hemispheric)
Traumatic brain injury
Tumors (gliomas, meningiomas, thalamic metastases)
Viral encephalitis (acute or postinfection)
Wilson's disease
<b>Other systemic conditions</b>
Cushing's syndrome
Hyperthyroidism
Niacin deficiency
Postoperative delirium
Puerperal psychosis
Uremia
Vitamin B <sub>12</sub> deficiency
<b>Selected medications</b>
Amantadine
Amphetamines
Anabolic steroids
Antidepressants
Benzodiazepines (triazolam, alprazolam)
Bromocriptine
Cimetidine and other H <sub>2</sub> antagonists
Cocaine
Corticosteroids; corticosteroid withdrawal
Cyclobenzaprine
Cyproheptadine
Dextromethorphan
Dronabinol
<i>Hypericum</i> (St. John's wort)
Isoniazid
Levodopa
Methylphenidate and other stimulants
Monoamine oxidase inhibitors (MAOIs)
Procarbazine
Sympathomimetic amines (e.g., ephedrine)
Yohimbine
Zidovudine

current neurological disorders was significantly higher than in a group of depressed patients (36% vs. 8%). Fourteen of the 50 patients (28%) presented with a first episode of mania after age 65. Patients with new-onset mania were twice as likely to have had a comorbid neurological disorder than were elderly patients with multiple episodes

of mania (71% vs. 28%). Neuroimaging studies of a very small number of patients suggest that the right frontal lobe or limbic connecting areas might be involved in the development of secondary mania and that the underlying mechanism may be related to interruption of the fronto-temporal pathways (Gafoor and O'Keane 2003). Mania in the elderly is also associated with an increased mortality rate. During a mean follow-up period of 5.6 years, the mortality rate was significantly higher among elderly manic patients than among elderly patients without mania (50% vs. 20%) (Shulman et al. 1992).

### *Neurological Causes of Secondary Mania*

Many neurological disorders—including stroke, movement disorders, some demyelinating diseases, epilepsy, and head trauma—can manifest manic symptoms (Evans et al. 1995; Rundell and Wise 1989). Neurological disorders appear to be particularly important as risk factors for new onset of mania in the elderly (Krauthammer and Klerman 1978; Stasiak and Zetin 1985). In a retrospective review of the charts of 92 consecutively admitted manic patients older than 65 years, almost a quarter of the patients manifested cerebral disease (Parkinson's disease, cerebrovascular disease, or epilepsy) (Stone 1989). Patients with comorbid neurological diseases had significantly later age at onset and were less likely to have a family history of affective illness. Neurological mania is more likely to manifest as a single episode than as multiple recurrent episodes of mania or as bipolar disorder (Starkstein et al. 1987, 1991).

Some patients who develop secondary mania after brain injury have been reported to have focal brain lesions in the right hemisphere, usually involving the structures of the limbic system (R.G. Robinson et al. 1988; Starkstein et al. 1987). It is postulated that lesions affecting the right hemisphere and limbic structures may produce euphoria, hypersexuality, insomnia, hyperactivity, and irritability (Starkstein et al. 1991). Despite these observations, specific lesion locations have not been clearly established in secondary neurological mania. In part, this is because secondary mania associated with stroke is believed to be quite rare (R.G. Robinson et al. 1988; Wiart 1997). In one study, only two cases of mania were observed among more than 700 consecutive stroke patients (R.G. Robinson et al. 1988). Although patients with primary bipolar disorder have more focal lesions on magnetic resonance imaging (MRI) studies compared with control subjects, no specific lesion locations have been identified (Swayze et al. 1990).

**Huntington's disease.** Psychiatric symptoms in Huntington's disease are variable, but depression, irritability,

and anxiety are common (Glosser 2001). (See Chapter 7, "Dementia," and Chapter 32, "Neurology and Neurosurgery.") Some patients may display irritability, elevated mood, overactivity, decreased need for sleep, and increased risk of suicide, consistent with a diagnosis of secondary mania (Rosenblatt and Leroi 2000). According to one estimate, 4.8% of patients with Huntington's disease have mania (Mendez 2000). In another study, episodes of hypomania and mania were observed in up to 10% of patients with Huntington's disease (Folstein and Folstein 1983).

**Multiple sclerosis.** Multiple sclerosis is the most common demyelinating autoimmune disease (see Chapter 32, "Neurology and Neurosurgery"). It is believed that strategically located multiple sclerosis lesions could be the cause of psychosis in multiple sclerosis, with a mean duration of neurological symptoms before onset of psychosis of 8.5 years (Feinstein et al. 1992). Patients with multiple sclerosis may have euphoria, pathological laughing and weeping, and other frontal lobe disinhibition symptoms (Minden 2000). It has been reported that the incidence of bipolar disorder is greater in patients with multiple sclerosis than among the general population (Schiffer et al. 1986), but it is not clear to what extent this represents primary or secondary bipolar disorder. Diffuse, multifocal white matter lesions might "unmask" primary bipolar disorder or cause secondary mania (Kellner et al. 1984). However, most cases of secondary mania in multiple sclerosis patients may have been due to corticosteroid treatment rather than multiple sclerosis (E.S. Brown et al. 1999).

Depression occurs in multiple sclerosis far more often than mania and affects up to 40%–60% of patients (Patten and Metz 1997). In addition to CNS lesions, causes of depression in multiple sclerosis patients include the psychological experience of an unpredictable debilitating disease and treatment with corticosteroids or interferons (Mohr et al. 1999). The rate of suicide in patients with multiple sclerosis has been reported to be 7.5 times that in the age-matched general population (Sadovnick et al. 1991). It is not known if mania is a risk factor for suicide in multiple sclerosis, but extrapolations from observations of patients with primary mania indicate that caution is warranted. Regardless of the cause, the symptoms of mood disorders in people with multiple sclerosis generally benefit from standard treatments (Minden 2000).

**Traumatic brain injury.** Mood disorders have been estimated to occur in 6%–7.7% of all patients with traumatic brain injury (TBI) (Rao and Lyketsos 2002), and secondary mania has been estimated to occur in 3%–10% (Jorge et al. 1993) (see also Chapter 35, "Physical Medicine and

Rehabilitation"). Estimates of the frequency of aggressive behaviors during the acute period after TBI have ranged from 11% to 96% (Tateno et al. 2003). Despite the frequency of TBI, the literature regarding TBI-associated bipolar disorder is limited to case reports and small series. In the largest case series of TBI patients with manic symptoms, 66 TBI patients were observed for 1 year after their initial injury (Jorge et al. 1993). Approximately 9% (6 of 66) met the DSM-III-R criteria for bipolar disorder (American Psychiatric Association 1987). Symptoms included expansive mood, irritability, increased motor or verbal activity, evidence of thought disorder, increased sexual interest, aggressive behavior, decreased need for sleep, and grandiose delusions. The duration of each manic episode was relatively brief (lasting only 2 months on average). Neuroimaging revealed a greater prevalence of anterior temporal lobe lesions.

The study by Jorge et al. (1993) found no apparent association between secondary mania of TBI origin and family history of mood disorder, personal history of psychiatric illness, severity of brain injury, degree of physical or cognitive impairment, social support, social level of functioning, or posttraumatic epilepsy. However, in one study of 20 patients with a history of TBI who were referred for schizoaffective or manic symptoms, 30% had at least one relative with a history of depression (Shukla and Cook 1987). The interval between injury and onset of symptoms ranged from less than 1 year to 12 years, although in 14 of 20 cases it was less than 2 years.

**HIV infection.** HIV infection is an important risk factor for the development of secondary mania, which is believed to result from brain infection with HIV (see also Chapter 28, "HIV/AIDS"). Secondary mania associated with HIV infection may be differentiated from primary mania in HIV-infected patients by its late onset in the course of the infection and its association with cognitive decline and AIDS dementia. Although mania has been reported to occur in 4%–8% of HIV-infected individuals, the prevalence of mania that is directly attributable to an HIV-related focus is not known (Kilbourne et al. 2001; Lyketsos et al. 1993a). Advanced disease is an ever-increasing risk factor for the evolution of HIV-related mania. Patients with later onset of manic symptoms (presumed to be secondary mania) were less likely than those with early-onset mania to have had a personal or family history of affective disorder but were more likely to have a concurrent diagnosis of dementia (Lyketsos et al. 1993a).

The mood of patients with secondary mania due to HIV infection is most often described as a combination of elevated, irritable, and labile (Ellen et al. 1999; Lyketsos et al. 1993a, 1993b, 1997). Imaging studies of one group

of HIV-infected patients with secondary mania revealed neurological abnormalities in 53%. The most common finding was bilateral white matter foci, usually in the periventricular areas (Ellen et al. 1999).

### ***Endocrine Abnormalities***

A variety of endocrine disorders, including Cushing's disease and thyroid abnormalities, are associated with secondary mania (Brownlie et al. 2000) (see also Chapter 23, "Endocrine and Metabolic Disorders"). Mania has been reported in patients with hyperthyroidism (Corn and Checkley 1983; Villani and Weitzel 1979). Hypothyroidism does not cause mania per se, but it is well known to induce rapid cycling in patients with primary bipolar disorder. Treatment with corticosteroids is probably the most common cause of secondary mania (Rundell and Wise 1989). Depression is more common than mania as a steroid side effect, but mixed states also occur. Steroid-induced mood disorder can be severe; in one study, 51% of patients exhibiting either hypomania or depression developed psychotic symptoms (K. Wada et al. 2001).

### ***Substance-Induced Mania***

Many other classes of illicit substances and prescription medications have induced well-documented cases of secondary mania (see Table 11-1 for full list). As mentioned above, corticosteroids and dopaminergic agonists (e.g., levodopa, bromocriptine, and amantadine) are frequent causes of secondary mania. Over-the-counter sympathomimetic agents and cocaine have precipitated severe cases of manic behavior. Because they inhibit monoamine oxidase, isoniazid and procarbazine have caused mania even in patients without histories of any mood disorder. Cimetidine and other histamine H<sub>2</sub> receptor antagonists have also been reported to cause secondary mania.

Other compounds that have been reported to lead to the development of mania include cyclobenzaprine; yohimbine; baclofen; phencyclidine; and several of the benzodiazepines, including alprazolam and triazolam (Goodman and Charney 1987; Weilberg et al. 1987).

### **Evaluation**

All patients with suspected secondary mania should have a complete evaluation, including a careful history and physical examination and appropriate laboratory and imaging studies. Depending on the likelihood of particular etiologies, testing may include metabolic and endocrine tests (especially cortisol and thyroid-stimulating hormone), complete blood cell count, HIV test, fluorescent treponemal antibody test, urine toxicology screen, com-

puted tomography (CT) or MRI brain scan, lumbar puncture, and other investigations.

### **Treatment of Primary and Secondary Mania in the Medically Ill**

There are essentially no data from controlled trials of drug treatments for secondary manic syndromes, so clinical practice has been guided by case reports and clinical experience (Evans et al. 1995; Halman et al. 1993; Shulman et al. 1987). The first step, whenever possible, is to treat the underlying disorder or eliminate the offending agent. When this is not possible (e.g., with steroid-induced mania in a patient with lupus), symptomatic treatment is indicated. Medications that are recommended are essentially the same as those used in primary bipolar disorder, with only occasional caveats.

As with primary mania, lithium, divalproex sodium, and carbamazepine are the mainstays of treatment and can be used prophylactically to prevent drug-induced mania (e.g., due to steroids). Lithium is difficult to use safely in patients with unstable fluid/electrolyte status or hyperthyroidism. Lithium is effective not only for manic symptoms but also for depression induced by corticosteroids (K. Wada et al. 2001), but it may be contraindicated by the underlying medical disorder (e.g., renal disease in systemic lupus erythematosus; see Chapter 25, "Rheumatology"). Some of the more recently developed anti-convulsants may also prove helpful in patients who do not respond to or cannot tolerate first-line drugs.

Both the older typical and newer antipsychotic drugs appear to have antimanic effects and may provide mood stability in secondary mania regardless of whether the patient also has psychosis. For patients with acute secondary mania, particularly when it is expected to be temporary, antipsychotics may be more helpful than lithium or anticonvulsants because of faster onset of benefit. In neurological secondary mania, atypical antipsychotics are generally preferable because of their lower risk of extrapyramidal side effects (Gupta et al. 1999; Masand and Gupta 2000). Bupirone may also be helpful in treating disruptive behaviors in patients with Huntington's disease or other neurological disorders (Bhandary and Masand 1997). Treatment of HIV mania is addressed in Chapter 28, "HIV/AIDS."

### **Catatonia in the Medically Ill**

Although it is a relatively rare condition, catatonia may be acute or chronic and can be caused by psychiatric disor-

ders, medical illnesses, or drugs. Catatonia occurs as a subtype of schizophrenia but more often as part of severe affective illness. We focus here primarily on secondary catatonia caused by medical illness or drugs and on the medical complications encountered in chronic catatonia of any cause.

## Secondary Catatonia

### Diagnosis

The core features of catatonia are stupor, motoric immobility, mutism, negativism, excitement, catalepsy, and posturing. The core features are the same regardless of whether the condition occurs in the context of a mood, psychotic, or medical state. The latter is recognized in DSM-IV-TR as the category of catatonia secondary to a general medical condition. A full history and those aspects of the physical examination requiring cooperation are usually not obtainable from a catatonic patient, so information must be sought from family members and other sources.

Other disease states can mimic catatonia and should be considered in the differential diagnosis. These conditions include stiff-person syndrome, akinetic Parkinson's disease, malignant hyperthermia, locked-in syndrome, elective mutism, and hyperkinetic and hypokinetic states (Fink and Taylor 2003). Stiff-person syndrome is an uncommon autoimmune disorder with progressive muscle stiffness, rigidity, and spasm, slowly progressive over the course of years (Helfgott 2003). Akinetic Parkinson's disease also can produce a state similar to catatonia, but it usually occurs after the diagnosis of Parkinson's disease has been well established. Malignant hyperthermia often includes some of the characteristics of catatonia, but it occurs in the context of anesthesia. Elective mutism shares only that one feature of catatonia and is usually associated with conversion or underlying personality disorders (Fink and Taylor 2003). Hyperkinetic (e.g., Gilles de la Tourette's syndrome, cerebral palsy) and hypokinetic (e.g., Huntington's disease, Wilson's disease) movement disorders can have some features of catatonia as well.

### Etiology

Catatonia has been associated with a number of medical conditions, including metabolic, neurological, and substance disorders (Table 11-2). In a review of the literature from 1966 to 1993, 261 cases of catatonia were identified (Carroll et al. 1994). In 76% of these cases, there was no relevant psychiatric disorder associated with the catatonic state. CNS injury or dysfunction—resulting from stroke, trauma, CNS tumor, seizures, infection, or anoxia—is the

most common cause of secondary catatonia. Strokes involving the anterior cerebral circulation have the propensity to cause akinetic and apathetic states (Kumral et al. 2002). Bilateral infarction of the cingulate gyri of the medial frontal lobes can lead to a lack of spontaneous motor movement and mutism (Reichman 1995). CNS tumors such as astrocytomas may initially present with catatonia (Muqit et al. 2001). Catatonia may also be caused by epilepsy or by endocrine or metabolic disorders, including hypothyroidism, adrenal insufficiency, and vitamin B<sub>12</sub> deficiency (Catalano et al. 1998).

**TABLE 11-2. Selected causes of secondary catatonia**

#### Neurological causes

Angiomas  
Basilar artery thrombosis  
Bilateral infarction of the anterior cingulate gyrus  
Bilateral infarction of the temporal lobes  
Cerebral anoxia  
Closed head injury  
Encephalitis or other central nervous system infection (e.g., neurosyphilis)  
Gliomas  
HIV encephalopathy  
Normal-pressure hydrocephalus  
Seizure disorders  
Surgery near the hypothalamus

#### Other medical causes

Addison's disease  
Bacterial sepsis  
Cushing's disease  
Encephalitis (acute or postinfectious)  
HIV encephalopathy  
Hyperthyroidism  
Malaria  
Neurosyphilis  
Postoperative states  
Postpartum psychosis  
Systemic lupus erythematosus  
Typhoid fever  
Uremia  
Viral hepatitis  
Vitamin deficiencies

#### Medications and toxic substances

Corticosteroids  
Cyclobenzaprine  
Disulfiram  
3,4-Methylenedioxymethamphetamine (MDMA; Ecstasy)  
Phencyclidine (PCP)  
Sedative-hypnotic withdrawal  
Tetraethyl lead poisoning

A number of drugs and toxins may cause catatonia (see Table 11–2). Persons under the influence of hallucinogens, such as phencyclidine (PCP) or 3,4-methylenedioxymethamphetamine (MDMA; Ecstasy) (Masi et al. 2002), may present in an excited catatonic state. Carbon monoxide toxicity can cause catatonia due to damage to the putamen, caudate nucleus, or globus pallidus.

Neuroleptics may cause a parkinsonian catatonic state. Serotonergic agents can cause serotonin syndrome, and antidopaminergic agents can cause neuroleptic malignant syndrome. Both serotonin syndrome and neuroleptic malignant syndrome may cause catatonia in addition to their other symptoms. Neuroleptic malignant syndrome can be particularly difficult to distinguish from severe agitated primary catatonia, often called lethal catatonia (Mann et al. 1986). If a patient with catatonia of any etiology is treated with a neuroleptic, it can be difficult, if not impossible, to discriminate the original catatonia from neuroleptic-induced catatonia and neuroleptic malignant syndrome.

### **Complications**

The care of patients in a chronic or relapsing catatonic state can be challenging from both a medical and a psychiatric standpoint. Although catatonia can encompass varying states of psychomotor abnormalities from excitement to rigid stupor, patients are often bedridden and undernourished, which contributes to their frequent long-term medical complications. The inability of catatonic patients to report their symptoms requires clinicians to be vigilant regarding such complications. In a chart review (1985–1991) of patients with catatonia, Carroll (1996) described complications, including deep venous thrombosis, nonfatal pulmonary embolism, urinary tract infection, urosepsis, cachexia, hypernatremia, rhabdomyolysis, acute tubular necrosis, aspiration pneumonia, and flexion contractures.

**Cardiovascular complications.** One problem for catatonic patients is cardiovascular deconditioning, especially orthostatic intolerance, which occurs after only a few weeks of bed rest. In addition to vascular changes, cardiopulmonary efficiency is also reduced. The use of psychotropic medications that have central and peripheral cardiovascular effects may further aggravate cardiovascular dysfunction in patients with catatonia (Gupta et al. 2001).

A significant source of morbidity and mortality in patients with catatonia is deep venous thrombosis and subsequent pulmonary embolism (Barbuto 1983; McCall et al. 1995; Morioka et al. 1997; Regestein et al. 1977; Sukov 1972). Prolonged immobilization and dehydration are

risk factors that promote venous thrombosis. Carroll (1996) observed that about 6% of catatonic patients developed venous thrombosis. Prevention of thrombosis and subsequent pulmonary embolism has been studied extensively in acute medical conditions associated with immobility, as well as after various surgical procedures (Turpie et al. 2002). Maintenance of hydration, physical therapy, support hose, and prophylactic anticoagulation have all been suggested for prevention. Although subcutaneous heparin and low-molecular-weight heparin are well supported by studies in patients following orthopedic surgery, a time when the risk of venous thromboembolism is high, the increased risk is much lower in chronically immobilized patients (Heit et al. 2002). Whether heparin would reduce morbidity and mortality in catatonia is unknown and is worthy of study.

**Pulmonary system complications.** The most frequent pulmonary complication seen in chronic catatonia is aspiration (Levenson and Pandurangi 2004), which is also the most common cause of death in patients with dysphagia caused by neurological disorders and the most common cause of death in patients nourished by tube feeding (Marik 2001). Aspiration can result in pneumonitis or pneumonia. Aspiration pneumonitis is the regurgitation of gastric contents into the pulmonary tree with an accompanying inflammatory response. Aspiration pneumonia is an infection by aspirated bacteria, usually from oropharyngeal secretions. Aspiration pneumonitis can be considered a chemical pneumonitis caused by gastric acid. Although antacids, histamine H<sub>2</sub> blockers, and proton-pump inhibitors can decrease stomach acidity, their use prevents the sterility of gastric contents and can make aspiration of gastric contents more likely and more severe (Marik 2001). Conventional neuroleptics may also increase the risk of aspiration, perhaps via the effects of dystonia on swallowing (H. Wada et al. 2001). Daily oral hygiene can lessen the risk of aspiration pneumonia (Shay 2002). Unfortunately, this is not a priority in the care of the chronically ill and is usually overlooked in patients with catatonia. Anticholinergic psychiatric medications that reduce salivation may also promote pathogenic oral flora. Prophylactic antibiotics are not recommended (Levenson and Pandurangi 2004).

**Gastrointestinal system complications.** Maintaining nutrition is a challenge in persistently catatonic patients. When required, enteral feeding can be provided either by nasally or surgically placed tubes. Nasogastric or nasoenteric tubes are preferred in patients who will need invasive feeding for 30 days or less (Koretz et al. 2001). Placement of these tubes is not benign. Patients with altered mental

status are especially at risk because of the inability to cooperate with the procedure and the presence of a decreased gag reflex. Cases of malpositioning, pulmonary intubation, and death have all been reported with the use of enteral feeding tubes (Raff et al. 1987). Also, contrary to common belief, nasogastric feeding tubes do not prevent aspiration (Finucane et al. 1999). For chronically catatonic patients requiring ongoing artificial feeding, surgical gastrostomy and jejunostomy are options. However, pathogenic colonization occurs in patients fed by either nasogastric or percutaneous enterogastric tubes (Leibovitz et al. 2003). In patients with acute or periodic catatonia, tube feeding with nutritional supplements is appropriate. However, the chronic catatonic patient presents an ethical dilemma (similar to that encountered in other chronic debilitating diseases such as dementia, amyotrophic lateral sclerosis, or Parkinson's disease) that requires careful weighing of the benefits of enteral feedings versus their complications and effects on general health and quality of life (Finucane et al. 1999; Levenson and Pandurangi 2004; Li 2002). These factors should all be considered before the initiation of tube feedings in any severely chronically ill patient.

**Dermatological complications.** Pressure ulcers (also called decubitus ulcers) are common in patients with chronic catatonia, and their complications include sepsis, osteomyelitis, and increased mortality risk (Thomas 2001). Frequent turning is necessary but is not always sufficient to prevent pressure ulcers. Although malnutrition is associated with risk of development of pressure ulcers, nutritional supplementation has not been proven to prevent their occurrence (Thomas 2001). The use of pressure-relieving beds helps, but no one device has proven to be superior (S.J. Brown 2001). Maintaining clean, dry skin prevents maceration and breakdown of the skin. Compared with diapering, the use of Foley catheters may actually increase the risk of pressure ulcers (Thomas 2001). Fecal contamination is a major risk in the development of pressure ulcers.

**Musculoskeletal system complications.** Skeletal muscle deconditioning occurs in patients with chronic catatonia as in other immobilized patients. Catatonic patients with muscle rigidity are particularly vulnerable to the development of flexion contractures in response to loss of muscle use and shortening of the ligaments. The best treatment is prevention through physical therapy; once contractures develop, treatment benefits are limited (Fox et al. 2000). Finally, prolonged immobility is a risk for the development of rhabdomyolysis. Although rhabdomyolysis is a recognized complication of lethal catatonia and neuro-

leptic malignant syndrome, its frequency in chronic catatonia is unknown (Levenson and Pandurangi 2004).

### *Treatment of Secondary Catatonia*

If a medical or neurological condition is determined to be the cause of catatonia, treatment should be directed at the underlying condition. When this is not possible or when catatonia persists or interferes with treatment, benzodiazepines and electroconvulsive therapy (ECT) are the mainstays of treatment (Bush et al. 1996). Benzodiazepines may provide almost immediate benefit for the motor and speech signs of catatonia. Bush and associates (1996) prospectively used lorazepam in 21 patients with catatonia and found symptom remission in 16 patients. After a 5-day trial of lorazepam, patients who were still not responding were administered ECT, with remission occurring in 4 of the remaining 5 patients. ECT is the most effective treatment for catatonia (American Psychiatric Association 2001) and can be used safely in almost all medically ill individuals (Christopher 2003) (see Chapter 39, "Electroconvulsive Therapy").

## **Psychosis in the Medically Ill**

---

In addition to their occurrence in major psychiatric disorders such as schizophrenia and mood disorders, psychotic symptoms frequently occur as a part of several medical illnesses. Psychotic symptoms may also be induced by psychoactive substances or by medications that are used to treat medical disorders. Psychotic symptoms in medically ill patients can complicate the diagnosis and management of the medical condition in several ways but can usually be ameliorated with appropriate interventions.

### **Primary Psychosis**

Because schizophrenia and related disorders occur in 1%–2% of the general population, the possibility of a primary psychotic disorder should be considered in a medically ill patient who manifests psychotic symptoms before attributing them to the medical illness. In general, the usual medications for treatment of primary psychosis can be used in the medically ill, but selection of a particular drug and determination of the dosage depend on the underlying medical illness.

There are a number of potential complications of primary psychotic disorders in the medically ill. Schizophrenia itself carries an increased risk for several medical comorbidities, such as obesity and diabetes (Dixon et al. 2000; Ryan et al. 2003), relative to the risk of these con-

ditions in the general population (Gupta et al. 1997; Jeste et al. 1996). Most antipsychotics add to these risks, causing weight gain (Allison et al. 1999; Masand 1999, 2000c), elevated glucose levels, and hyperlipidemia (Wirshing et al. 2003). Patients with schizophrenia often have poor health habits, such as inadequate nutrition, physical inactivity, and high rates of smoking and substance abuse (Dixon 2003; Patkar et al. 2002). Poverty, institutionalization, self-neglect, and social isolation may all adversely affect health in chronic psychosis. Patients with chronic schizophrenia often have problems with access to health care and with adherence to complex treatment regimens. Among the homeless, those with schizophrenia have fewer medical visits and documented medical complaints than those with depression and are less likely to have careful physical examinations and screenings for medical disorders (Folsom et al. 2002). Somatic delusions and hallucinations, psychotic denial, and thought disorder may lead to physical symptoms being misperceived or ignored by patients and clinicians, leading to delay in medical treatment (Reeves and Torres 2003). Psychosis may negatively affect the patient's relationship with health care providers, interfering with communication and eliciting a variety of negative countertransference reactions. Finally, poor integration between the mental health care and general health care systems disrupts continuity of care for these patients.

## Secondary Psychosis

### *Diagnosis*

When psychotic symptoms are observed in a patient who has a concurrent medical illness, the following possibilities should be considered:

1. Preexistence, exacerbation, or new onset of a "primary" psychotic disorder (e.g., schizophrenia, bipolar disorder)
2. Delirium or dementia
3. Psychotic disorder due to a general medical condition (American Psychiatric Association 2000)
4. Psychoactive substance use or withdrawal (including medications)

In a medically ill patient, an attempt should be made to distinguish between a primary and a secondary psychotic disorder on the basis of the patient's history and clinical features (Table 11–3). Distinguishing the two is often challenging because of the similarities in the clinical features and difficulties in establishing a cause-and-effect relationship between a putative etiological medical condition or medication and psychotic symptoms. Certain his-

torical information makes a secondary psychosis more likely; this includes first onset of psychotic symptoms at an older age, absence of a past or family history of primary psychotic disorders, a concomitant medical condition known to cause psychotic symptoms, active substance use or withdrawal, and atypical clinical features. Visual hallucinations are more frequent in secondary psychoses, as are olfactory, gustatory, and tactile hallucinations. Cognitive deficits and focal abnormalities on the neurological examination also point toward secondary psychosis. The temporal pattern of the symptoms should be carefully delineated and may be the most important factor in making the diagnosis. Onset of psychotic symptoms much earlier than the putative cause usually suggests primary psychosis, but the possibility that the psychosis was the first symptom of an evolving medical condition should be considered. If the onset and resolution of the psychotic symptoms parallel the course of the putative causative factor, a diagnosis of secondary psychosis is more likely. Rapid and complete resolution of psychotic symptoms on elimination of the suspected factor may confirm the causative relationship. The diagnosis often becomes more obvious with the evolution of the syndrome. Specific tests (see subsection "Evaluation" below) may also provide useful information to distinguish between primary and secondary psychoses.

### *Etiology*

Selected medical conditions that may cause psychotic symptoms are listed in Table 11–4. Although many medications can cause psychotic symptoms at toxic doses, Table 11–5 lists selected medications that have caused psychotic symptoms at therapeutic doses.

Delirium and dementia are perhaps the most common causes of psychotic symptoms in the medically ill. Delusions occur in approximately 20% of patients with delirium and 45% of those with dementia (Rabins et al. 1982). Psychosis is also discussed in Chapter 6, "Delirium," and Chapter 7, "Dementia."

Psychotic symptoms due to brain disease or injury occur most often with subcortical or temporal lobe lesions. Psychosis related to seizure disorders is more common during the interictal phase, after a long history of seizures, and when there is evidence of temporal lobe lesions or left-sided foci (Cummings 1985). Psychotic symptoms can occur ictally, postictally, or interictally. Brief psychotic symptoms can occur in nonconvulsive status epilepticus, most commonly with partial complex status (Sachdev 1998). In such cases, automatisms (e.g., lip smacking, picking at clothes), mutism, altered consciousness, or amnesia may be present. Postictal psychosis follows an increase in the frequency of seizures, usually with

**TABLE 11-3. Clinical features differentiating primary from secondary psychotic disorders**

	<b>Primary psychosis (e.g., schizophrenia, mood disorder)</b>	<b>Secondary psychosis (due to a general medical condition or substance related)</b>
Gross cognitive function	Relatively normal	Abnormal
Level of consciousness	Normal	Often abnormal or fluctuating
Focal neurological signs	Absent	May be present
Hallucinations	Auditory most common Tactile/olfactory/gustatory uncommon	Visual most common Tactile/olfactory/gustatory may be present
Delusions	Often complex	Usually simple
Thought disorder	May be prominent in schizophrenia (thought process often includes loose associations and idiosyncratic language)	Not prominent (thought process may be concrete or perseverative)
Incontinence	Usually absent	May be present
Vital signs	Usually normal	Often abnormal

**TABLE 11-4. Selected medical disorders that may cause psychosis****Brain diseases**

Central nervous system vasculitis  
 Encephalitis or other central nervous system infection (e.g., neurosyphilis)  
 HIV encephalopathy  
 Huntington's disease  
 Paraneoplastic encephalitis  
 Psychomotor seizures (ictal, postictal, or interictal)  
 Stroke  
 Tumor  
 Wilson's disease

**Endocrine disorders**

Cushing's syndrome  
 Hypothyroidism or hyperthyroidism

**Metabolic disorders**

Acute intermittent porphyria  
 Hepatic encephalopathy  
 Hypoglycemia  
 Hyponatremia  
 Uremia  
 Vitamin deficiency (e.g., Korsakoff's psychosis with thiamine deficiency, B<sub>12</sub> deficiency)

a nonpsychotic period of 1–7 days between the last seizure and the psychosis. Finally, interictal psychosis can occur even in the absence of frequent seizures, but it usually occurs in patients with poorly controlled seizures. It is typically self-limiting but can last for a few weeks. Unlike postictal psychosis, interictal psychosis is sometimes ameliorated by the occurrence of one or more seizures (Sachdev 1998). Chronic interictal psychosis differs from schizophrenia by the presence of better preservation of

affect, mood swings, mystical experiences, and visual hallucinations (Slater et al. 1963; see also Chapter 32, "Neurology and Neurosurgery").

Substance-induced psychotic disorder (see Chapter 18, "Substance-Related Disorders") is commonly caused by intoxication with cocaine, amphetamines, or phencyclidine and may persist after the elimination of the drug or its metabolites (Hill et al. 2001; Serper et al. 1995). A negative drug screen does not exclude the possibility that psychotic symptoms were caused by drugs that are not routinely tested for (e.g., hallucinogens) or that may have been eliminated from the body or are otherwise undetectable. Although transient paranoia may be observed in association with cannabis use, cannabis-induced psychotic disorder is rare. Substances most likely to cause psychotic symptoms during withdrawal are sedative-hypnotics and alcohol.

**Evaluation**

A careful workup of secondary psychosis includes chart review, history, physical examination, and laboratory and radiological investigations (Patkar and Kunkel 1997). Some tests that are performed are considered routine, and others are obtained only if there are more specific reasons to justify them. Usually included in the former category are complete blood cell count, metabolic panel, serum calcium, liver function tests, thyroid-stimulating hormone level, syphilis test, urinalysis, and urine toxicology screen. Common optional tests include chest radiograph, serum drug levels (e.g., theophylline), arterial blood gases, vitamin B<sub>12</sub> and folate levels, HIV, CT or MRI scan, and lumbar puncture. Additional investigations may be necessary depending on the clinical features and course of symptoms (e.g., if porphyria is suspected).

**TABLE 11–5. Selected medications that may cause psychotic symptoms**

Type of medication	Examples
<b>Psychotropic</b>	Antidepressants Anticholinergics (e.g., benztropine, diphenhydramine) Disulfiram
<b>Cardiovascular</b>	Antiarrhythmics (lidocaine, mexiletine, procainamide, quinidine, tocainide) Beta-blockers Digitalis
<b>Antihistaminic</b>	Cimetidine, ranitidine, diphenhydramine
<b>Antineoplastic</b>	Asparaginase, cytarabine, fluorouracil, ifosfamide, methotrexate, vincristine
<b>Anti-infective</b>	Antimalarials Antituberculars (cycloserine, isoniazid) Antivirals (acyclovir, interferon, vidarabine, zidovudine) Ciprofloxacin
<b>Anticonvulsant</b>	Carbamazepine, ethosuximide, lamotrigine, phenytoin, valproate
<b>Anti-inflammatory</b>	Corticosteroids, indomethacin
<b>Dopaminergic</b>	Amantadine, bromocriptine, levodopa, pramipexole, ropinirole
<b>Opioid</b>	Meperidine, pentazocine
<b>Sympathomimetic</b>	Ephedrine, pseudoephedrine
<b>Other</b>	Baclofen, cyclosporine, metrizamide, methysergide

### Complications

Perhaps the most important complication associated with secondary psychosis in the medically ill is when the diagnosis is missed and the patient is treated as if he or she had schizophrenia or another primary psychotic disorder. As noted earlier, psychosis of any cause can adversely affect the doctor–patient relationship and the patient’s ability to cooperate with medical evaluation and treatment.

### Treatment

The overall goals are to maintain the safety of the patient and others, to identify and treat the underlying medical condition, and to treat the psychotic symptoms. Close collaboration between the psychiatrist and the medical staff involved in the care of the patient is required. Constant observation, restraints, or both may be necessary to prevent self-injury or disruptive behavior (see Chapter 8, “Aggression and Violence”). To ensure safety of the patient and staff, involuntary treatment may be necessary (see Chapter 3, “Legal Issues”). Psychological support includes reassurance and education of the patient and the family about the symptoms and their causes, if known. Vital signs, nutritional status, and fluid–electrolyte balance should be closely monitored.

### Treatment of Patients With Primary Psychosis

Psychotic patients who are unstable should not undergo repeated interviews by groups of trainees or by other personnel (Adler and Griffith 1991). Simple, straightforward

information is indicated rather than detailed technical descriptions of medical interventions. Whenever feasible, efforts should be made to psychiatrically stabilize any acutely psychotic patient before any medical or surgical procedures are performed. Close collaboration between psychiatric and medical staff is needed to coordinate the patient’s medical care and determine whether inpatients are best treated on a medical unit with psychiatric consultation or on a psychiatric unit with medical consultation. Treatment of psychosis during pregnancy and the postpartum period is discussed in Chapter 33, “Obstetrics and Gynecology.”

**Antipsychotic agents.** The elderly and the medically ill are particularly sensitive to the adverse effects of antipsychotics (Masand 2000a, 2000b), but they also tend to respond to lower doses. The time-honored principle of “start low and go slow” is particularly important in the medically ill. However, the dosage should be individualized, and increasing the dosage should be considered if the patient’s response is inadequate. The use of antipsychotics in the medically ill is covered in detail in Chapter 37, “Psychopharmacology,” but we review some highlights here.

In general, antipsychotics are selected on the basis of potential side effects, some of which may be desired. Of the typical antipsychotics, haloperidol is preferred in medically ill patients because of extensive experience with its use and because it has minimal sedative and anticholinergic properties, has little or no effect on respiration, and

can be administered parenterally. Although there are few data from controlled studies, clinical experience suggests that atypical antipsychotics may be safe and effective in the medically ill and have the advantages of fewer extrapyramidal side effects compared with older agents (Caley and Cooper 2002; Duggan et al. 2003; Marder et al. 2003; Masand 1998; Nasrallah and Tandon 2002). Therefore, atypicals are preferred, especially if there is a history of extrapyramidal side effects, tardive dyskinesia, or a coexisting movement disorder (e.g., Parkinson's disease). For agitated patients, atypical agents with sedative properties, such as quetiapine, may be appropriate. On the other hand, when sedation is not necessary, an agent such as risperidone, aripiprazole, or ziprasidone should be considered.

The patient's medical status may require a particular method of drug administration. It may be preferable to give the antipsychotic as a liquid (e.g., haloperidol, risperidone, ziprasidone) or as an orally disintegrating tablet (e.g., olanzapine, risperidone) to patients who have difficulty swallowing pills (Kelleher et al. 2002). For treatment of patients who are not allowed oral medication, at present only haloperidol, olanzapine, and ziprasidone are available for intramuscular injection. If many doses are required, intramuscular administration is not practicable, and intravenous haloperidol should be considered.

Antipsychotics can be used in cardiac patients even after an acute myocardial infarction. Haloperidol has generally been used safely but has been implicated as causing torsades de pointes when used intravenously in patients with cardiomyopathy (M.J. Robinson and Levenson 2000).

Although cholestatic hepatitis has been reported with atypical antipsychotics and with some low-potency typical antipsychotics, liver disease does not appear to increase the risk of hepatotoxicity of antipsychotic agents. Mild elevations in liver enzymes do not contraindicate the use of antipsychotics, because these changes may be transient and do not always lead to more severe hepatotoxicity (Stoudemire et al. 1991). All antipsychotics are metabolized in the liver to a large extent, and therefore they should be used more cautiously in patients with hepatic failure. Reduction in quetiapine dosage has been recommended for the elderly and for patients with hepatic impairment (Nemeroff et al. 2002). Mild to moderate hepatic impairment does not significantly alter the pharmacokinetics of ziprasidone (Everson et al. 2000), and the pharmacokinetics of risperidone were not significantly altered even in patients with cirrhosis (Snoek et al. 1995).

In renal failure, clearance of risperidone is decreased. Therefore, risperidone should be started at lower doses than usual and the dose increases should be gradual in pa-

tients with renal failure (Snoek et al. 1995). Although the manufacturers do not specifically recommend dose adjustments for other atypical antipsychotics in renal failure, it is prudent to be similarly cautious when treating renal patients because of their comorbidities. Mild to moderate impairment in renal function and hemodialysis do not seem to have a significant effect on the pharmacokinetics of ziprasidone (Aweeka et al. 2000). Dehydration increases the risk of neuroleptic malignant syndrome, so fluid intake should be carefully monitored when medically ill patients are given antipsychotics.

The presence of any type of brain injury increases the likelihood of seizures, and therefore the use of antipsychotics that lower seizure threshold to a greater extent (e.g., clozapine) should be avoided (Stoudemire et al. 1991).

**Benzodiazepines.** Benzodiazepines are sometimes used for agitation in medically ill patients with psychosis. Lorazepam and oxazepam are desirable because of their lack of active metabolites, their shorter half-lives, and their minimal hepatic metabolism. In general, however, benzodiazepines should be avoided (except in alcohol or sedative withdrawal), particularly in patients with brain injuries, because these agents may paradoxically aggravate agitation. If a benzodiazepine is used for control of severe agitation, intramuscular lorazepam (1 mg, repeated after 1 hour if needed) is preferred because of its reliable absorption. It can also be given intravenously (0.5–1.0 mg administered over 2 minutes).

**Other medications.** Anticonvulsants are not specifically indicated for the treatment of psychotic symptoms (except for those attributed to seizure disorder) but may be used for the treatment of bipolar disorder, a potential cause of psychotic symptoms.

### *Treatment of Secondary Psychosis in the Medically Ill*

In addition to the measures discussed in the previous subsections, there are some additional considerations in patients with secondary psychosis. All nonessential medications should be discontinued or reduced in dosage if they are possible contributors. Antipsychotics should be used when psychotic symptoms interfere with treatment, present risk of harm to the patient or others, or cause personal distress (American Psychiatric Association 1999). In using antipsychotics, the patient's condition should be assessed repeatedly. If there is a rapid and complete resolution of symptoms, the possibility that an "organic" cause has been reversed should be considered and the antipsychotic tapered.

Second-generation antipsychotics are being increasingly used in the treatment of delirium (Schwartz and Masand 2002). There are open-label data to support the use in delirium for olanzapine (Breitbart et al. 2002; Sipahimalani and Masand 1998; Skrobik et al. 2004), low-dose risperidone (Horikawa et al. 2003; Sipahimalani et al. 1997), and quetiapine (Pae et al. 2004; Sasaki et al. 2003). Haloperidol, however, remains the first choice if repeated parenteral administration is needed or cost is a significant factor (Masand et al. 2002).

In dementia with psychotic symptoms, low-potency typical antipsychotics or adjunctive anticholinergics should be avoided. Second-generation antipsychotics are being increasingly used for psychosis or agitation in patients with dementia. At present, double-blind studies support the use of risperidone (Katz et al. 1999) and olanzapine (De Deyn et al. 2004; Schatz 2003 [review of four studies]).

Benzodiazepines are used in alcohol or sedative-hypnotic withdrawal and in seizure disorders. Anticonvulsants are indicated for the treatment of psychosis associated with seizure disorders, but antipsychotics and/or benzodiazepines may be necessary in addition. At this time, there is no evidence to suggest that more recently developed anticonvulsants—including gabapentin, topiramate, and levetiracetam—provide specific benefits for the treatment of psychosis.

## Conclusion

The diagnosis and treatment of psychiatric symptoms in medically ill patients can be challenging, not only because of the wider differential diagnosis that must be considered but also because of the complex interactions of psychiatric symptoms, medical illnesses, and medications. However, with careful attention to obtaining accurate and complete clinical data, consideration of the effects of medical and psychiatric illnesses on each other, and comprehensive treatment planning, tremendous benefit can accrue to these often very sick and suffering patients.

# 12 Anxiety Disorders

---

Steven A. Epstein, M.D.

Daniel Hicks, M.D.

**ANXIETY IS AN** extremely common problem in primary care and specialty medical settings. Because the lifetime prevalence rate of any anxiety disorder in the general population is approximately 25% (Kessler et al. 1994), many medically ill patients will have concurrent anxiety unrelated to the experience of medical illness. The profound physical and psychological stressors of medical illness often precipitate anxiety, particularly in individuals with preexisting vulnerability. Therefore, when evaluating a medically ill patient, the psychosomatic medicine psychiatrist should always determine if anxiety symptoms are present. Although the presence of anxiety may reflect a mood disorder or other psychiatric disorder, formal assessment for the presence of an anxiety disorder should be considered in all patients. Unfortunately, medical professionals often neglect to screen for these highly treatable disorders. Even when they recognize anxiety, some practitioners minimize its significance by considering it to be a “normal” response to the uncertainty and adversity associated with having a disease.

Once the psychiatrist has determined that a patient has anxiety, the more complex task of determining etiology must be undertaken. Although it is advisable to use a biopsychosocial approach to formulation, there are surprisingly few data regarding medical and pharmacological causes of anxiety. Nonetheless, the psychiatrist must carefully assess their potential etiological roles. Finally, it is important to consider medical comorbidity when designing pharmacological and psychotherapeutic treatment plans. In this chapter, we discuss each of these topics. For detailed reviews of anxiety among individuals with specific medical comorbidities, the reader is referred to the corresponding chapters in this text.

## General Features and Diagnostic Considerations

---

The symptom of anxiety may reflect the presence of an anxiety disorder but may also be a symptom of another psychiatric disorder such as depression. In the medical setting, it is also important to remember that anxiety may be a symptom of delirium, dementia, or a somatoform disorder such as hypochondriasis. Anxiety may also be due to a medical disorder (e.g., hyperthyroidism) or a medication side effect. Furthermore, some symptoms and signs of medical disorders (e.g., tachycardia, dyspnea, and diaphoresis) may be mistaken for anxiety.

An interview using DSM-IV-TR criteria (American Psychiatric Association 2000) is the gold standard for diagnosis of an anxiety disorder. In primary care settings, it is often useful to ask brief screening questions to determine whether a full diagnostic assessment is necessary. The Primary Care Evaluation of Mental Disorders (PRIME-MD) Patient Health Questionnaire is a valuable screening instrument. This self-administered survey includes screening questions for panic disorder, general health worries, and posttraumatic stress disorder (Spitzer et al. 1999). Other scales specifically designed to assess anxiety include the Hamilton Rating Scale for Anxiety (Hamilton 1959), State-Trait Anxiety Inventory (Spielberger et al. 1970), Beck Anxiety Inventory (Beck et al. 1988), Panic Disorder Severity Scale (Houck et al. 2002), Clinician-Administered PTSD Scale (Weathers et al. 2001), and Yale-Brown Obsessive Compulsive Scale (Goodman et al. 1989).

Many patients with anxiety do not present to mental health providers. Of all anxiety disorder visits in the Na-

tional Ambulatory Medical Care Survey in 1998, 48% were to primary care physicians (Harman et al. 2002). Among a sample of 3,000 adult primary care patients, 11% were diagnosed with an anxiety disorder (Spitzer et al. 1999). Individuals with chronic medical conditions such as arthritis, heart disease, diabetes, and hypertension are more likely to have anxiety disorders (Wells et al. 1988, 1989). Unfortunately, many individuals treated in primary care settings do not receive appropriate care for anxiety (Roy-Byrne et al. 1999; Young et al. 2001). Some physicians lack the skill or time to treat anxiety. In addition, some primary care patients are reluctant to consider either psychosocial or pharmacological treatment for their conditions (Hazlett-Stevens et al. 2002).

Anxiety disorders have clearly been shown to impair functioning and well-being among individuals with chronic medical conditions (Sherbourne et al. 1996). Anxiety may be a risk factor for the development of medical illness and may physiologically exacerbate some conditions (e.g., angina, arrhythmias, movement disorders, labile hypertension, and irritable bowel syndrome). There is some evidence that phobic anxiety is a risk factor for fatal coronary artery disease (Kawachi et al. 1994), but some studies have shown no relationship between anxiety and mortality (e.g., Herrmann et al. 2000; Lane et al. 2001). Anxiety may also lead to increased risk of developing hypertension in the future (Jonas et al. 1997). Although depression is more clearly a predictor of poor adherence to medical treatment (DiMatteo et al. 2000), in some individuals excessive anxiety about one's health might reduce adherence (e.g., due to fear of visiting a physician). Anxiety may lead some individuals to refuse diagnostic procedures or surgery and even to sign out of the hospital against medical advice.

## Specific Anxiety Disorders

### Panic Disorder

Primary care patients with panic attacks (see Table 12-1 for diagnostic criteria) are high utilizers of medical care (Roy-Byrne et al. 1999). In particular, many patients who present with chest pain are found to have panic disorder. For example, in one recent study panic disorder was found in approximately 25% of 441 patients presenting to an emergency room with chest pain (Fleet et al. 1996). Researchers estimate that at least one-third of individuals with chest pain and normal coronary arteries have panic disorder (e.g., Beitman et al. 1989; Cormier et al. 1988; Fleet et al. 1998; Maddock et al. 1998). These rates contrast with lifetime prevalence rates of 3.5% found in the

**TABLE 12-1. DSM-IV-TR criteria for panic attack**

#### Physical symptoms

Palpitations, pounding heart, or accelerated heart rate  
Sweating  
Trembling or shaking  
Sensations of shortness of breath or smothering  
Feeling of choking  
Chest pain or discomfort  
Nausea or abdominal distress  
Feeling dizzy, unsteady, lightheaded, or faint  
Paresthesias (numbness or tingling sensations)  
Chills or hot flushes

#### Cognitive symptoms

Derealization (feelings of unreality) or depersonalization  
(being detached from oneself)  
Fear of losing control or going crazy  
Fear of dying

*Source.* American Psychiatric Association 2000.

National Comorbidity Survey (Kessler et al. 1994). A recent meta-analysis identified five variables that correlate with higher rates of panic disorder among individuals seeking treatment for chest pain in emergency rooms or cardiology clinics: 1) absence of coronary artery disease; 2) atypical quality of chest pain; 3) female sex; 4) younger age; and 5) a high level of self-reported anxiety (Huffman and Pollack 2003).

Patients with benign palpitations have high rates of panic disorder (Barsky et al. 1994; Ehlers et al. 2000). One explanation for such high rates is that individuals with panic disorder may have heightened cardiac sensitivity to symptoms such as chest pain and palpitations (Barsky 2001; Mayou 1998). Panic symptoms may also be linked to physiological changes in peripheral organ systems. For example, low vagal tone and decreased heart rate variability may be biological traits that predispose an individual to the development of panic disorder (Friedman and Thayer 1998). Panic attacks may be difficult to distinguish symptomatically from paroxysmal atrial tachycardia; both occur frequently in young, otherwise healthy women, and they are frequently comorbid. Before palpitations are attributed to anxiety, it is important for patients to undergo cardiac evaluation (e.g., ambulatory electrocardiographic monitoring) to rule out arrhythmias (Lessmeier et al. 1997; Zimetbaum and Josephson 1998).

Panic disorder also leads patients to present to other medical specialists. For example, patients who present for evaluation of dizziness have elevated rates of this disorder (Simon et al. 1998; M.B. Stein et al. 1994). Panic disorder is also common among individuals with irritable bowel syndrome who present for treatment (Walker et al. 1995).

In patients with irritable bowel syndrome, anxiety may be due to locus coeruleus activation by afferent signals from the bowel. Thus, with irritable bowel syndrome and other medical disorders such as asthma, anxiety symptoms may be due to central nervous system responses to afferent information from the viscera (Zaubler and Katon 1998).

Recent work has shown that collaborative care interventions can improve outcomes for primary care patients with panic disorder. In one model, collaborative care consisted of patient education, treatment with paroxetine, two visits with an on-site consulting psychiatrist, and follow-up telephone calls. Patients who received this intervention, compared with those receiving usual primary care, had significantly fewer days with anxiety (Katon et al. 2002; Roy-Byrne et al. 2001).

For an excellent review of panic disorder in the general medical setting, see the article by Zaubler and Katon (1998). (For further discussion of panic disorder in cardiac patients, see Chapter 19, "Heart Disease.")

## Posttraumatic Stress Disorder

The National Comorbidity Survey estimated the lifetime prevalence of DSM-III-R (American Psychiatric Association 1987) posttraumatic stress disorder (PTSD) in the general population to be 7.8% (Kessler et al. 1995). Prevalence in medical settings appears to be higher. For example, in one primary care sample the current prevalence of PTSD was approximately 12% (M.B. Stein et al. 2000). Trauma victims and individuals with PTSD are frequent users of health care. Factors contributing to increased medical symptom reporting and health care utilization include increased levels of somatization, comorbidity with depression, the association of hyperarousal with cardiovascular complaints, and heightened perception of autonomic changes (Golding 1994; Wolfe et al. 1994).

It is not surprising that PTSD symptoms are common among individuals who experience acute physical traumas. For example, burn victims have been reported to have PTSD at rates ranging from 20% to 45% (Difede et al. 2002; Perry et al. 1992; Roca et al. 1992; Yu and Dimsdale 1999). In one study, 30%–40% of survivors of a motor vehicle crash or an assault reported PTSD symptoms for months after the trauma. Higher symptom levels were associated with female gender, stimulant intoxication, and greater prior trauma (Zatzick et al. 2002). PTSD has also been reported among individuals with automatic implantable cardioverter defibrillators (Hamner et al. 1999). Intensive care unit experiences can result in PTSD symptoms. In one study, recall of "delusional memories" (paranoia, hallucinations, or nightmares presumably due to delirium) from an intensive care unit

hospitalization was shown to be associated with the development of PTSD symptoms (C. Jones et al. 2001). PTSD symptoms may occur after many other medical conditions or treatments, including myocardial infarction and the diagnosis of HIV infection. For a comprehensive review, see the article by Tedstone and Tarrier (2003).

Acute stress disorder may also occur after life-threatening illnesses or injuries. In one study, 19% of 83 hospitalized adult burn patients developed acute stress disorder within 2 weeks of injury. The presence of acute stress disorder strongly predicted the presence of PTSD at least 6 months later (Difede et al. 2002). Similarly, the degree of fright experienced at the time of myocardial infarction was associated with PTSD symptoms 3 months later (Bennett et al. 2001).

Life-threatening illness such as cancer is a stressor that can precipitate PTSD (Kangas et al. 2002; M. Y. Smith et al. 1999). However, this trauma is different from more usual PTSD stressors such as rape in two principal ways: 1) the threat arises from one's own body; and 2) once the patient has been treated, the ongoing stressor is often not the memory of past events, but the fear of recurrence (B.L. Green et al. 1997). Some researchers have speculated that the trauma associated with the diagnosis and treatment of serious medical illness might be sufficient to cause PTSD even in the absence of a catastrophic event. The rate of current PTSD in cancer survivors is approximately 3%–5%, but many more patients experience some symptoms of PTSD (Alter et al. 1996; Andrykowski and Cordova 1998; B.L. Green et al. 1998). The likelihood of developing PTSD symptoms after cancer treatment has been shown to be increased among individuals with past trauma, prior psychiatric diagnoses, lower levels of social support, and recent life stressors (B.L. Green et al. 2000; Jacobsen et al. 2002). As is the case with other medical illnesses, severity of cancer is not a strong predictor of the development of PTSD.

## Other Anxiety Disorders

There are relatively few studies regarding the characteristics and significance of other anxiety disorders in medical settings. Although the 12-month prevalence rate of generalized anxiety disorder (GAD) in community samples is approximately 3% (Kessler et al. 1994), an international study found the 1-month prevalence rate in primary care to be 7.9%. In that study, GAD was usually comorbid with other psychiatric conditions (Maier et al. 2000). GAD may also lead to excess health care utilization (G.N. Jones et al. 2001). GAD symptoms such as fatigue, muscle tension, and insomnia often lead the patient to present

initially to a primary care physician. As is the case with depression, it is important for physicians to consider GAD in the differential diagnosis for such patients. A simple screening question can be extremely useful in helping the physician to determine if GAD may be present, for example, “In the past 4 weeks how often have you been bothered by feeling nervous, anxious, on edge, or worrying a lot about different things?” (Spitzer et al. 1999).

Although specific phobias are quite common, they rarely come to the attention of medical professionals. Exceptions include blood-injection-injury phobias and claustrophobia. Blood-injection-injury phobias may lead to fainting during medical procedures or to avoidance of injections and blood tests. In the Baltimore Epidemiologic Catchment Area study, approximately 3% of the sample was found to have one of these phobias. Of that sample of 60 individuals, 23% reported fear of blood; 47%, fear of injections; and 78%, fear of dentists. Although this condition may have serious implications for an affected individual, little is known about its public health significance (Bienvenu and Eaton 1998). Syncope or presyncope in individuals with health care phobias may be due to an underlying predisposition toward neurally mediated syncope (Accurso et al. 2001). Claustrophobia comes to medical attention most commonly when individuals need a magnetic resonance imaging (MRI) procedure. The procedure commonly causes anxiety that is severe enough to require sedation (e.g., with a short-acting benzodiazepine such as midazolam or lorazepam; McIsaac et al. 1998; Murphy and Brunberg 1997). Behavioral techniques such as relaxation exercises may also be helpful.

Compulsive skin picking or scratching may be a manifestation of obsessive-compulsive disorder (OCD). In one study of 31 individuals with self-injurious skin picking, 52% were found to have OCD (Wilhelm et al. 1999). However, in another study of 34 patients with psychogenic excoriation, OCD was not a common disorder (Arnold et al. 1998). (For further discussion, see Chapter 29, “Dermatology.”)

## **Causes of Anxiety in the Medically Ill**

In evaluating an anxious patient who is also medically ill, it is essential for the psychiatrist to consider the full range of potential causes of anxiety. In addition to the possibility of a preexisting primary anxiety disorder, three categories of causes of anxiety should be considered for every patient. First, is the patient having a psychological reaction to the experience of medical illness? Second, is the patient’s anxiety directly due to the biological effects of a substance? Third, is the patient’s anxiety directly due to

the biological effects of a medical illness? As is the case for many medically ill patients, the etiology of anxiety is often multifactorial and may vary with the course of illness.

## **Anxiety as a Psychological Reaction to the Experience of Illness**

The importance of one’s health added to the often unavoidable uncertainty associated with medical illness leads many medically ill patients to feel anxious. Particularly for individuals with a predisposition to anxiety, the psychosocial stress of illness may be sufficient to induce an anxiety disorder. Just as when evaluating a depressed patient, psychiatrists should never make assumptions regarding the cause of anxiety in an individual patient. For example, it is easy to assume that the patient who is awaiting cardiac surgery is afraid of dying, when in fact the patient might actually be more concerned about potential disability. When approaching the anxious patient, the psychiatrist should consider all potential psychological causes of anxiety. The following discussion reviews the major causes among medically ill populations. For seminal reviews of this topic, the reader is referred to the work of Strain and Grossman (1975) and Kahana and Bibring (1964) (see also Chapter 5, “Psychological Responses to Illness”).

### ***Uncertainty Regarding Medical Diagnosis***

Some individuals worry excessively that they might have a serious illness. Routine evaluations may cause anxiety, especially in those with a personal or family history of illness. For example, an individual with a family history of breast cancer might become quite anxious in the period preceding routine mammography. In one study, 8% of first-degree relatives of women with breast cancer were so anxious that they performed daily breast self-examinations (Epstein et al. 1997). Anxiety may also occur during the period between initial evaluation and receipt of the definitive result—for example, after the physician tells the patient, “It’s probably nothing, but let’s perform a brain MRI just to be sure.” Prolonged uncertainty regarding diagnosis is even more anxiety-provoking, such as when the patient is told, “Your PSA [prostate-specific antigen] is slightly elevated, but at this point we should simply wait and reevaluate your level in a few months.” Although physicians are acutely aware that there is significant uncertainty inherent in medical diagnoses, patients are generally not reassured by this fact.

### ***Uncertainty Regarding Medical Prognosis***

For most medical illnesses and medical procedures, prognosis is uncertain. Many patients will experience ongoing

fears of recurrence, especially when they have illnesses that frequently do recur (e.g., arrhythmias, cancer, and multiple sclerosis). Similarly, many fear that their treatments will fail, even if they are initially successful. Examples include fear of rejection of a transplanted organ and development of graft-versus-host disease. Physicians often realize that the potential for a poor prognosis—for example, in cases of relatively advanced cancer—often leads to anxiety. However, it is important to keep in mind that patients who have favorable prognoses often experience anxiety. For example, a 95% cure rate is reassuring to many patients, but some will have difficulty coping with the prospect of a 5% recurrence rate. Complicating the problem is the fact that prognoses may be inaccurate when they are derived from aggregate data, which may have been based on treatments that are now outmoded. For patients who learn about their prognoses through personal medical searches, physicians may be able to provide reassurance by reminding the anxious patients of this information: “You are not a statistic; those data were published before the newest treatments became available.”

### *Anxiety About One’s Body*

Many individuals experience anxiety regarding the future effects of illness on their bodies (see Strain and Grossman 1975). Patients may fear that they will lose body parts (e.g., due to amputation). Ongoing fears of amputation are particularly problematic for some patient populations (e.g., those with diabetes mellitus and peripheral vascular disease). Others may fear that they will lose functional capacities or that they will become overly dependent on others. For example, individuals with diabetes mellitus may fear eventual blindness, patients with chronic obstructive pulmonary disease may fear “being hooked to a breathing machine,” and men with prostate cancer may fear impotence. Others are afraid of the experience of pain. For example, individuals with metastatic cancer are often afraid that they will have unremitting, severe pain. Knowledge of these fears can help the physician to provide appropriate reassurances (e.g., that pain will be aggressively treated).

### *Fear of Death*

All individuals, regardless of their physical health, fear death at some time in their lives. The experience of physical illness often heightens that fear, because everyone either has faced life-threatening illness or has known someone who has died from a physical illness. Physicians must be comfortable assessing fears of death in both patients and their families. This assessment must include an exploration of specific reasons for fear of death (e.g., a patient may fear death from childbirth because that occurred

many years earlier to a close relative). Exploration of the reasons for an irrationally high estimate of risk of death may lead to straightforward reassurance. Assessment of death anxiety should also include the opportunity for individuals to discuss existential thoughts about dying (e.g., reflections about the meaning of one’s life [Adelbratt and Strang 2000]). When interviewing the patient with a fear of dying, the physician should assess for particular dying-related fears (e.g., a patient may actually be at peace with dying but may be afraid that her family will not be able to survive without her). In that case, involvement of the family may lead to reassurance and a more peaceful dying process (see also Chapter 40, “Palliative Care”).

### *Anxiety About the Impact of Illness on Identity and Livelihood*

Even if illness alone is not sufficient to cause anxiety, patients may be concerned about the potential impact of illness on their ability to work, to perform essential household functions, or to maintain income. Uncertainties regarding medical reimbursements may make insured individuals justifiably concerned. The uninsured are often so anxious about how they would pay for medical procedures that they avoid medical visits altogether. Patients may be anxious that the costs of medical treatment might cause financial burdens for their families, and they may decline treatment for this reason. In these situations, meetings with family members and health care financial counselors may help to assuage unjustifiable fears that treatments will cause more harm than good.

### *Anxiety Regarding Strangers and Being Alone in the Hospital*

Individuals with medical illnesses become anxious even when their own personal physician performs a medical procedure. Thus, it is not unusual for an acutely ill patient to become intensely anxious when asked to trust his or her life to the new physician he or she has just met in the emergency room or the intensive care unit. Patients who are so anxious that they refuse a medical procedure may be labeled as noncompliant when, in fact, fear is the underlying explanation. As noted by Muskin (1995), acceptance of the involvement of unfamiliar clinicians may be particularly difficult for individuals with preexisting problems with trust (e.g., those with paranoia or borderline personality disorder). Similarly, it is often difficult for some patients to tolerate being alone in the hospital. Because many individuals regress while hospitalized, it is not surprising that patients with dependency needs might become unduly anxious when left alone in an unfamiliar environment.

### *Anxiety Regarding Negative Reactions From Physicians*

Many individuals with medical illness worry about their physician's opinion of them. Excessive concern may lead to reluctance to seek health care. Persons who feel guilty for not following their physician's recommendations might cancel appointments for fear of being scolded (e.g. for failure to lose weight, stop smoking, or check blood sugar levels more reliably). Similarly, some individuals' anxiety might lead them to deny or fail to disclose important information (e.g., regarding sexual risk factors or level of alcohol intake). Anxiety may be particularly prominent among patients who have caused or aggravated their own illness. It is important for the physician to be vigilant for clues that a patient might have excessive anxiety. Awareness of negative countertransference is essential; it is appropriate to provide consistent, firm reminders of the need for proper medical care, but harsh criticism is unwarranted and may contribute to poor adherence.

### Substance-Induced Anxiety

In evaluating the anxious medical patient, it is important to consider whether medications or medication withdrawal might be contributory. Because they can be obtained without prescriptions, caffeine and over-the-counter sympathomimetics are common causes of anxiety in the general population. Caffeine is widely used and commonly causes anxiety. It may be present in significant quantities in coffee, tea, caffeinated soda, caffeinated water (e.g., Java-Water), and coffee ice cream, as well as in over-the-counter preparations for alertness (e.g., NoDoz), weight loss, and headache (e.g., Excedrin). Even at low doses, caffeine may induce anxiety in susceptible individuals (Bruce et al. 1992). In individuals with anxiety disorders, reduction of caffeine intake often reduces anxiety symptoms (G.A. Smith 1988). Over-the-counter sympathomimetics used as decongestants (e.g., pseudoephedrine) frequently cause anxiety, and tachyphylaxis develops rapidly. Some individuals may use large quantities in the form of nasal spray. Similarly, the widely used herbal preparation ephedra may also cause anxiety.

The most important medication classes that are associated with anxiety are summarized in Table 12-2, which includes examples of specific medications in each class. Where appropriate, notes have been added for further clarification. General references in this area are the book by Brown and Stoudemire (1998), *The Medical Letter on Drugs and Therapeutics* ("Drugs That May Cause Psychiatric Symptoms" 2002), and the *Physicians' Desk Reference* (2003).

### Anxiety Secondary to General Medical Conditions

Many medical problems have been reported to cause anxiety, but their significance is in some cases uncertain due to reporting bias and lack of controlled studies (Caine and Lyness 2000; Popkin and Tucker 1992). Nonetheless, it is important for the psychosomatic medicine physician to consider medical causes of anxiety when evaluating an anxious patient. It is particularly important to evaluate medical causes when the history is not typical for a primary anxiety disorder (e.g., lack of personal or family history, lack of psychosocial stressors) and when the onset of anxiety is at a later age (Pollack et al. 1998). In addition, it is important to evaluate medical causes when the anxiety is accompanied by disproportionate physical symptoms (e.g., marked dyspnea, tachycardia, or tremor) or atypical physical symptoms (e.g., syncope, confusion, or focal neurological symptoms).

It is important for the clinician to keep in mind the distinction between anxiety that is physiologically secondary to a general medical condition and anxiety that is comorbid with, or a psychological reaction to, a general medical condition. (For example, hyperthyroidism appears to biologically cause anxiety, whereas diabetes mellitus usually does not.) The DSM-IV-TR diagnosis of anxiety due to a general medical condition refers to the former, not the latter. This difference has not been clearly articulated in some reviews in this area, and it can also be confusing for patients. One source of confusion results from the assumption of causality when there is an epidemiological association between anxiety and a specific medical condition. For example, in one young adult cohort, the odds ratio of any anxiety disorder among individuals with migraine was 2.7 (Merikangas et al. 1990), but the onset of anxiety disorders generally precedes that of migraine (Merikangas and Stevens 1997).

Components of the medical evaluation of the anxious patient should be determined by the patient's specific medical symptoms. For example, it may be necessary to obtain electroencephalograms and a neurological consultation for a patient with seizure-like episodes. The general evaluation of all anxious patients should include the following elements (Colon and Popkin 2002; Pollack et al. 1998):

1. History and physical examination, including neurological examination
2. Evaluation of the potential role of medications and substances (see Table 12-2)
3. Screening diagnostic studies (e.g., routine blood chemistries, complete blood cell count, calcium concentration, thyroid hormone levels, electrocardiogram)

**TABLE 12–2. Substances that may cause anxiety**

<b>Class</b>	<b>Examples</b>	<b>Notes</b>
Androgens	Nandrolone Methyltestosterone	Most problems occur when abused
Angiotensin-converting enzyme inhibitors	Captopril Lisinopril	Often stimulating
Anticholinergics	Atropine Benztropine Dicyclomine Hyoscyamine	
Antidepressants	Serotonin reuptake inhibitors Bupropion Tricyclic agents	
Antiemetics	Prochlorperazine Promethazine	Anxiety may actually be akathisia
Antimigraine agents	Sumatriptan Naratriptan	
Antimycobacterial agents	Isoniazid	
Antineoplastic agents	Vinblastine Ifosfamide	
Antipsychotics	Thiothixene Haloperidol	Anxiety may actually be akathisia
Antiviral agents	Acyclovir Didanosine Foscarnet Ganciclovir Efavirenz	
Beta-adrenergic agonists	Albuterol Metaproterenol	
Cannabinoids	Dronabinol	
Class I antiarrhythmics	Lidocaine Procainamide Quinidine	
Corticosteroids	Prednisone Methylprednisolone	
Dopaminergic agents	Carbidopa-levodopa Amantadine Pergolide	
Estrogens	Conjugated estrogens Ethinyl estradiol Levonorgestrel implant	May cause panic attacks and depression
Gonadotropin-releasing hormone active agents	Leuprolide	
Histamine H <sub>2</sub> receptor antagonists	Cimetidine Famotidine Nizatidine	
Interferons	Interferon-alfa Interferon-beta	
Methylxanthines	Caffeine Theophylline	

**TABLE 12-2. Substances that may cause anxiety (continued)**

<b>Class</b>	<b>Examples</b>	<b>Notes</b>
Sympathomimetics	Ephedrine Epinephrine Phenylephrine nasal Pseudoephedrine	
Nonsteroidal anti-inflammatory drugs	Indomethacin Naproxen Salicylates	
Opiates	Meperidine	Owing to drug withdrawal, meperidine may directly cause anxiety with progression to delirium (Kaiko et al. 1983)
Opioid antagonists	Naltrexone	Observe for opiate withdrawal
Progestins	Medroxyprogesterone acetate Norethindrone	
Prokinetic agents	Metoclopramide	Anxiety may be due to akathisia
Psychostimulants	Methylphenidate Dextroamphetamine	
Sedative-hypnotics	Benzodiazepines Barbiturates Alcohol	Anxiety due to drug withdrawal

In the following subsections, we discuss common medical conditions that are associated with anxiety for which data are strongly supportive of a causal relationship.

### ***Thyroid Disease***

Anxiety symptoms commonly occur among individuals with thyroid disease (Jadresic 1990). Trzepacz et al. (1988) found that 7 of 13 patients with untreated Graves' disease met research diagnostic criteria for GAD and major depression. In another study, 15 of 32 hyperthyroid patients reported increased anxiety symptoms compared with baseline levels (Kathol and Delahunt 1986) (see also Chapter 23, "Endocrine and Metabolic Disorders").

Hyperthyroidism may be difficult to distinguish from a primary anxiety disorder. Signs that may be suggestive of thyrotoxicosis include persistent tachycardia, palms that are warm and dry (not cold and clammy), and fatigue accompanied by the desire to be active (Colon and Popkin 2002). However, data differentiating the two are not definitive in this regard (see Iacovides et al. 2000), and much of the research in this area is not current. Some individuals with hyperthyroidism may also have cognitive impairment. Improvement in anxiety usually parallels successful treatment of the hyperthyroidism (Kathol et al. 1986). Therefore, specific antianxiety treatment may not be necessary. Nonetheless, antianxiety treatment should be considered during normalization of thyroid hormone levels,

particularly for individuals with moderate to severe symptoms. Beta-blockers, which are used routinely for acute treatment of hyperthyroidism, will relieve peripheral manifestations of anxiety.

Because thyroid dysfunction is so common among individuals with anxiety, a screening thyroid-stimulating hormone (TSH) assay should be considered for patients with new-onset anxiety disorders and treatment-resistant anxiety, particularly when the anxiety is generalized and accompanied by prominent physical symptoms. If the TSH level is abnormal, further evaluation of the thyroid axis is recommended (e.g., free thyroxine index or free thyroxine measurement).

There are a number of putative mechanisms for the association between abnormalities of the thyroid axis and mood or anxiety symptoms. A blunted TSH response to thyrotropin-releasing hormone stimulation occurs in up to one-third of depressed patients, many of whom may have concomitant anxiety symptoms (Joffe 2000). The adrenergic overreactivity that accompanies hyperthyroidism provides a ready explanation for its association with anxiety. Finally, thyroid hormones interact with brain neurotransmitters (e.g., the serotonergic and noradrenergic systems; Altshuler et al. 2001). Nonetheless, the association between the thyroid axis and anxiety is not well understood.

Anxiety has been reported to be a symptom of hypothyroidism (Hall and Hall 1999), but data are minimal. Its

association may be better explained by the association between depression and hypothyroidism, in which anxiety is conceptualized as a symptom of depression as opposed to a direct biological result of a hypothyroid state.

### *Pulmonary Disease*

Patients with pulmonary disease often experience symptoms of anxiety. Rates of panic disorder among individuals with asthma and chronic obstructive pulmonary disease are higher than among the general population (e.g., Bussing et al. 1996; Yellowlees et al. 1987). The psychological stress and uncertainty of living with asthma certainly make important contributions to this association. In addition, it is essential to consider physiological factors intrinsic to asthma (Yellowlees and Kalucy 1990). For example, both hypercapnia and hyperventilation may lead to symptoms of a panic attack; in one model, hypercapnia may lead to increased locus coeruleus activity, which could cause panic and hyperventilation (Carr 1998; Zaubler and Katon 1998). Furthermore, carbon dioxide inhalation has been shown to precipitate panic attacks among individuals with panic disorder. Asthma may also be associated with panic attacks through a process of classical conditioning. In this paradigm, because a severe asthma attack is so terrifying, a future sensation of mild dyspnea might precipitate a full-blown panic episode (Carr et al. 1992). In addition, anxiety may worsen asthma, thereby contributing to a vicious circle in which pulmonary and anxiety symptoms exacerbate each other (Carr 1998). Several asthma medications may cause anxiety (see Table 12–2). Pulmonary emboli may also lead to symptoms of anxiety (Tapsos 2000); this diagnosis is more easily missed when the emboli are small (see also Chapter 20, “Lung Disease”).

### *Parkinson’s Disease*

Anxiety is often seen in individuals with Parkinson’s disease (Walsh and Bennett 2001). Most studies of the prevalence of anxiety disorders among patients with Parkinson’s disease involve small samples, but they indicate that these disorders are much more common among Parkinson’s disease patients than in the general population (Richard et al. 1996). Anxiety often appears after the manifestations of symptoms of Parkinson’s disease. For example, some individuals may develop social anxiety disorder symptoms because they are embarrassed about manifestations of the Parkinson’s disease (e.g., tremor) (American Psychiatric Association 2000). Anxiety may also be due to the uncertainty associated with Parkinson’s disease, with respect to both day-to-day functioning and long-term prognosis. Some authors have found that anxiety may be

worse during “off” periods compared with “on” periods, but findings are not definitive (Richard et al. 1996; Siemens et al. 1993; Vazquez et al. 1993).

Depression and anxiety symptoms often coexist among individuals with Parkinson’s disease (Henderson et al. 1992; Vazquez et al. 1993). In one study of 42 patients with Parkinson’s disease, of the 12 patients with an anxiety disorder (5 of whom had panic disorder and 5 of whom had GAD), 11 had a depressive disorder. In the same study, of the 18 patients with a depressive disorder, 12 also had an anxiety disorder (Menza et al. 1993).

The neurobiology of anxiety in Parkinson’s disease has not been clearly delineated, but there is limited evidence supporting the roles of neurotransmitter abnormalities, particularly in central noradrenergic systems (Richard et al. 1996). The dopaminergic neural circuits implicated in Parkinson’s disease have intimate connections with systems involved with anxiety (e.g., serotonin). Anxiety may also be due to medications used to treat Parkinson’s disease, such as levodopa and pergolide (see Table 12–2; Vazquez et al. 1993). Anxiety may also occur with declining dopamine levels (Factor et al. 1995).

### *Poststroke Anxiety*

Poststroke anxiety may occur as a symptom of the more widely described syndrome of poststroke depression (Robinson and Starkstein 2002; Wise and Rundell 1999). Less commonly, anxiety may appear alone. When they appear after a stroke, anxiety symptoms have been shown to persist in many individuals. For example, in one study, 31% of patients had GAD at 3 months, and 19% had it at 3 years (Astrom 1996). Anxiety has been associated with right-hemisphere lesions, whereas depression and mixed depression and anxiety are more commonly associated with left-hemisphere lesions (Astrom 1996; Castillo et al. 1993).

### *Seizures*

Anxiety symptoms may be caused by seizures. For example, complex partial seizures may be accompanied by symptoms of panic disorder, including fear, depersonalization, derealization, dizziness, and paresthesias (Tucker 2002; Wise and Rundell 1999). One group used ambulatory electroencephalographic monitoring with sphenoidal electrodes to study patients with atypical panic attacks (i.e., panic attacks with concomitant neurological symptoms such as change in level of consciousness, aphasia, and focal paresthesias). Focal paroxysmal electroencephalographic changes were found in 5 of 11 patients who had panic attacks during monitoring (Weilburg et al. 1995). Animal models provide some support for the hypothesis that limbic kindling might lead to interictal anxiety (Depaulis et al. 1997).

For further discussion of neurophysiological and neuroanatomic aspects of anxiety disorders, the reader is referred to Chapter 32, "Neurology and Neurosurgery," and D.J. Stein and Hugo (2002).

### *Other Conditions*

In addition to the disorders discussed above, anxiety has reportedly been caused by many other medical conditions. For example, anxiety may be associated with hypocalcemia and hypomagnesemia. Relatively rare conditions for which there are only limited data supporting a causal relationship include carcinoid syndrome, hyperparathyroidism, and pheochromocytoma (Colon and Popkin 2002). In the absence of other findings suggestive of one of these rare disorders, it is not advisable to screen for them (e.g., serotonin metabolites to rule out carcinoid, parathyroid hormone levels to rule out hyperparathyroidism, or catecholamine metabolites to rule out pheochromocytoma).

## **Treatment of Anxiety in the Medically Ill**

---

### Psychotherapy

An overemphasis on psychopharmacology in the care of medically ill patients may result in overlooking the value of psychotherapy. The first step in the treatment of anxiety is to spend time listening to and talking with the patient. Just as in psychotherapy with any patient, empathic listening is a powerful tool to relieve distress. With medically ill patients, the goal is to help patients understand and discuss their emotional reactions to their illness so that they can then manage these feelings by using their own coping mechanisms (S. Green 1994). Psychotherapeutic approaches include supportive, psychodynamic, and cognitive-behavioral therapies.

### *Supportive Therapy*

Supportive therapy involves listening and providing reassurance, sympathy, education about the medical process and the underlying illness, advice, and suggestions (Generalized anxiety disorder 2003). The process includes listening for fears and misperceptions about illness or its treatment and giving patients appropriate information so that they can be as prepared as possible (House and Stark 2002). Effective communication, using language the patient and family can understand, can lead to a great decrease in anxiety. It is also helpful to give patients as much choice in their treatment decisions as possible so that they

feel they have some control over the course of their treatment.

Reassurance is an important skill that all physicians use in treating patients. In some highly anxious patients, however, simple reassurance can actually cause increased anxiety and lead to a cycle of maladaptive behavior. For example, if a patient who has been told that a procedure is simple or painless subsequently experiences pain or untoward results, the resulting anxiety can lead to more reassurance-seeking behavior, mistrust, and decreased cooperation. Many anxious patients tend to interpret bodily symptoms as evidence of serious disease, and as a result, they may seek multiple consultations for reassurance. Understanding the patient's beliefs, concerns, and perceptions can be helpful in challenging misperceptions, educating the patient about his or her illness, and devising a realistic plan to monitor symptoms. Having a realistic plan to help patients differentiate minor symptoms from those that may need medical attention will reduce anxiety and decrease the excessive need for reassurance (Stark and House 2000). It is also important that the physician not assume that a patient's anxiety is due to fear of dying. When reassurance is directed at the wrong fear, it may accentuate anxiety and lead patients to believe that their physician does not understand them.

The consultant can also serve as a liaison between the patient and the health care team. For example, the psychiatrist might help the primary physician understand the importance of clarifying the risks and benefits of treatment and of informing the anxious patient when there are delays in scheduling. It also may be helpful for the treatment team to consult directly with the psychiatrist about how to care for the anxious patient. Facilitating communication among the patient and the treatment team can help avoid misperceptions or mistrust that will only serve to heighten anxiety.

Another important aspect of supportive therapy is the involvement of the patient's support system of family, friends, and religious community. Working with the support network is important to ensure that their anxiety and misperceptions do not add to the stress of the patient. Helping a patient to expand his or her social network can be an important component of a supportive program. In addition, hospital staff such as nurses, chaplains, social workers, volunteers, and other allied professionals can help provide support and encouragement to the medically ill patient (Colon and Popkin 2002).

Patients confronting life-threatening or terminal illnesses such as cancer may experience death anxiety (Yalom 1980). Relief of physical pain, dyspnea, and other physical symptoms is critical for the alleviation of anxiety

(Payne and Massie 2000). Some patients have strong religious or spiritual beliefs that may help reduce their distress, and pastoral counseling is often beneficial (Alvarado et al. 1995). Open discussions with patients about death help to reduce anxiety and distress (Spiegel et al. 1981), and psychological interventions alone can help patients manage their death anxiety (Payne and Massie 2000). Maintaining hope is an important aspect of minimizing anxiety, although goals can change from full recovery to having more time to accomplish specific short-term goals. Helping patients find meaning and value in their lives, despite their illness and suffering, helps to relieve emotional distress (Frankl 1987). For example, anxiety can be reduced when patients see that they are still important to their families or that they still have unfinished business to address. The hospice movement has been instrumental in helping provide relief for many patients (Byock 1997). Despite recent improvements in physician education, caregivers need more training to be able to overcome their own death anxiety so that they can provide comfort to end-of-life patients (Adelbratt and Strang 2000) (see Chapter 40, "Palliative Care").

Supportive group interventions are very effective in reducing anxiety and distress in medically ill patients (Fawzy et al. 1995). HIV, cancer, cardiac, and other support groups have proliferated in recent years. They can be quite helpful in providing emotional support and education in stress management, coping skills, and other behavioral techniques (Payne and Massie 2000). Participants have been shown to have decreased stress levels and improved functioning (Spiegel et al. 1989).

### ***Cognitive-Behavioral Therapy***

Cognitive-behavioral therapy has been proven to be as effective as medication in treating many anxiety disorders, including GAD and panic disorder (Generalized anxiety disorder 2003). Cognitive techniques are used to uncover and correct misinterpretations and irrational thoughts that lead to increased anxiety and distress. Behavioral techniques, such as systematic desensitization, can also be used to help overcome irrational fears that can interfere with effective treatment, such as blood or needle phobias and claustrophobia during MRI (Goldberg and Posner 2000). Since cognitive-behavioral therapy techniques usually take several sessions to be effective, medications may be needed initially to help reduce anxiety. A brief course of cognitive-behavioral therapy can have long-lasting effects, but occasional "booster" sessions may be needed.

A variety of therapies that involve teaching self-awareness and self-regulation of body functions have been

found effective in reducing anxiety and physical symptoms in medically ill patients. These include muscle relaxation techniques (such as Jacobson's progressive muscle relaxation), autogenic training (such as biofeedback, which uses technology to control internal processes), and relaxation techniques (such as meditation, breathing exercises, and self-hypnosis). Muscular conditions such as tension headaches and musculoskeletal disorders may respond better to muscle relaxation; migraine headaches and hypertension, to autogenic training; and anxieties and phobias, to more cognitive techniques; however, further research is needed (Lehrer et al. 1994). When used by a skilled practitioner with a patient who is open to this approach, all of these techniques may be helpful in reducing symptoms of various conditions exacerbated by anxiety and stress. Guided imagery with relaxation and hypnosis has also been an effective technique to reduce anxiety (Payne and Massie 2000). Relaxation techniques have been used to decrease the use of medications in hypertensive patients, to decrease pain in patients with chronic pain, and to expedite recovery and decrease complications in postsurgical patients (Benson 1988). Meditation has been shown to reduce panic attacks (Kabat-Zinn et al. 1992), and biofeedback and relaxation have been used to help wean patients from the ventilator (Acosta 1988) as well as to reduce dyspnea and anxiety in patients with chronic obstructive pulmonary disease (Renfroe 1988; Smoller et al. 1999).

### ***Psychodynamic Therapy***

For patients who are not too ill and who have sufficient emotional resilience, brief dynamic psychotherapy can be useful in uncovering the conscious and unconscious meaning of the illness to the patient. Understanding patients' developmental history, interpersonal dynamics, and defense mechanisms can help the psychiatrist to assist them in finding healthier ways to cope with medical illness (Viederman 2000). What coping strategies have helped in the past? When did the individual feel most fulfilled in his or her life? How can those memories and skills be used now, even in the presence of significant medical illness? Psychotherapy can uncover areas leading to increased distress, such as real or imagined guilt, unhealthy coping strategies like avoidance and denial, and recognition of past conflicted relationships that may be repeated in the current doctor-patient relationship. An understanding of the patient's underlying dynamics can help identify and resolve conflicts with the treatment team that may be interfering with recovery. Psychotherapy started in the hospital may then be continued on an outpatient basis, to help patients cope with

their illness and achieve optimal functioning (Colon and Popkin 2002). An understanding of psychodynamic principles can also help psychiatrists in working with the primary treatment team that is caring for the anxious patient.

Countertransference reactions can cause a number of problems for providers of anxious patients. For example, physicians may overidentify with their patients, leading to frustration because of lack of progress or poor prognosis. As a result, they may then overcompensate by offering excessive reassurance, or they may minimize or overlook symptoms in an unconscious attempt to reduce their own anxiety. Caregivers may also become withdrawn and distant, providing care mechanically with little empathy or awareness of the emotional needs of the patient. Psychiatrists can play a role in helping the health care team to be cognizant of these defenses so they do not interfere with the provision of optimal patient care (S. Green 1994). (See Chapter 38, "Psychosocial Treatments," for further discussion of psychotherapy for the medically ill.)

## Pharmacotherapy

Psychotherapeutic techniques are often not sufficient to manage anxiety in the medically ill. An increasingly broad range of psychopharmacological agents can be used safely with this population. (For further details, see Chapter 37, "Psychopharmacology," and specific discussions in Chapter 19, "Heart Disease," through Chapter 35, "Physical Medicine and Rehabilitation.")

### *Benzodiazepines*

For acute anxiety symptoms, the most immediately effective and frequently used agents are the benzodiazepines (Table 12-3). Diazepam and chlordiazepoxide were among the first of these to be used. They also have established efficacy for other conditions—diazepam as an anticonvulsant and muscle relaxant and chlordiazepoxide for alcohol detoxification. Diazepam can be given orally or intravenously but should not be given intramuscularly. However, newer benzodiazepines have better safety profiles and shorter half-lives, so they tend to be used more frequently.

**TABLE 12-3. Selected benzodiazepines used for anxiety in the medically ill**

Medication	Route	Dosage	Elimination half-life	Comments
Alprazolam	Oral	0.25–1.0 mg tid	9–20 hours	Rapid onset. Interdose withdrawal a problem, but new extended-release form is available.
Chlordiazepoxide	Oral, intramuscular	5–25 mg qid	28–100 hours (including metabolites)	Useful for alcohol withdrawal.
Clonazepam	Oral	0.25–1 mg bid-tid	19–60 hours	Also used for absence seizures, periodic leg movements, and neuropathic pain.
Diazepam	Oral, intravenous	2–10 mg qid	30–200 hours (including metabolites)	Also used as an anticonvulsant and muscle relaxant.
Lorazepam	Oral, intramuscular, intravenous	0.5–2.0 mg up to qid	8–24 hours	Intravenous availability is an advantage. Metabolized by conjugation. Also approved for chemotherapy-related nausea and vomiting.
Midazolam	Intramuscular, intravenous	Intramuscular: 5 mg single dose Intravenous: 0.02–0.10 mg/kg per hour	1–20 hours (including metabolites)	Used for preoperative sedation and intravenous induction.
Oxazepam	Oral	10–30 mg qid	3–25 hours	Metabolized by conjugation. May also be useful for alcohol withdrawal.

Source. Adapted from *Physician's Desk Reference* 2003; Bezchlibnyk-Butler and Jeffries 2002.

Alprazolam works rapidly and is eliminated quickly, but as a result there may be rebound anxiety and withdrawal symptoms. Because lorazepam can be given orally, intravenously, or intramuscularly and does not have an active metabolite, it is often a preferred medication in hospitalized patients. Lorazepam can be given in an intravenous bolus or drip, but as doses increase to provide sedation and treat delirium tremens, respiratory status must be watched closely. Like lorazepam, oxazepam and the hypnotic temazepam are metabolized through conjugation and so are less problematic in patients with liver disease than the other benzodiazepines, which are oxidatively metabolized (Stoudemire 1996). Midazolam, a benzodiazepine with a very short half-life that can only be given intravenously or intramuscularly, is used for short-term procedures such as bone marrow biopsies, endoscopies, and MRI scans in claustrophobic patients (Goldberg and Posner 2000).

For patients who need long-term benzodiazepines, it is often helpful to change to a medication with a longer half-life, such as clonazepam (Katon 1994).

Hypnotics are commonly used in medically ill patients who are kept awake by their anxiety. Triazolam has been used less frequently in recent years because it can cause retrograde amnesia. Temazepam is occasionally still used for persons who tend to awaken when taking the shorter-acting hypnotics. Newer agents such as zolpidem and zaleplon are nonbenzodiazepines that act on the benzodiazepine receptor. They are preferred for short-term use because they have very short half-lives and as a result cause less daytime sedation, impaired coordination, and cognitive disturbance. Generally all of the hypnotics are best used for short intervals to decrease the chance of side effects, to maintain effectiveness (i.e., prevent tolerance), and to prevent dependence.

All benzodiazepines can cause excessive sedation. They may also cause motor and cognitive disturbances, especially in older persons and individuals with impaired brain functioning (e.g., due to dementia, head injury, or mental retardation; Salzman et al. 1993). Therefore, they should be used with caution, if at all, in these patients. Anxiety in delirious patients is usually better treated with antipsychotics than with benzodiazepines (Breitbart et al. 1996). Benzodiazepines can cause respiratory suppression, so they should be used cautiously in persons with pulmonary disease who retain carbon dioxide, or in patients with sleep apnea. Because of potential teratogenicity, benzodiazepines should be avoided in the first trimester of pregnancy. They should also be avoided at the very end of pregnancy, because there are reports of sedation and withdrawal symptoms in the fetus (McGee and Pies 2002). All benzodiazepines can lead to tolerance and de-

pendence, so they should be avoided or used judiciously (i.e., for detoxification) in persons with a substance abuse history. However, compared with barbiturates and earlier sedative-hypnotics such as meprobamate, they are much safer in overdose and have fewer side effects. In persons who are conscientious and do not have a history of chemical dependence, benzodiazepines can often be safely used for years without causing problems or tolerance. As an individual ages, use should be reevaluated. Similarly, long-term benzodiazepine use may need to be reduced or discontinued among patients who develop specific medical conditions (e.g., end-stage liver disease, dementia, chronic obstructive pulmonary disease, and cerebellar dysfunction).

### *Antidepressants*

The pharmacological treatment of choice for GAD, panic disorder, posttraumatic stress disorder, obsessive-compulsive disorder, and social anxiety disorder is one of the selective serotonin reuptake inhibitors (SSRIs): fluoxetine, sertraline, paroxetine, citalopram, escitalopram, and fluvoxamine. Venlafaxine, which inhibits both serotonin and norepinephrine reuptake, has been approved for GAD and social anxiety disorder and will probably also be shown to be effective for other anxiety disorders (Gorman 2002). These medications have few side effects and therefore are generally quite safe for the medically ill; they do not result in cardiac conduction problems, orthostatic hypotension, or physical dependence. Because antidepressants may take 2–6 weeks to relieve anxiety, the patient may need initial treatment with benzodiazepines. Once the patient has been stabilized on the antidepressant medication, the benzodiazepines can usually be gradually withdrawn without recurrence of anxiety. The antidepressant should be used for at least 3–6 months before stopping it, and it should be tapered to avoid discontinuation symptoms. Antidepressants can be used safely on a long-term basis if anxiety returns.

One of the main drawbacks of the SSRIs and venlafaxine is a relatively high incidence of sexual dysfunction in both men and women. This side effect may be particularly problematic for persons with medical problems already associated with sexual dysfunction, such as diabetes or vascular disease (see Chapter 17, “Sexual Disorders”). In addition, psychiatrists must be concerned about the potential for drug interactions, for example, with fluoxetine and paroxetine (cytochrome P450 2D6 inhibitors) and fluvoxamine (a cytochrome P450 3A4 inhibitor; see Chapter 37, “Psychopharmacology”). Serotonin reuptake inhibitors may cause initial gastrointestinal distress and nausea, so they are generally given with food. It is important to reassure the patient with gastrointestinal disease

that these side effects are almost always transient. SSRIs are also associated with the syndrome of inappropriate secretion of antidiuretic hormone, especially in older patients. In a small percentage of patients, venlafaxine produces a unique side effect of sustained blood pressure elevation, which is dose-related. Blood pressure should be monitored when this drug is being initiated and with each dosage increase. If diastolic blood pressure increases occur, the dosage should be reduced or the drug stopped. Although SSRIs may help some individuals with migraine headaches, they can also exacerbate headaches. It has been reported that SSRIs can exacerbate parkinsonism in individuals with Parkinson's disease; however, this appears to be an uncommon side effect (Dell'Agnello et al. 2001). Because all SSRIs are equally efficacious in studies, medication choice is often based on side-effect profile. For example, the more sedating SSRIs (e.g., fluvoxamine and paroxetine) may be advantageous for the highly anxious patient with insomnia, whereas fluoxetine may be more stimulating. For medically ill patients taking multiple medications, agents with the fewest drug interactions are preferred: sertraline, citalopram, escitalopram, and venlafaxine.

Mirtazapine—an alpha-adrenoceptor antagonist and an antagonist at serotonin 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, and 5-HT<sub>3</sub> receptors—may be helpful in reducing anxiety. Its use in medically ill patients has increased recently for two reasons: 1) it has few drug interactions, and 2) the side effects of sedation and increased appetite are helpful in patients who have insomnia and anorexia with weight loss. Nefazodone is another unique antidepressant with some anxiolytic properties, but it can be problematic for medically ill patients because of its inhibition of the cytochrome P450 3A4 enzyme, the need for gradual dose adjustment, and its recent black-box warning of rare liver toxicity. Neither of these medications causes sexual dysfunction.

Tricyclic antidepressants and monoamine oxidase inhibitors are well established as effective treatments for anxiety disorders as well as for depression. Tricyclics can be efficacious for the treatment of anxiety in the medically ill (e.g., in patients with chronic pain or diarrhea-predominant irritable bowel syndrome). The main reasons these medications are currently not used frequently as first-line treatment are their numerous side effects and their toxicity in overdose. Tricyclics often cause dry mouth, weight gain, constipation, sedation, orthostatic hypotension, urinary retention, and falls, especially in elderly patients. In addition, because of their quinidine-like effects, they can cause heart block and arrhythmias. Because there is a relatively small margin of safety between efficacy and toxicity, overdose can be dangerous and even fatal. Persons with liver and kidney disease may develop toxicity due to

impaired metabolism and excretion (Stoudemire and Moran 1993). Monoamine oxidase inhibitors can cause dizziness, orthostatic hypotension, and weight gain. These side effects, as well as the potential for serious hypertensive crises, limit their usefulness in medically ill patients.

### *Antipsychotics*

Antipsychotic medications are not approved for the treatment of anxiety, although there are limited data clearly supporting their efficacy (El-Khayat and Baldwin 1998). Nonetheless, psychiatrists often find them to be efficacious and safe to use in selected medical populations. Because antipsychotics do not cause confusion or respiratory compromise, they may be preferable to benzodiazepines for the more severe anxiety associated with agitation or delirium or in patients with respiratory compromise. For example, antipsychotics may be helpful in assisting the anxious patient who is being weaned from a ventilator (Cassem and Murray 1997). Of the older, or typical, antipsychotics, the agent used most often in medically ill patients is haloperidol, which can be given orally, intramuscularly, or intravenously. In acutely agitated patients who may be violent or psychotic, 5–10 mg of haloperidol is often given orally or intramuscularly, usually in conjunction with a benzodiazepine such as lorazepam, and sometimes with benztropine to prevent a dystonic reaction. In medically ill patients who are delirious, haloperidol rarely causes extrapyramidal side effects or dystonia. For mild agitation, 0.5–2.0 mg might be given, but much higher doses can be used. If a high-potency typical antipsychotic such as haloperidol is used in treating anxiety, it is important to monitor for akathisia because it can be mistaken for worsening anxiety. Newer atypical antipsychotics such as olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole are also used selectively in the management of anxiety, especially in lower doses. Ziprasidone is the only one available in intramuscular formulation at this time. Compared with the older agents, they have relatively favorable side-effect profiles. There are no data regarding their use for anxiety in general and specifically in medically ill populations, but they can be a safe alternative for those who might not do well with benzodiazepines, such as delirious patients or those with respiratory compromise.

### *Buspirone*

Buspirone is a partial serotonin agonist approved for treatment of GAD. It may be useful in treating medically ill patients with anxiety because there are few drug interactions; it does not cause sedation, respiratory depression, or cognitive problems; and its metabolism is not greatly

affected by liver disease (Stoudemire and Moran 1993). The main drawbacks with buspirone are that it may take 2–4 weeks to become effective, and its benefits seem modest. Because of its short half-life, buspirone needs to be given 2–3 times a day. Some patients complain of dizziness and excessive sedation when first beginning the medication, but it is usually well tolerated.

### **Beta-Blockers**

Beta-adrenergic blockers produce anxiolytic effects by blocking autonomic hyperarousal (elevated pulse, elevated blood pressure, sweating, tremors) associated with anxiety responses. They work best for specific anxiety-producing situations, such as performance anxiety and public speaking, and are less efficacious for panic disorder and social phobias. All beta-blockers are contraindicated in persons with asthma or chronic obstructive lung disease, and they can worsen peripheral vascular disease (Barnes 2000). Patients with insulin-dependent diabetes should not be prescribed nonselective beta-blockers; because those medications block the sympathetic nervous system response to hypoglycemia, the patient may be unaware of symptoms and may be less likely to respond appropriately (Kaplan 2001). Central nervous system side effects such as nightmares, hallucinations, and sleep disturbance are infrequent. They may be more likely to occur with lipophilic drugs such as propranolol and pindolol, which cross the blood-brain barrier, and less likely to occur with atenolol, nadolol, and timolol (McAinsh and Cruickshank 1990). The reported association between beta-blockers and depression has not been supported by data from clinical trials (Ko et al. 2002).

### **Antihistamines**

Sedating histamine H<sub>1</sub> receptor blockers are sometimes used to treat anxiety and insomnia. Hydroxyzine has been shown to be as effective and safe as benzodiazepines in treating anxiety (Llorca et al. 2002) in a general study population. Diphenhydramine, which is often used to treat insomnia, is available in over-the-counter preparations. Because these medications are not addicting, many physicians consider them to be benign. However, they can cause dizziness, excessive sedation, incoordination, and confusion, especially when used with alcohol or other central nervous system depressants. Elderly patients and those with brain disease or injury are more sensitive to these medications and may become delirious even with low doses. Despite these risks, these medications are still an option when benzodiazepines must be avoided due to concerns about dependence or respiratory depression (Stoudemire 1996).

### **Anticonvulsants**

Anticonvulsants are primarily prescribed by psychiatrists for patients with bipolar disorder who cannot tolerate or do not respond to lithium, but they can also be helpful for some individuals with anxiety. Patients with recurrent panic attacks and temporal lobe electroencephalographic abnormalities may respond to anticonvulsants (McNamara and Fogel 1990). Gabapentin works on the gamma-aminobutyric acid system and can be effective for relief of neuropathic pain. It has also been shown to have efficacy for panic disorder (Pande et al. 2000) and social anxiety disorder (Pande et al. 1999). Because gabapentin is not metabolized through the liver, it has few drug interactions and can be used safely in persons with liver disease. Side effects include sedation, headache, and dizziness. Divalproex sodium and carbamazepine have been found to be helpful in calming agitated, anxious patients, especially those with brain injury, mental retardation, or dementia. The newer anticonvulsants lamotrigine, topiramate, and tiagabine show some promise in treatment of mood disorders and may also prove to be beneficial for the treatment of anxiety.

## **Conclusion**

---

The experience of medical illness often leads to clinically significant anxiety symptoms. Despite the fact that many individuals with medical illnesses have anxiety disorders, these disorders are often underrecognized and undertreated. Both psychotherapy and pharmacotherapy can significantly ameliorate anxiety symptoms, even among patients with severe medical problems. Thus, careful assessment and treatment of anxiety disorders are important components of the psychiatric care of the medically ill.

## Somatization and Somatoform Disorders

---

Susan E. Abbey, M.D., F.R.C.P.C.

**SOMATIZATION IS A** poorly understood “blind spot” of medicine (Quill 1985). Somatoform disorders remain neglected by psychiatrists despite their associated significant functional impairments and economic burden (Bass et al. 2001). Important conceptual and clinical questions exist about the validity and utility of the concepts, particularly in clinical settings, and new paradigms might lead to more effective management (Epstein et al. 1999; Mayou et al. 2003; Sharpe and Carson 2001).

Somatization and somatoform disorders challenge consulting psychiatrists, who often wade into emotionally charged clinical situations in which diagnosis is difficult, both the referring physician and the patient are frustrated and angry, and the involvement of a psychiatrist may be stigmatizing. The complex set of emotions that patients with somatoform disorders engender has resulted in the application of disparaging names both to these patients (e.g., “crocks”) (Lipsitt 1970) and to the discipline (e.g., “psychoceramic medicine”). The evidence base for diagnosing and treating these patients remains suboptimal, but there is a strong clinical literature that can help psychiatrists to work effectively with these patients, produce substantial improvements in the patients’ and their families’ well-being, and decrease direct and indirect costs of their illness. The medical training of psychosomatic medicine psychiatrists facilitates management of difficult cases, such as patients who somatize or have a somatoform disorder and have a concurrent general medical condition with overlapping symptoms.

This chapter begins with a discussion of the process of somatization, followed by a review of the DSM-IV-TR (American Psychiatric Association 2000) somatoform disorders. The chapter focuses on adults. Somatization and somatoform disorders in children are discussed in Chap-

ter 34, “Pediatrics,” and in several reviews (Garralda 1999; Silber and Pao 2003). Conversion disorder is also discussed in Chapter 32, “Neurology and Neurosurgery.”

### Somatization as a Process

---

Somatization can be conceptualized in a variety of different ways, but fundamentally it appears to be a way of responding to stress. It is a ubiquitous human phenomenon that at times becomes problematic and warrants clinical attention. Somatization is extremely common in medical settings and among the patients referred to psychosomatic medicine psychiatrists. Not all somatizing patients have a somatoform disorder. Many have another Axis I disorder or transiently somatize in the context of significant life stress.

### Definitions and Clinically Useful Theoretical Concepts

The area of somatization is complicated by a lack of uniformity in the use of terminology. Theoretical concepts that are clinically useful in management are described below.

#### *Somatization*

Historically, *somatization* was defined by Steckel as a deep-seated neurosis that produced bodily symptoms (Lipowski 1988). In the past 20 years, the term *somatization* has been used to describe the tendency of certain patients to experience and communicate psychological and interpersonal problems in the form of somatic distress and medically unexplained symptoms for which they seek

medical help (Katon et al. 1984; Kleinman 1986; Lipowski 1988). Although it has become a widely used term, Sharpe (2002) cautions that its use should be restricted to cases in which the somatic symptoms are an expression of an identifiable emotional disorder. In essence, somatization is a culturally sanctioned idiom of psychosocial distress (Katon et al. 1984; Kleinman 1986). Kirmayer and Young (1998) note that, depending on circumstances, somatization “can be seen as an index of disease or disorder, an indication of psychopathology, a symbolic condensation of intrapsychic conflict, a culturally coded expression of distress, a medium for expressing social discontent, and a mechanism through which patients attempt to reposition themselves within their local worlds” (p. 420).

Three components of somatization described by Lipowski (1988) can offer targets for intervention: experiential, cognitive, and behavioral (Table 13–1).

### **Medically Unexplained Symptoms**

Somatization is frequently implicated in *medically unexplained symptoms*, defined as symptoms that are not attributable to or are out of proportion to identifiable physical disease (Sharpe 2002). Medically unexplained symptoms are discussed in other chapters in this volume, including noncardiac chest pain (see Chapter 19, “Heart Disease”), hyperventilation syndrome (see Chapter 20, “Lung Disease”), irritable bowel and functional upper gastrointestinal tract disorders (see Chapter 21, “Gastrointestinal Disorders”), chronic fatigue syndrome and fibromyalgia (see Chapter 26, “Chronic Fatigue and Fibromyalgia Syndromes”), idiopathic pruritus (see Chapter 29, “Dermatology”), chronic pelvic pain and vulvodynia (see Chapter 33, “Obstetrics and Gynecology”), and pain syndromes (see Chapter 36, “Pain”).

**TABLE 13–1. Clinical implications of the components of somatization**

<b>Component</b>	<b>Potential intervention</b>
Experiential	Techniques to decrease somatic sensations (e.g., biofeedback, pharmacotherapy for concomitant psychiatric disorder)
Cognitive	Reattribution of sensation from sinister to benign cause Distraction techniques
Behavioral	Operant techniques to reduce medication consumption Contract to “save” symptoms for regular visit with primary care physician rather than visiting emergency room

### **Somatosensory Amplification**

Symptoms are the result of bodily sensations and their subsequent cortical interpretation. *Somatosensory amplification* refers to the tendency to experience somatic sensations as intense, noxious, or disturbing (Barsky et al. 1988b). It is composed of three elements: 1) hypervigilance to bodily sensations, 2) predisposition to select out and concentrate on weak or infrequent bodily sensations, and 3) reaction to sensations with cognitions and affect that intensify them and make them more alarming (Barsky et al. 1988b). It has both trait and state components.

### **Illness Versus Disease**

The distinction between illness and disease (Eisenberg 1977) is useful for psychosomatic medicine psychiatrists. *Illness* is the response of the individual and his or her family to symptoms; this contrasts with *disease*, which is defined by physicians and is associated with pathophysiological processes and documentable lesions. Mismatches between illness and disease are common and are at the root of many management problems. Hypertensive patients may not perceive themselves as ill and therefore might not comply with treatment regimens. Patients with somatoform disorders view themselves as very ill despite not having a disease. In somatizing patients with some disease component, their subjective illness experience is assessed to be disproportionate to the degree of disease.

### **Illness Behavior and Abnormal Illness Behavior**

*Illness behavior* refers to “the manner in which individuals monitor their bodies, define and interpret their symptoms, take remedial action, and utilize sources of help as well as the more formal health care system. It also is concerned with how people monitor and respond to symptoms and symptom change over the course of an illness and how this affects behavior, remedial actions taken, and response to treatment” (Mechanic 1986, p. 1). Illness behavior may be regarded as a syndrome, as a symptom, as a dimension, or as an explanation of behavior (Mayou 1989). Illness behavior is affected by a wide variety of social, psychiatric, and cultural factors and can be used “to achieve a variety of social and personal objectives having little to do with biological systems of the pathogenesis of disease” (Mechanic 1986, p. 3).

*Abnormal illness behavior* is identified by a physician when there is an “inappropriate or maladaptive mode of perceiving, evaluating or acting in relation to one’s own health status, which persists despite the fact that a doctor (or other appropriate social agent) has offered an accurate and reasonably lucid explanation of the nature of the illness and the appropriate course of management to be fol-

lowed, based on a thorough examination of all parameters of functioning, and taking into account the individual's age, educational and sociocultural background" (Pilowsky 1987, p. 89). It may be somatically or psychologically focused and may be either illness affirming or illness denying. The construct has been criticized as dangerous in that it places physicians in the position of defining what is normal and what is "abnormal." It has been counterargued that a corresponding medical behavior of "abnormal treatment behavior" may be described.

## Somatization as a Clinical Problem

Somatization becomes clinically significant when it is associated with significant occupational and social dysfunction or with excessive health care use. The relation between acute and persistent forms of somatization is unclear; they may form a continuum or may be discrete conditions. A longitudinal study of primary care "somatizers" (defined as patients with emotional disorder presenting with recent-onset physical symptoms) found that 16 of 44 patients went on to develop chronic somatoform disorders over a 2-year follow-up period (Craig et al. 1993). Somatization and somatoform disorders pose a significant economic burden (Bass et al. 2001). In addition to the higher-than-average inpatient, ambulatory, and physician service costs of care of such patients, there are social costs, including decreased occupational productivity. Many patients with somatization also have severe distress, particularly depression and anxiety. In addition, somatizing patients are at increased risk of iatrogenic disease and injury. For example, in pseudoseizures, the most frequent cause of morbidity and death is the misdiagnosis of epilepsy and resulting aggressive treatment with anticonvulsants (Kanner 2003).

## Relation Among Psychiatric Disorders, Somatization, and Medically Unexplained Symptoms

Strong interrelations exist among somatization, psychiatric disorders, and health care utilization. Four models (Figure 13-1) have been advanced to explain these relations (Simon 1991). Different models may apply to different patients.

### *Somatization as a Masked Presentation of Psychiatric Illness*

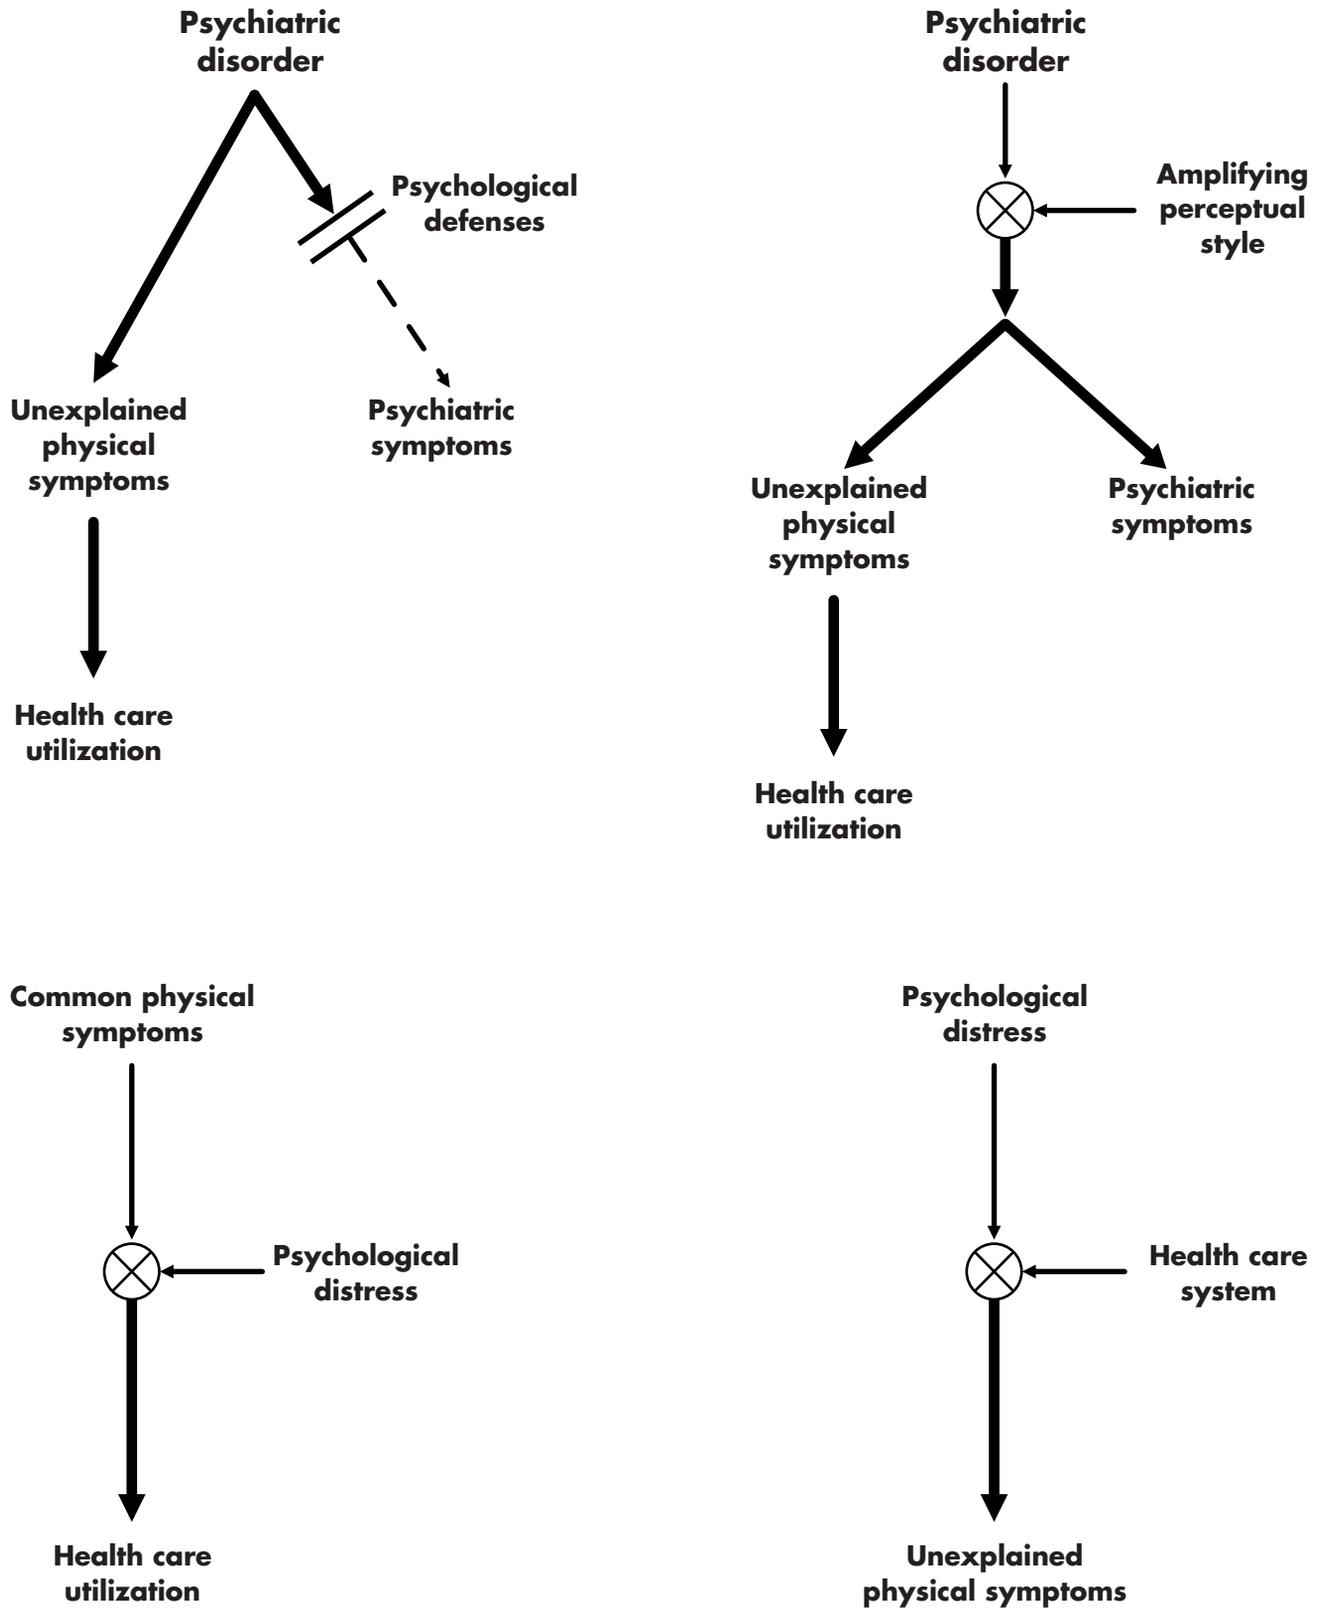

Physical symptoms are an integral part of most psychiatric disorders. Somatizing patients focus on these symptoms to the exclusion of psychological symptoms. They may then attribute the psychological symptoms to the distress

resulting from the physical symptoms (e.g., "Yes, doctor, I am sad, but you would be too if you couldn't sleep or eat and had no energy!"). This masking of the psychiatric syndrome is important, because major depressive disorder and anxiety disorders are significantly underrecognized in patients presenting with somatic complaints (Kirmayer et al. 1993). Somatization does not appear to be a defense against acknowledging the presence of a psychiatric disorder (Hotopf et al. 2001).

**Depression and somatization.** Physical symptoms are common in major depressive disorder (Simon et al. 1999; see also Chapter 9, "Depression"). The mechanism by which they are produced is unclear and may be related to 1) psychophysiological concomitants of depression, 2) somatosensory amplification, and 3) a depressive attributional style in which symptoms are perceived as indicating poor health. Primary care patients with depression have higher health care utilization and report more somatic symptoms than do patients without depression (Kroenke 2003). It is estimated that 50% or more of the patients presenting in primary care with major depressive disorder do so with predominantly somatic complaints rather than with cognitive or affective symptoms of depression (Simon and Gureje 1999). These somatic presentations of depression have been referred to as *masked depression* or *depressive equivalents*. Somatic symptoms in depression are related to concomitant anxiety, the tendency to amplify somatic distress, and difficulty identifying and communicating emotional distress (Sayar et al. 2003). Comorbidity among depression, somatization, and somatoform disorders is high (G.R. Smith 1992). Consequently, it has been argued that medically unexplained symptoms are a manifestation of an affective-spectrum disorder (Hudson et al. 2003).

**Anxiety and somatization.** Anxiety disorders are also accompanied by prominent physical symptoms and are frequently mistaken for or associated with somatization in patients presenting in primary care and medical subspecialty settings (Sullivan et al. 1993; see also Chapter 12, "Anxiety Disorders"). Somatization and hypochondriacal fears and beliefs are common among patients with panic disorder, particularly those who also have agoraphobia and focus more on seeking an explanation for, than on treatment of, their symptoms (Starcevic et al. 1992). In addition, posttraumatic stress disorder often presents with somatic complaints (Andreski et al. 1998; Moreau and Zisook 2002).

**Other Axis I diagnoses.** Substance abuse is associated with somatization (Mehrabian 2001) and is reported in

**FIGURE 13-1. Four models of the relation between psychiatric symptomatology and psychiatric disorder.**

subsets of patients with substance abuse. Finally, somatization is also prevalent in patients with schizophrenia and is associated with emotional distress, medication side effects, and expressed emotion within families. A recent study found that more than a quarter of patients with schizophrenia had five or more unexplained medical symptoms, both at admission and 12 months later (Ritsner 2003). Psychotic somatic symptoms (somatic delusions, hallucinations, and misperceptions) are common in schizophrenia and in somatic delusional disorders such as delusions of parasitosis (see Chapter 29, “Dermatology”).

### *Somatization as an Amplifying Personal Perceptual Style*

An amplifying personal perceptual style may be a stable personality trait or a consequence of abnormal neuropsychological information processing (Barsky et al. 1988a). Some somatizing patients show a lowered threshold for reporting physical symptoms (Barsky et al. 1988b; Pennebaker and Watson 1991).

### *Somatization as a Tendency to Seek Care for Common Symptoms*

This model posits that emotional distress prompts people to seek care for common symptoms for which they would not seek care in the absence of emotional distress. It is supported by research in patients with a variety of medically unexplained symptoms in whom medical help seeking is associated with higher levels of emotional distress rather than physical symptoms (Drossman 1999; McBeth and Silman 2001).

### *Somatization as a Response to the Incentives of the Health Care System*

The health care system tends to reinforce illness behavior and symptom reporting and may produce “iatrogenic somatization” (Simon 1991).

## Etiological Factors in Somatization and Somatoform Disorders

### *Pathophysiological Mechanisms*

Understanding and acknowledging the physiological as well as the psychological mechanisms associated with somatization helps both patient and physician to avoid dualistic “mind versus body” thinking—which often devolves into stigmatized notions of “imaginary” versus “real” symptoms—and to develop a therapeutic alliance (Sharpe and Bass 1992). Some of the proposed patho-

physiological mechanisms of somatization are summarized in Table 13–2.

### *Genetic Factors*

Somatization and somatization disorder appear to have a genetic component (Guze 1993; Kendler et al. 1995). Adoption studies of Swedish men suggested that the psychiatric processes associated with somatization in men and women may be qualitatively different (Cloninger et al. 1986). More studies addressing this question are needed.

### *Developmental Factors*

The cognitive appraisals patients make of somatic symptoms often have some of their roots in early family experiences. Physical symptoms are a major form of interpersonal communication in some families (Stuart and Noyes 1999). Childhood exposure to parental chronic illness or abnormal illness behavior appears to increase the risk of somatization in later life (Bass and Murphy 1995; Craig et al. 1993). Negative parenting styles are associated with somatization in irritable bowel syndrome patients (Lackner et al. 2004). Anxious attachment behavior arising from early life experiences may also be the basis for persistent care-seeking behavior that frustrates both health care professionals and family members (Noyes et al. 2003; Stuart and Noyes 1999).

### ***Cognitive Theories***

Cognitive distortions and preferential memory bias for disorder-congruent information have been demonstrated in patients with somatoform disorders (Brown et al. 1999; Pauli and Alpers 2002).

### ***Personality Characteristics***

A variety of psychological traits or personality factors have been linked with somatization, although it is unclear whether they primarily influence symptom production and help-seeking behavior or are a consequence of living with chronic symptoms. Introspectiveness (i.e., the tendency to think about oneself) is associated with increased symptom reporting, greater physical and psychological distress, and more medical help seeking (Mechanic 1986). Negative affectivity, a construct based on negative mood, poor self-concept, and pessimism, is also associated with increased symptom reporting and with greater worry about perceived symptoms (Pennebaker and Watson 1991).

### ***Psychodynamic Factors***

Bodily symptoms have been interpreted as metaphors through which a patient expresses emotional distress or psychic conflict (McDougall 1989). Self psychologists argue that bodily preoccupation develops in response to a fragmented sense of self and can be best understood as an attempt to restore a sense of integration (Rodin 1984). *Alexithymia* refers to impairment in the ability to verbalize affect and elaborate fantasies that results from deficits in the cognitive processing and regulation of emotions (Taylor 2000). It has been implicated as a mechanism of some forms of somatization. Although repressed anger or aggression was thought by classical psychodynamic theorists to be important, Kellner et al. (1985) found no evidence that anger or hostility plays a specific etiological role in somatization and hypochondriasis.

### ***Sexual and Physical Abuse***

Sexual and physical abuse, in both childhood and adulthood, has been linked with somatization, medically unexplained symptoms, and somatoform disorders in numerous studies since the late 1980s. The development of insight into the relation of the abuse to subsequent somatization is helpful for some patients and may decrease subsequent health care use (Walling et al. 1994). The mechanisms by which physical and sexual trauma is associated with somatization are poorly understood. Sexual abuse negatively affects “embodiment” (i.e., the experience of the self in and through the body) (Young 1992). Abuse also causes a tendency to dissociate, and dissociation

is associated with a tendency to report increased physical symptoms (Salmon et al. 2003). Higher hypnotic susceptibility, a marker of the capacity to self-evolve dissociative experiences, has been found to partially mediate the relationship between abuse and conversion symptoms in patients with conversion disorder (Roelofs et al. 2002).

### ***Sociocultural Factors***

Somatization was originally thought to be more common among non-Western cultures, but recent work suggests that somatization is ubiquitous, although prevalence and specific features vary across cultures (Kirmayer and Young 1998). The World Health Organization Cross-National Study of Mental Disorders in Primary Care found that all sites (14 countries) reported high rates of somatization (Gureje et al. 1997) and correlation of somatic symptoms and emotional distress (Simon et al. 1996). The stigmatization of psychiatric distress may be a powerful factor promoting somatization. “Organic” or physical illnesses are seen as more real and less blameworthy than psychiatric disorders, which are seen as being under voluntary control and are often associated with connotations of malingering and weak moral fiber (Kirmayer and Robbins 1991). Somatization may be the only form of communication permissible for the socially powerless.

### ***Gender***

The relation between gender and somatization is complex and poorly understood. Although it has traditionally been believed that women somatize more than men, the literature is problematic (Barsky et al. 2001). A recent international study of somatization in primary care found few sex differences (Piccinelli and Simon 1997). A longitudinal study of primary care attendees found that somatizers were more likely to be men (Kirmayer and Robbins 1996), whereas data from the Epidemiologic Catchment Area study found that women report more unexplained symptoms overall (Liu et al. 1997).

### ***Iatrogenesis***

The health care insurance and disability systems may foster somatization by providing reinforcement (Ford 1983; Simon 1991). Insurance policies with better coverage and fewer barriers for nonpsychiatric medical care than mental health care also provide incentives to somatize (Ford 1992). Well-intentioned but uninformed actions by physicians may also contribute, through unnecessary diagnostic testing and treatments (and their adverse effects) and reinforcement of the sick role (Page and Wessely 2003).

## Assessment and Diagnosis of Somatization

Assessment for somatization or somatoform disorders is often difficult and requires special interviewing skills (Creed and Guthrie 1993; Sharpe et al. 1992).

### *Building an Alliance With the Patient*

Early in the interview, the patient's ambivalence about seeing a psychiatrist must be addressed, as well as what the patient has been told about the consultation process. The specific approach to the examination will vary according to the patient. For very resistant patients, the initial interview is often dominated by gaining sufficient cooperation to allow a more detailed assessment to take place at a later time. The initial phase of the assessment should focus on the history of physical symptoms. Allowing the patient to report a detailed history of his or her physical symptoms provides reassurance that the symptoms are being taken seriously, which aids immeasurably in later phases of the assessment and treatment process. The psychiatrist's use of empathic comments such as "You have had a terrible time" or "The symptoms sound very difficult" help to build an alliance and may lead the patient to volunteer information (Creed and Guthrie 1993). The question "How has this illness or symptom affected your life?" may go a long way toward answering the question "How has your life affected this illness?" Making interpretive or linking statements that bring together the patient's physical and emotional states may encourage the patient to be more forthcoming with regard to emotional distress and may further the sense of engagement (Creed and Guthrie 1993). However, caution must be exercised because premature or maladroit interpretations can be detrimental to the developing trust between patient and physician. For especially skeptical patients, the psychiatrist can emphasize his or her expertise in helping people develop the skills they need to cope with symptoms, regardless of the "cause."

### *Collaborating With the Referral Source*

Collaboration with the referral source is essential for a clear understanding of the reason for referral and of what the patient has been told about it. Psychiatrists can provide guidance about how to explain the psychiatric referral to the patient to make it more acceptable.

### *Reviewing the Medical Records*

Medical records should be reviewed before the consultation to help the psychiatrist devise an approach to the patient. Familiarity with the history fosters an alliance. The type, number, and frequency of the patient's symptoms, as

well as comments about the patient's prior attitude toward symptoms and behavior, should be documented (Creed and Guthrie 1993). The importance of a thorough chart review cannot be overestimated, because the psychosomatic medicine psychiatrist may be the first person to thoroughly review the typically thick chart and thus may be in a better position than any other member of the medical team to reach a diagnosis of either a general medical condition or a psychiatric disorder.

### *Gathering Collateral Information From Family and Friends*

Collateral information can be invaluable to the accurate assessment of current and past functional capacity and current and past psychosocial stressors.

### *Performing a Psychiatric and Mental Status Examination*

In addition to routine psychiatric observations, the examination of the patient with somatic symptoms should include observations about abnormal illness behavior, symptom amplification, and the quality of the patient's description of his or her symptoms. It is essential to evaluate the individual's ideas about the meaning, cause, implications, and significance of his or her symptoms and the individual's emotional response to his or her situation (Barsky 1998; Creed and Guthrie 1993; Sharpe et al. 1992). If it is performed after taking a history of the physical complaints (but not before), a mental status examination is usually acceptable to the patient.

### *Performing a Physical Examination*

A physical examination of the patient is a prerequisite for accurate diagnosis and treatment for several reasons. In some cases, elements of the physical examination should be performed by the psychiatrist (see Chapter 1, "Psychiatric Assessment and Consultation"), who may be in the best position to diagnose a general medical condition because "something about the patient (personality, behavior, affect, odd cognition) has effectively distracted the primary physician and other consultants from the diagnosis" (Cassem and Barsky 1991, p. 132). A case example follows.

Ms. P, a 42-year-old woman who had had a renal transplant 2 months earlier, was referred for psychiatric evaluation of "suspected conversion disorder in a patient with history of obsessive-compulsive disorder" after she developed "constant rocking movement that she can voluntarily stop." The psychiatrist found on examination that the patient had an obvious resting rhythmic truncal tremor. The psychiatrist's examination revealed

subtle choreiform movements in the patient's tongue and fingers. Noting that metoclopramide had been started at the time of the transplant, the psychiatrist diagnosed a movement disorder, which resolved after drug discontinuation.

The physician who is managing a persistently somatizing patient must also tolerate the patient's perpetual concern about symptoms with some degree of equanimity. A medical education that repeatedly emphasizes the danger of "missed diagnoses" and the current medicolegal climate mean that the physician must be confident that a thorough medical evaluation has been completed.

The physical examination may also help to establish a positive diagnosis of somatization disorder. For example, awareness of physical signs associated with stress (e.g., tender anterior chest wall, tender abdomen, spurious breathing, short breath-holding time) leads to a more confident diagnosis rather than a diagnosis of exclusion, the latter of which always has an implication of doubt associated with it (Sharpe and Bass 1992). A variety of physical signs may be useful, but some are controversial in making a diagnosis of a somatoform disorder (see Fishbain et al. 2003). A somatoform disorder should be diagnosed (as the sole diagnosis) only if the examination also confirms normal functioning of the system being tested (Newman 1993).

## Clinical Management of Somatization

The key to clinical management is to adopt caring rather than curing as a goal. Management is a much more realistic goal than cure in this population (Bass and Benjamin 1993; Creed and Guthrie 1993; Epstein et al. 1999; Sharpe et al. 1992; G.C. Smith et al. 2000). Management must be tailored to the individual's somatic symptoms, thoughts and beliefs, behavior, and emotional state (Epstein et al. 1999). Three potential management approaches to the patient with somatization disorder have been described:

1. A *retribution approach* emphasizes helping the patient to link his or her physical symptoms with psychological or stressful factors in his or her life. This is accomplished via a three-step process that links psychosocial stressors (e.g., marital strife) through physiological mechanisms (e.g., increased muscle tension) to physical symptoms (e.g., headache) (Goldberg et al. 1989).
2. A *psychotherapeutic approach* concentrates on developing a close and trusting relationship with the patient (Guthrie et al. 1991).
3. A *directive approach* treats the patient as though he or she has a physical problem, and interventions are framed in a medical model (Benjamin 1989).

The three management approaches vary in their suitability for different patients. The retribution approach is particularly useful in primary care settings, in medical-surgical inpatient settings with patients who have a fair degree of insight, and in psychiatric settings with patients who have less lengthy histories of somatization. The retribution technique can be easily taught to primary care practitioners (Goldberg et al. 1989). The psychotherapeutic approach is most suitable for patients with persistent somatization who are willing to explore the effect of psychosocial factors on their symptoms. The directive approach is most useful for hostile patients who deny the importance of psychological or social factors in their symptomatology.

## Principles of Management

The fundamental principles of management are similar for patients with somatization and with somatoform disorders.

**Providing a positive explanation of symptoms.** In order to engage in treatment, patients require a sense that their primary physician is taking them seriously, appreciates the magnitude of their distress, and has a rationale for the proposed management plan. Most somatizing patients hold explanatory models of their symptoms that are in conflict with their physician's model (Salmon et al. 1999). The clinical challenge is therefore to provide explanations that empower patients with tangible mechanisms, exculpation, and encouragement of self-management rather than explanations that reject or collude with the patient's model (Salmon et al. 1999). Reassurance is helpful to many patients (Page and Wessely 2003), but it must be carefully dosed and targeted. Facile or excessive reassurance may exacerbate disease fears or cause patients to redouble efforts to prove they are sick and may undermine the doctor-patient relationship (Warwick 1992). It is important to emphasize to patients that the psychiatrist is not dismissing their symptoms as being "all in their head" but rather sees the symptoms as being "real" and "in their body" and wants to explore all opportunities for symptom control. The use of metaphors and analogies is often helpful. The metaphor of a radio has been reported to be particularly useful (N.H. Cassem, personal communication, July 1985). The radio channel playing is the symptom that is of concern, and given that it cannot be changed by medical or surgical interventions, the patient must gain greater control over the volume control knob (i.e., factors that exacerbate or relieve symptoms) or the sensitivity of the antenna (i.e., factors that amplify symptoms). Physiological mechanisms underlying symptoms

may be usefully explained (see Table 13–2) (Sharpe and Bass 1992). Understanding the personal meaning of the symptoms to the patient and tailoring one's explanations and reassurance in light of this meaning may improve the doctor–patient relationship (Epstein et al. 1999; Priel et al. 1991).

**Ensuring regular follow-up.** Regular follow-up is the key to effective management; it results in decreased health care utilization overall and is less stressful for both patients and physicians than symptom-driven visits. The best choice for most patients is management by their primary care practitioner in consultation with a psychiatrist. However, the psychiatrist may provide primary follow-up if significant comorbid Axis I or Axis II pathology is present or if the primary care physician cannot manage the symptoms.

**Treating mood or anxiety disorders.** Mood or anxiety disorders have significant morbidity in their own right and interfere with participation in rehabilitation and psychotherapy. Their physiological concomitants may fuel the somatization process or heighten somatic amplification.

**Minimizing polypharmacy.** Polypharmacy may produce iatrogenic complications. Unnecessary medications should be tapered and withdrawn using a staged approach over time with small, realistically achievable steps.

**Providing specific therapy when indicated.** A variety of specific therapies have been recommended for the somatoform disorders and are discussed below under “Management of Somatoform Disorders.” For example, physiotherapy or massage may be helpful in diminishing musculoskeletal pain for patients with somatoform disorders.

**Changing social dynamics that reinforce symptoms.** Many patients' lives come to revolve around their symptoms and their use of the health care system. Regularly scheduled follow-up means that the patient no longer has to present a symptom as a “ticket of admission” to the physician's office. Important members of the patient's social support system may be persuaded to consistently reward non-illness-related behaviors. Social skills building, life skills training, assertiveness training, and physical reactivation programs may be indicated. Group therapy may be useful because it provides social support, increases interpersonal skills, and provides a nonthreatening environment in which to learn to experience and express emotions and desires more directly.

**Resolving difficulties in the doctor–patient relationship.** Somatizing patients often have difficult relationships with their caregivers because of attention seeking, demands, and anger. These difficulties have multiple determinants, including problematic early attachment (Stuart and Noyes 1999), differences in expectations and beliefs about the meaning and management of symptoms, and prior frustrating experiences with the health care system (Page and Wessely 2003). Consequently, addressing shortcomings in doctor–patient interactions can be helpful (Page and Wessely 2003).

**Recognizing and controlling negative reactions or countertransference.** Somatizing patients can evoke powerful emotional responses in physicians, which may result in less than optimal clinical care (Hahn et al. 1994; Sharpe et al. 1994). The range of emotions experienced by physicians may include guilt for failing to help the patient, fear that the patient will make a complaint, and anger at the patient's entitlement. The physician may be dismissive of the patient or, alternatively, may collude with the patient in excessive investigations to exclude physical disease in “a suspension of professional judgment” (Bass and Murphy 1990). Excessive investigation might result from a conscious attempt to avoid a “painful, embarrassing and time-consuming confrontation” (Bass and Murphy 1990) or may represent an unconscious solution to the conflicts and emotions that the patient evokes in the physician. The treating physician should seek to identify something about the patient that is either likable or interesting that will help to sustain his or her involvement—in the most difficult patients, it may simply be a sense of amazement at the degree of somatization. A physician caring for these patients must also set clear limits as to his or her availability. If all else fails, the physician should transfer the care of the patient to a colleague, either temporarily or permanently.

## Somatoform Disorders

---

The DSM-IV-TR somatoform disorders are somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, body dysmorphic disorder, and somatoform disorder not otherwise specified (American Psychiatric Association 2000). The feature they have in common is the presence of unexplained physical symptoms that are not intentionally produced. In DSM-IV-TR it is emphasized that these disorders are grouped together because of the need to exclude medical and substance-induced etiologies (American Psychiatric Association 2000).

Somatoform disorders are more common in ambulatory than in inpatient settings. They have been diagnosed in 3%–4% of psychiatric consultations in general hospitals in Australia (G.C. Smith et al. 2000) and the Netherlands (Thomassen et al. 2003). In the latter study the somatoform diagnoses were conversion disorder, 40%; hypochondriasis, 24%; somatoform pain disorder, 20%; and somatization disorder, 17%. Studies of the general population have reported more variable rates. A recent study of German adolescents and young adults found a lifetime rate for somatoform disorders of 3%; a further 11% of subjects had subsyndromal conditions (Lieb et al. 2000).

There are a number of difficulties in the clinical application of the somatoform diagnoses as defined in the DSM. First, excluding a medical cause for symptoms is problematic, particularly for those with comorbid medical diseases. The focus on exclusion promotes dualistic thinking, but failure to demonstrate a medical cause for symptoms does not necessarily mean the patient has a psychiatric disorder (Kirmayer and Young 1998). Second, the question of intentionality or consciousness in symptom production is a vexing one. Distinguishing somatoform disorders from the factitious disorders and malingering is discussed in Chapter 14 (“Deception Syndromes: Factitious Disorders and Malingering”), but these disorders can overlap. Third, dimensional rather than categorical approaches may be more helpful in describing hypochondriacal preoccupation, medically unexplained symptoms, and help seeking. Fourth, the clinical descriptions of specific disorders are largely derived from tertiary care or psychiatric hospital samples and emphasize chronicity.

Finally, the separate existence of a discrete category of somatoform disorders reinforces the mind–body dualism of Western medicine and implies a separation of affective, anxiety, dissociative, and somatic symptoms (Kirmayer and Young 1998). In fact, somatic symptoms and somatization cut across DSM-IV-TR diagnostic categories. Some recent critics have suggested extensive reformulation, reclassification, and even abolition of the somatoform disorders (Mayou et al. 2003; Phillips et al. 2003).

## Somatization Disorder

### *Definition*

Somatization disorder is based on the earlier diagnosis of Briquet’s syndrome, which required 25 of 59 physical symptoms, an illness onset before age 30 years, and a pattern of recurrent physical complaints, and was shown to have validity, reliability, and internal consistency (Feighner et al. 1972). The long-term stability of the diagnosis

was documented by the finding that 80%–90% of patients continued to meet diagnostic criteria at 6- to 8-year follow-up (Guze et al. 1986). DSM-III criteria for somatization disorder were a modification of Feighner’s criteria, with a total symptom count of 14 symptoms in women and 12 symptoms in men from a total list of 36 physical symptoms (American Psychiatric Association 1980). In DSM-III-R the criteria were further modified by simplifying the requirement to 13 of 35 physical symptoms and specifically excluding symptoms occurring only during a panic attack (American Psychiatric Association 1987). The diagnostic criteria were again simplified in DSM-IV, and they have been found to be concordant with prior criteria (Yutzy et al. 1995).

### *Epidemiology*

The lifetime prevalence of somatization disorder has varied widely across studies, ranging from 0.2% to 2.0% among women and less than 0.2% in men (American Psychiatric Association 2000), reflecting variations in research methodology and study samples. Because patients with somatization disorder actively seek medical help, their prevalence in medical settings is higher than in the general population. Somatization disorder has been diagnosed in 1%–5% of primary care patients (Simon and Gureje 1999). Changes in practice patterns have likely led to fewer somatization disorder patients being admitted to hospitals. Patients with somatization disorder accounted for 0.7% of Dutch psychiatric consultations (Thomassen et al. 2003) and 0.2% of Australian consultations to medical and surgical inpatients (G.C. Smith et al. 2000). Recent work has emphasized the instability of recall of somatic symptoms, with implications for underdiagnosing somatization disorder (Simon and Gureje 1999). By definition, the syndrome must begin before age 30, but most often symptoms begin in the teens, often with menarche, or less commonly in the early 20s. The risk for depression, alcohol abuse, and antisocial personality disorder is increased in the first-degree relatives of individuals with somatization disorder (Golding et al. 1992).

### *Specific Culture and Gender Factors*

There is cultural variability in the presentation of somatization disorder. Symptoms used in DSM-IV-TR are those that have been found to be most diagnostic in the United States (American Psychiatric Association 2000). The disorder is uncommon in American men (Golding et al. 1991), although in an American sample women and men with somatization disorder had similar clinical characteristics, including comorbid psychopathology (Golding et al. 1991). Women with somatization disorder are

more likely to have a history of sexual abuse than are women with primary mood disorders (Morrison 1989).

Ms. L is a 28-year-old woman referred for psychiatric assessment based on 25 primary care visits, 18 emergency room visits, and 2 hospitalizations in the past 12 months for a variety of symptoms, including unexplained headaches, pelvic pain, dysmenorrhea, back pain, nausea, dysphagia, and irregular menses. She has been “sickly” since childhood; is unemployed as a result of her multiple medical problems; and is socially isolated, having had difficulties in interpersonal relationships for many years.

### **Clinical Features**

The classic patient with somatization disorder is a woman who subjectively is “sickly” and who began to experience medically unexplained symptoms in early adolescence. Her condition has shown a waxing and waning course over the years, with a medical history that documents repeated, unexplained physical complaints. Patients with somatization disorder are often difficult historians who provide dramatic and colorful but vague descriptions of their medical history (Cassem and Barsky 1991) and may present as odd or anxious (Rost et al. 1992). There is often more to be learned in a review of their medical records.

### **Associated Features**

Patients with somatization disorder have high rates of psychiatric comorbidity. As many as 75% of patients with somatization disorder have comorbid Axis I diagnoses (Katon et al. 1991), of which the most common are major depressive disorder, dysthymia, panic disorder, simple phobia, and substance abuse. Because patients with somatization disorder have a low threshold for endorsing symptoms, in some cases comorbid diagnoses may reflect an amplifying response tendency rather than significant symptomatology. However, many patients do have bona fide comorbid Axis I disorders with significant negative impact on functioning. Personality disorders appear to be especially common in patients with somatization disorder. The most common comorbid Axis II diagnoses in psychiatric settings are Cluster B diagnoses, whereas in primary care settings Cluster C and paranoid personality diagnoses are more frequent (Rost et al. 1992). The association between personality disorder and somatization disorder may result from a common biological substrate or social-environmental factors such as childhood abuse (G.R. Smith 1991). Patients with somatization disorder often have multiple social problems and chaotic lifestyles characterized by poor interpersonal relationships, disruptive or difficult behavior, and substance abuse (Cassem and Barsky 1991) and show significant occupational and social impairment.

### **Clinical Course and Prognosis**

Somatization disorder is “a chronic but fluctuating disorder that rarely remits completely. A year seldom passes without the individual’s seeking some medical attention prompted by unexplained somatic complaints” (American Psychiatric Association 2000, p. 488). Patients may experience iatrogenic disease or injury secondary to unnecessary diagnostic investigations, polypharmacy, and poly-surgery. They are particularly at risk for abuse and dependence on drugs prescribed for symptom control (e.g., analgesics, sedative-hypnotics).

### **Differential Diagnosis**

*Occult medical diseases* affecting multiple organ systems and manifesting with vague or nonspecific symptoms (e.g., systemic lupus erythematosus, sarcoidosis, lymphoma) should be excluded. Patients with these diagnoses, in contrast to somatization disorder, look chronically ill and usually have abnormal physical examinations or laboratory tests. *Panic disorder* may be mistakenly diagnosed as somatization disorder, given a history of many physicians and extensive diagnostic investigations, although symptom patterns differ, with panic disorder patients describing acute symptoms occurring simultaneously, in contrast to the chronic, protean, and fluctuating symptoms of somatization disorder. Chronic physical symptoms may be a part of a *depressive disorder* but occur in the context of the mood disturbance without the long duration and dramatic symptom fluctuations seen in somatization disorder. Some patients with *schizophrenia* or *delusional disorder* develop multiple somatic delusions, distinguished from somatization disorder by their bizarre content. By definition, somatization disorder includes symptoms compatible with other *somatoform disorders*, and diagnostic overlap is common. Somatization disorder differs from *factitious disorder* and *malingering* by the lack of intentional symptom production.

## Undifferentiated Somatoform Disorder

### **Definition**

Undifferentiated somatoform disorder is a residual category for individuals who do not meet the full criteria for somatization disorder or another somatoform disorder. The diagnosis requires one or more physical complaints persisting for more than 6 months that cannot be accounted for by a general medical condition, direct effects of a substance, or another psychiatric disorder.

### **Epidemiology**

No studies of undifferentiated somatoform disorder per se have been conducted, but investigators have studied vari-

ously defined subsyndromal somatization syndromes. Using a cutoff score of four DSM-III somatization symptoms for men and six symptoms for women, a group of patients were identified whose characteristics, including increased medical utilization, resembled those of patients meeting the full criteria for somatization disorder (Escobar et al. 1987, 1989). Studies of distressed high utilizers of medical care documented significant increased health care utilization by patients endorsing functional somatic symptoms falling below the DSM-III-R cutoff score of 13 symptoms (Katon et al. 1991). It is estimated that 4%–11% of the population have multiple medically unexplained symptoms that are consistent with a subsyndromal form of somatization disorder (Escobar et al. 1987, 1989).

Alternative diagnoses have been proposed as being more clinically useful than undifferentiated somatoform disorder. “Multisomatoform disorder” is characterized by three or more medically unexplained, currently bothersome physical symptoms in addition to a greater than 2-year history of somatization (Kroenke et al. 1997). “Specific somatoform disorder” requires at least one unexplained physical impairment and a substantial impairment in more than one life domain (Rief and Hiller 1998, 1999) and identifies a more impaired group than does the DSM-IV-TR diagnosis of undifferentiated somatoform disorder (Grabe et al. 2003).

### ***Clinical Course, Prognosis, and Differential Diagnosis***

It is likely that the course of this heterogeneous disorder is variable, although there has been little systematic study (American Psychiatric Association 2000). The differential diagnosis is similar to that of somatization disorder.

## **Conversion Disorder**

### ***Definition***

Conversion symptoms have been described since antiquity (Mace 1992). DSM-IV-TR diagnostic criteria for conversion disorder include neurological (voluntary motor or sensory) symptoms or deficits that are associated with psychological factors (American Psychiatric Association 2000). Conversion presentations can be quite dramatic and can include paralysis, pseudoseizures, amnesia, ataxia, or blindness (see Chapter 32, “Neurology and Neurosurgery”).

Controversies surrounding the diagnosis of conversion disorder include whether 1) it is a symptom rather than a disorder, because it has not been validated on the basis of longitudinal or family studies (Martin 1992); 2) it

is better classified with the dissociative disorders as in ICD-10 (Phillips et al. 2003; Toone 1990); and 3) the determination that the symptom is unconsciously produced can be a valid and reliable judgment. Critics have also questioned what constitutes “relevant psychological conflict,” how malingering is excluded, and the extent to which organic disorders can and should be excluded (Halligan et al. 2000).

### ***Epidemiology***

The reported prevalence of conversion disorder has varied and is likely influenced by several factors. Toone’s 1990 review noted rates of 0.3% in the general population, 1%–3% in medical outpatients, and 1%–4.5% in hospitalized neurological and medical patients. Settings such as combat, in which substantial secondary gain may be involved, have increased rates of conversion. Studies of associations with social class and urban versus rural distribution have yielded equivocal findings (Murphy 1990).

Onset is typically in adolescence or early adulthood, but cases have been described in children as well as in older adults. An often-quoted early study cautioned that many patients given a conversion disorder diagnosis subsequently received a diagnosis of a neurological or medical condition that explained the symptom (Slater and Glithero 1965). Recent studies have found lower (5%–12%) rates of explanatory neurological diagnoses (Crimlisk et al. 1998; Moene et al. 2000). These more recent findings may be partially explained by increasing caution on the part of clinicians in making a diagnosis of conversion disorder and by modern neuroimaging and electrophysiological tests. The relationship between childhood traumatization, particularly physical and sexual abuse, and the subsequent development of conversion disorder was first described by Freud and is supported by recent empirical research (e.g., Roelofs et al. 2002), although this association has not been found in all samples (Binzer and Eisemann 1998). Clinically, this association appears especially frequently among patients with pseudoseizures, with trauma reported by 84%, which included sexual abuse by 67%, physical abuse by 67%, and other traumas by 73% in one study (Bowman and Markand 1996).

### ***Specific Culture and Gender Factors***

Much higher prevalence rates have been described in developing countries (Murphy 1990) and in isolated rural American settings (Ford 1983). Women outnumber men with the disorder in a ratio varying from 2:1 to 10:1 (Murphy 1990). Men are more likely to present with conversion symptoms related to military service and industrial accidents (Ford 1983).

Mr. T is a 36-year-old male payroll officer presenting with frequent seizures despite a 10-year history of excellent anticonvulsant control after originally developing seizures following a severe head injury sustained in a motor vehicle accident. There is a strong family history of epilepsy and a history of childhood febrile seizures. Anticonvulsant levels remained therapeutic, and there were no changes in his neurological examination. Detailed history taking revealed markedly increased workplace stress with little chance of changing jobs and a precarious marital relationship. His wife noted that the first seizure occurred on the morning after he had been reprimanded at work.

### **Clinical Features**

Conversion symptoms typically begin abruptly and dramatically. Common conversion symptoms include motor symptoms (e.g., paralysis, disturbances in coordination or balance, localized weakness, akinesia, dyskinesia, aphonia, urinary retention, and dysphagia), sensory symptoms (e.g., blindness, double vision, anesthesia, paresthesia, deafness), and seizures or convulsions that may have voluntary motor or sensory components. Unilateral symptoms may be more likely to occur on the left side of the body, as may be true for other somatoform disorders, although the neurophysiological basis for this finding is unclear (Toone 1990) and not all data support it (Roelofs et al. 2000). Some patients with conversion symptoms also have or had the same symptoms from a neurological disease (e.g., conversion pseudoseizures in a patient with epilepsy, as in the case illustration above; Iriarte et al. 2003). In many patients with conversion disorder there is a discrepancy between the presumably frightening symptoms and the patient's bland, even cheerful emotional response ("la belle indifférence"), but this is not a pathognomonic sign and if present does not have prognostic value (Toone 1990).

Psychological factors are associated with symptom onset or exacerbation. Psychodynamic views of conversion focus on the etiological role of *primary gain*, which refers to "the effectiveness of the conversion symptom in providing a satisfactory symbolic expression for the repressed wishes" (Engel 1970, p. 660). For example, a conflict about aggression might be symbolically expressed through a paralyzed arm. *Secondary gain* refers to the potential tangible benefits accruing from the sick role, which may include alterations in the behavior of significant others that are deemed positive by the patient (e.g., increased attentiveness) and permission to withdraw from disliked responsibilities. Secondary gain is believed to occur, but not to be consciously sought, in patients with conversion disorder. This contrasts with malingering, in which symptoms are produced intentionally and are mo-

tivated by external incentives, or factitious disorders, in which symptoms are produced intentionally from the unconscious motivation of assuming the sick role. Caution must be exercised in making judgments about secondary gain because it is intrinsic to the sick role and may be found in patients with any medical or psychiatric illness.

### **Associated Features**

There has been little systematic study of comorbid Axis I diagnoses. The literature on associated personality features suggests that "hysterical personality may be seen, but only in a minority of conversion cases; other forms of personality disorder of immature, dependent type are more usual" (Toone 1990, p. 229). Protracted conversion reactions may be associated with secondary physical changes (e.g., disuse atrophy).

### **Clinical Course and Prognosis**

The course of conversion disorder is difficult to predict. Individual episodes of conversion are usually of short duration with sudden onset and resolution, although recurrence of symptoms over time is common (American Psychiatric Association 2000; Murphy 1990). In some cases, conversion symptoms may last years. Factors reported to predispose to conversion disorder are antecedent physical disorders in the individual or a close contact, which provides a model for the symptoms occurring; and severe social stressors, including bereavement, rape, incest, warfare, and other forms of psychosocial trauma (Toone 1990). The prognosis depends on a number of factors, including acuity of onset, presence of major stressors, duration of symptoms before treatment, symptom pattern, personality, and sociocultural context within which the illness developed. Most patients show a rapid response to treatment, but some do not. Patients with pseudoseizures, tremor, and amnesia are particularly likely to have a poor outcome (Toone 1990).

### **Differential Diagnosis**

The differential diagnosis of conversion disorder includes *neurological conditions* that present with evanescent signs and symptoms (e.g., multiple sclerosis, complex partial seizures, myasthenia gravis). *Pain disorder* is diagnosed if pain is the only conversion symptom. Conversion symptoms may occur in *other psychiatric disorders* (e.g., pseudoseizures as a manifestation of panic disorder or post-traumatic stress disorder; Bowman and Coons 2000) or during *bereavement*. Psychogenic amnesia, fugue, or stupor may represent conversion or *dissociative disorders*, although this appears to be an arbitrary semantic distinction. As with other somatoform disorders, symptoms are

generated unconsciously, whereas they are intentional in *factitious disorder* and *malingering*, although in practice the distinction may be blurry.

## Pain Disorder

Pain disorder in DSM-IV-TR is the latest incarnation of somatoform pain disorder (DSM-III-R) and psychogenic pain disorder (DSM-III) (see Chapter 36, "Pain").

## Hypochondriasis

### *Definition*

Hypochondriasis is characterized by persistent fears of having a disease or the belief that one has a serious disease based on the misinterpretation of one or more bodily symptoms that persist despite medical reassurance (American Psychiatric Association 2000). The validity of the construct in medical outpatients has been documented (Barsky et al. 1986b; Noyes et al. 1993). Secondary hypochondriasis (i.e., hypochondriasis developing in the context of another Axis I psychiatric disorder, a major life stress, or a medical disorder) has been described (Barsky et al. 1992), although it is not recognized in DSM-IV-TR.

### *Epidemiology*

No large-scale epidemiological studies of hypochondriasis have been conducted. Prevalence rates for primary and secondary forms of hypochondriasis of 3%–13% have been reported for study samples from medical and psychiatric settings (Kellner 1986) and 4%–6% of general medical outpatients (Barsky 2001). The prevalence in the general population is 1%–5% (American Psychiatric Association 2000). The disorder can begin at any age, but onset is most commonly in early adulthood (American Psychiatric Association 2000).

### *Specific Culture and Gender Factors*

The reported data on ethnic and cultural differences are equivocal (Barsky et al. 1986a; Kellner 1986), and these factors may be most important when an individual's concerns are reinforced by a traditional or alternative healer who disagrees with the medical reassurance provided (American Psychiatric Association 2000). Gender has received little attention.

Mr. J, a 44-year-old sales manager, was referred for assessment of anxiety by an infectious disease doctor who felt that the patient did not have chronic fatigue syndrome. Mr. J was reluctant to speak with a psychiatrist but was grateful to have someone listen in detail to his various medical concerns. On the second assessment in-

terview, he confided that he was convinced that he had multiple sclerosis or amyotrophic lateral sclerosis and that he repeatedly measured the muscle mass in his legs, tested for changes in strength, and watched for "muscle twitches." His preoccupation with his health had negatively affected his work, because he spent much of the day searching the Internet for information, and he reported feeling distant from his wife and children as he "prepared to go downhill and die."

### *Clinical Features*

The core feature of hypochondriasis is fear of disease or a conviction that one has a disease despite normal physical examination results and investigations and physician reassurance. Bodily preoccupation (i.e., increased observation of and vigilance toward bodily sensations) is common. The preoccupation may be with a particular bodily function or experience (e.g., heartbeat); a trivial abnormal physical state that is taken as evidence of disease (e.g., cough); a vague physical sensation; or a particular organ (e.g., heart) or diagnosis (e.g., cancer). Patients with hypochondriasis believe that good health is a relatively symptom-free state, and compared with control patients, they are more likely to consider symptoms to be indicative of disease (Barsky et al. 1993). The concern about the feared illness "often becomes a central feature of the individual's self-image, a topic of social discourse, and a response to life stresses" (American Psychiatric Association 2000, p. 504).

### *Associated Features*

Patients with hypochondriasis have a high rate of psychiatric comorbidity, with the most common comorbid diagnoses being generalized anxiety disorder, dysthymia, major depressive disorder, somatization disorder, and panic disorder (Barsky et al. 1992). Personality disorders as assessed by questionnaire were three times more likely to be diagnosed in hypochondriacal patients compared with a control group (Barsky et al. 1992). High medical utilization is common, and the potential exists for iatrogenic damage from repeated investigations. Involvement with complementary health care practices is common. Interpersonal relationships typically deteriorate because of the preoccupation with disease. Occupational functioning is often compromised, with increased time taken off from work and decreased performance when the individual is at work because of the preoccupation with disease.

### *Clinical Course and Prognosis*

The clinical course and prognosis of hypochondriasis are poorly understood. There appear to be multiple pathways to the diagnosis. Primary hypochondriasis appears to be a chronic condition, and therefore some have argued that it

might be better classified as a personality style or trait (Barsky and Klerman 1983; Fallon and Feinstein 2001; Mayou et al. 2003; Tyrer et al. 1990). In DSM-IV-TR the course is described as “usually chronic, with waxing and waning symptoms, but complete recovery sometimes occurs” (American Psychiatric Association 2000, p. 506). Positive prognostic features include an acute onset, brief duration, mild symptoms, absence of secondary gain, presence of a comorbid general medical condition, and absence of psychiatric comorbidity (American Psychiatric Association 2000). Secondary hypochondriasis may develop in the context of either current or past serious illness in the patient or family, bereavement, and psychosocial stressors or during the course of another Axis I disorder, principally a mood or anxiety disorder characterized by prominent somatic symptoms. Some forms of secondary hypochondriasis remit with resolution or treatment of the underlying condition (e.g., major life stressors, mood or anxiety disorders). A prospective study found that hypochondriacal patients had a considerable decline in symptoms and improvement in role functioning over 4–5 years, but two-thirds still met diagnostic criteria (Barsky et al. 1998).

### **Differential Diagnosis**

The differential diagnosis of hypochondriasis includes *general medical conditions*, particularly the early stages of a variety of rheumatological, immunological, endocrine, and neurological diseases in which the patient may notice symptoms that may not be associated with signs detectable on physical examination or with abnormal laboratory investigation. Of course, hypochondriasis may coexist with medical pathology (Barsky et al. 1986a). Transient hypochondriacal preoccupations related to medical illness do not constitute hypochondriasis (American Psychiatric Association 2000). Hypochondriacal concerns may accompany *other psychiatric diagnoses* characterized by prominent somatic symptoms (e.g., *major depressive disorder, dysthymia, panic disorder, generalized anxiety disorder, obsessive-compulsive disorder*). *Psychotic disorders* are characterized by the fixed quality of the patient’s delusional belief, in contrast to the hypochondriacal patient, who is convinced of the veracity of his or her concerns but is able to consider the possibility that the feared disease is not present. In clinical practice sorting out delusional from nondelusional hypochondriasis is sometimes difficult.

## **Body Dysmorphic Disorder**

### **Definition**

The hallmark of body dysmorphic disorder (BDD) is the preoccupation with an imagined defect in appearance (if a

slight physical anomaly is present, the individual’s concern with it is judged to be markedly excessive) that is accompanied by significant distress or impairment in social or occupational functioning (American Psychiatric Association 2000). Although BDD is classified in DSM-IV-TR as a somatoform disorder, it is increasingly seen as an obsessive-compulsive spectrum disorder (Phillips 1998, 2001; Phillips and Hollander 1996; Phillips et al. 2003). There have been several recent reviews of the topic (A. Allen and Hollander 2000; Cororve and Gleaves 2001; Phillips 2001; Sarwer et al. 2003).

### **Epidemiology**

The prevalence of BDD is greater than many clinicians recognize (Phillips 1998). BDD has been reported to occur in about 5% of patients seeking cosmetic surgery in the United Kingdom (Veale et al. 2003), 5% of female Turkish college students (Cansever et al. 2003), and 9% of Turkish patients presenting for acne treatment (Uzun et al. 2003). Otto et al. (2001) estimated a point prevalence of 0.7% in a community sample of women ages 36–44 years in Boston, Massachusetts. Structured interviewing is more likely to identify cases (Zimmerman and Mattia 1998), supporting the claim that it is an underrecognized disorder. Onset is typically in adolescence (Phillips 1998), although the disorder may begin in childhood (Albertini and Phillips 1999). Many years may pass before diagnosis because of the individual’s reluctance to reveal symptoms (American Psychiatric Association 2000).

### **Specific Culture and Gender Factors**

Cultural variation in BDD has received relatively little attention, although it is clear that concerns about physical appearance vary across cultures and likely color the presentation in different cultures. A comparative study of American and German college students concluded that body image concerns and preoccupation were significantly greater in American than in German students, although the prevalence of probable BDD was not (Bohne et al. 2002). The sex distribution of BDD varies across case series (Phillips 1998). Men and women describe differential preoccupations in line with cultural norms: women are more likely to be preoccupied with their hips and weight, and men with body build, genitals, and thinning hair (Phillips and Diaz 1997).

Ms. Y is a 32-year-old woman who was referred to a psychiatrist for “support” by a plastic surgeon whom she had consulted regarding revisions of a rhinoplasty (“still not right”) and breast augmentation (“I don’t look balanced”). The breast augmentation had been complicated by infection, and there was an objective imbalance

and excessive scarring, but her nose appeared aesthetically pleasing. She believed that plastic surgery would make her more attractive, thus “allowing” her to leave her married abusive boyfriend and find a new partner. Collateral information from her mother revealed long-standing bodily preoccupation dating from early adolescence, difficulties in relationships with men, and poor occupational functioning and underemployment.

### **Clinical Features**

Most patients with BDD have concerns about more than one body part (Phillips 1998). The intensity of the preoccupation with the bodily “defect” has been described as “torturing” and “tormenting,” dominating the patients’ lives and severely limiting social and occupational functioning. Many patients engage in compulsive “checking” behaviors, such as observing themselves in the mirror or measuring the body part of concern. Medical intervention, including surgery, is sought by many patients—75% in one study, with 66% receiving treatment (Phillips et al. 2001b). Delusional BDD—classified as delusional disorder, somatic type—may reflect a difference in insight rather than a distinct syndrome (Phillips et al. 1994).

### **Associated Features**

BDD has substantial comorbidity. Major depressive disorder is the most common comorbid disorder, with a current comorbidity rate of about 60% and a lifetime rate of more than 80% (Phillips and Diaz 1997). Other disorders with lifetime rates of more than 30% include social phobia, substance use disorders, and obsessive-compulsive disorder. Some case series have lower rates of comorbidity (Veale et al. 1996a). Social phobia usually begins before the onset of BDD, whereas depression and substance use disorders typically develop after the onset of BDD (Gunstad and Phillips 2003). Personality disorder is common (Phillips 2001), with the most common diagnosis being avoidant personality disorder (Veale et al. 1996a). Psychosocial dysfunction is often profound, with social withdrawal and occupational functioning below capacity (Phillips 1998) as well as suicidal behavior (Phillips et al. 1993). BDD can profoundly reduce quality of life; in a study using the SF-36 questionnaire, BDD subjects’ scores in all mental health domains were worse than norms for patients with depression, diabetes, or a recent myocardial infarction (Phillips 2000).

### **Clinical Course and Prognosis**

No long-term prospective studies of clinical course have been conducted, but case series suggest that BDD is usually chronic, with few symptom-free intervals. The intensity of the symptoms may vary over time (American Psy-

chiatric Association 2000). Patients with BDD often seek and obtain inappropriate medical and surgical treatment (Phillips et al. 2001b). Cosmetic surgeons have begun to recognize the importance of identifying BDD, because it occurs in 7%–15% of those seeking surgery, and operating on BDD patients may worsen the BDD, placing the surgeon at risk of litigation and physical harm (Sarwer et al. 2003).

### **Differential Diagnosis**

A diagnosis of BDD is not made when another *Axis I disorder* (e.g., *mood disorder, schizophrenia, anorexia nervosa*) better accounts for the behavior. Distinguishing between BDD and *delusional disorder, somatic type*, can be difficult (Phillips 2001; Phillips et al. 1993), as can sorting out “*normal body dissatisfaction*” (Murphy 1990), because concerns about appearance are common and are reinforced by unrealistic media ideals.

## **Management of Somatoform Disorders**

---

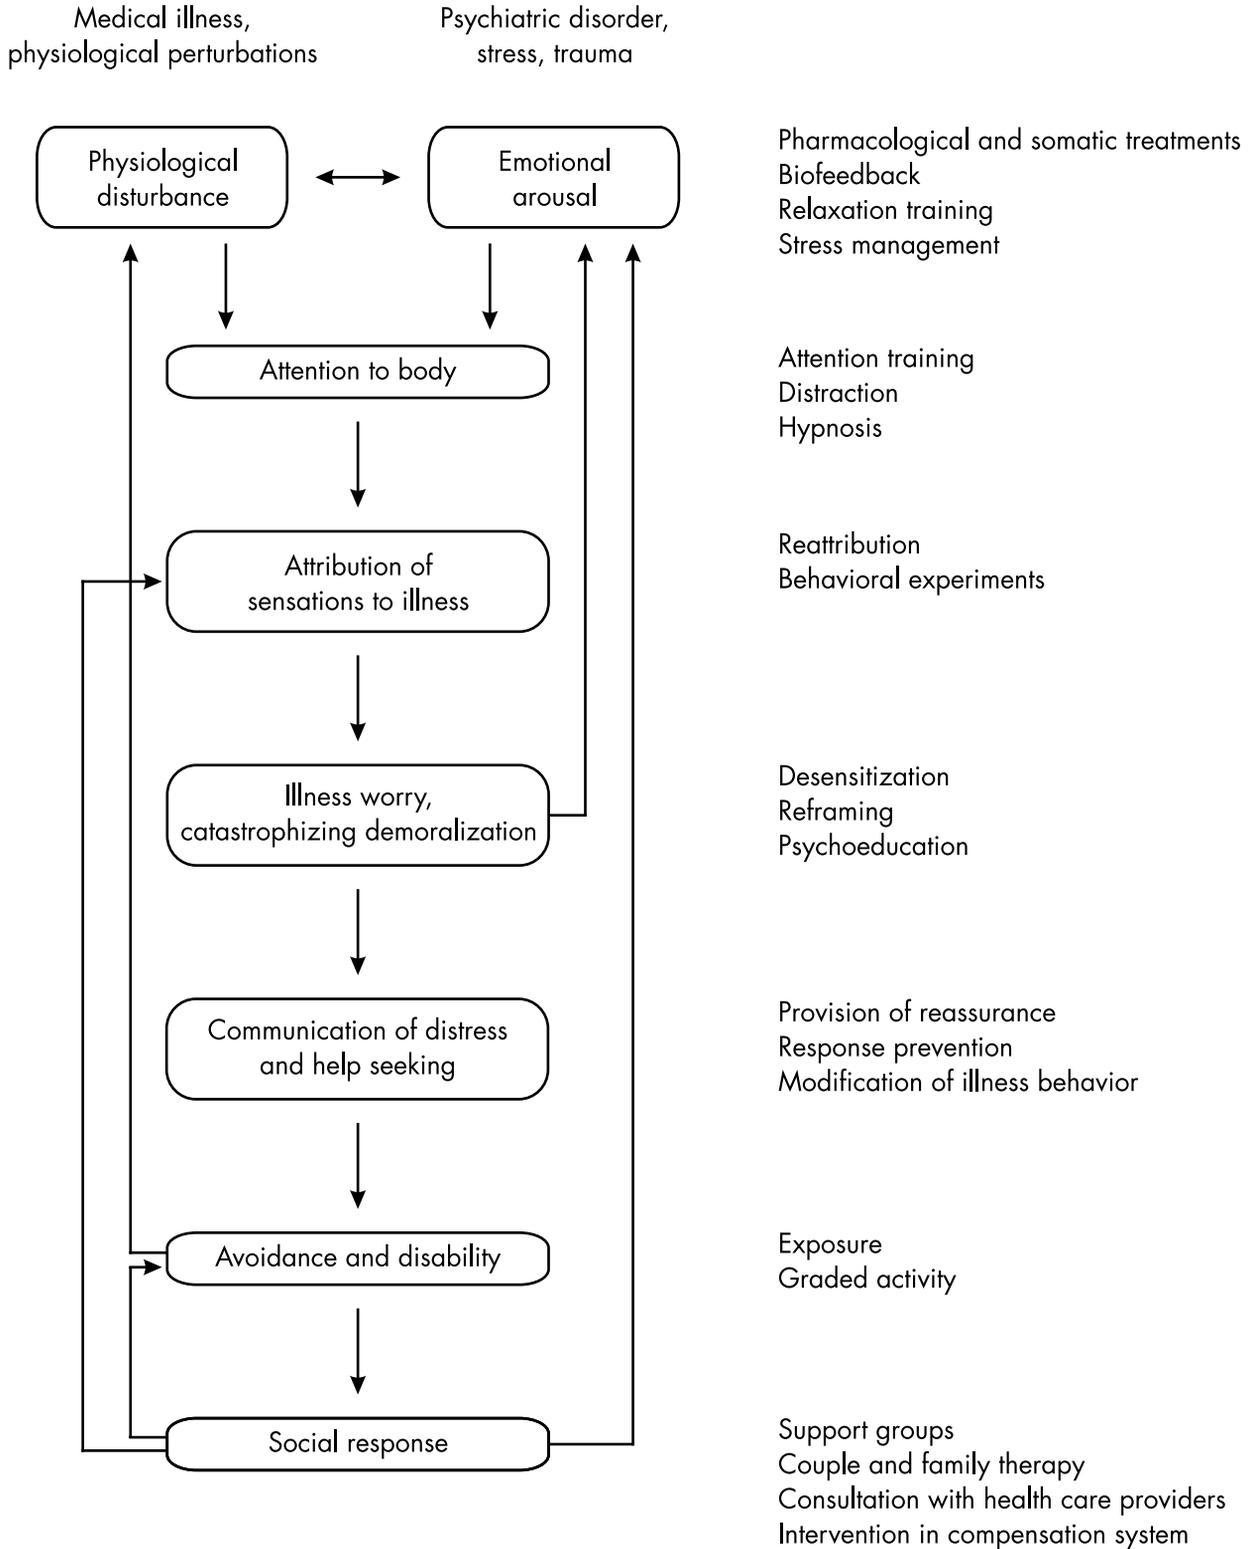

Management of the somatoform disorders shares many features with the management of somatization described earlier in this chapter. Limit setting and caring rather than curing have been the traditional foci, although newer pharmacological and psychotherapeutic approaches offer the potential for substantial improvement in some patients. Because many patients with somatoform disorders refuse mental health treatment, the psychiatrist’s role is often that of a consultant developing a management plan that integrates multiple treatment modalities and different health care disciplines. In this section, issues specific to the management of somatoform disorders are summarized. Several recent reviews have discussed psychosocial treatments for unexplained physical symptoms (L.A. Allen et al. 2002; Looper and Kirmayer 2002). Cost-effective integrated programs have shown decreased health care utilization (Hiller et al. 2003). Treatment interventions can be tailored to the relevant underlying mechanisms in specific patients, as illustrated in Figure 13–2 (Looper and Kirmayer 2002).

### **Approach to the Patient**

In addition to the general approach to the somatizing patient discussed earlier in this chapter, specific management strategies have been described for patients with conversion disorder, including 1) explaining to the patient that his or her conversion symptoms are not caused

**Mechanisms**

**Treatment interventions**

**FIGURE 13-2. Matching mechanisms and interventions in the management of somatoform disorders.**  
 Source. Reprinted from Loper KJ, Kirmayer LJ: "Behavioral Medicine Approaches to Somatoform Disorders." *Journal of Consulting and Clinical Psychology* 70:810-827, 2002, p. 812. Copyright 2002, the American Psychological Association. Used with permission.

by a serious disease, 2) refraining from confronting the patient, and 3) providing some form of “face-saving” mechanism for symptom resolution such as physical therapy or the suggestion that the patient will improve over a specified period. Eisendrath (1989) observed that “when dealing with behavior with prominent unconscious motivation such as conversion reactions...the therapist provides no benefit by revealing understanding of the psychological processes too early in the treatment” (p. 386). Although many clinicians feel uncomfortable about the risks inherent in “legitimizing” the illness, this approach seems justified based on considerable anecdotal experience of good outcome with treatment and prolonged disability without it. The consulting psychiatrist often must help the referring physician and other health care professionals manage their emotional responses to these patients, whom they may view as deceiving them. The choice of words in talking to patients is very important: terms such as *stress-related seizures* or *functional seizures* are much more acceptable, while remaining truthful, than *pseudoseizures* or *psychogenic seizures*, which may be seen as offensive or pejorative (Stone et al. 2003).

There has been little study of the treatment preferences of patients. Walker et al. (1999) studied 23 volunteers with a diagnosis of hypochondriasis and found that cognitive-behavioral therapy (CBT) was rated as more acceptable than medications and was perceived as more likely to be effective in the short and long term. CBT was the first choice of 74% of participants, in contrast to medication in 4% and equal preference in 22%. Of note, 48% reported they would accept only CBT.

## Pharmacotherapy

Pharmacotherapy for somatoform disorders is in its infancy and is limited to studies of small heterogeneous samples, chart reviews, and open-label trials. There is great interest in the potential role of antidepressants in ameliorating somatic symptoms associated with depression, as well as functional somatic symptoms in nondepressed patients (Stahl 2003). Norepinephrine and serotonin have important functions in mediating physical symptoms, and therefore their modulation with antidepressants may bring about changes in somatic experiences (Stahl 2003). An open-label trial of fluoxetine found moderate improvement in 61% of 29 patients with a variety of somatoform disorders (Noyes et al. 1998). In a European placebo-controlled trial, opipramol (a histamine H<sub>1</sub>, serotonin 5-HT<sub>2</sub>, and dopamine D<sub>2</sub> blocker) demonstrated efficacy in a diverse group of somatoform patients with high rates of depressive and anxiety comorbidity (Volz et al. 2000).

Pharmacotherapy has limited effectiveness in somatization disorder except for treatment of comorbid mood and anxiety disorders. Drugs that have been studied for hypochondriasis include high-dose fluoxetine, which was reported to improve the condition in 10 of 16 patients meeting DSM-III-R criteria who did not have marked depressive features (Fallon et al. 1993), and paroxetine in an open-label study (Oosterbaan et al. 2001) in which 8 of 9 patients (from a sample of 11) who finished the study demonstrated clinical improvement (and 5 of these subjects showed scores consistent with the normal population). Secondary hypochondriasis in patients with depression has been treated with amitriptyline (Kellner et al. 1986). A number of studies of BDD have reported success with selective serotonin reuptake inhibitors (SSRIs) in about two-thirds of patients treated (Phillips 1998; Phillips et al. 2001a). It has also been reported that augmentation strategies and changing antidepressants may be helpful in nonresponders (Phillips et al. 2001a). High relapse rates were reported with discontinuation of pharmacotherapy (Phillips et al. 2001a). Clomipramine (a potent serotonin reuptake inhibitor) was more effective than desipramine (a norepinephrine reuptake inhibitor) in treating BDD in a 16-week double-blind crossover trial (Hollander et al. 1999). The SSRIs appear to be effective even among patients with a delusional variant of BDD (Hollander et al. 1999; Phillips et al. 2001a). The time to response is longer than with major depression for at least one-third of patients.

## Physical Reactivation and Physical Therapy

Physical reactivation via a gradually escalating program of exercise (e.g., walking, swimming) often improves the quality of life in patients with a variety of somatoform disorders. It may be difficult to engage patients in exercise, but once they become more active, they often find it pleasurable and report feelings of accomplishment, reduced stress, and greater confidence in their body. Physical reactivation should start at a level just below what the patient can do on his or her worst day, and the patient should then strive for consistency with activity at least 5 days a week. Physical therapy is invaluable for patients who have conversion disorder and may be the only treatment required to restore physical function in some cases (Delargy et al. 1986; Dvovch et al. 1991). In a recent report of 34 consecutive referrals for inpatient rehabilitation treatment of conversion disorder patients with motor paralysis, 9 had complete recovery, 10 had partial recovery, and 15 remained unchanged (Heruti et al. 2002).

## Relaxation Therapies, Meditation, and Hypnotherapy

Various forms of relaxation therapies, biofeedback, meditation, and hypnotherapy have been used with somatoform disorder patients. Relaxation therapies modulate somatic sensations and may be used as part of a more comprehensive group treatment program for hypochondriasis (Barsky et al. 1988a). These therapies may be used either as a primary form of treatment based on a psychophysiological model or as an adjuvant to other forms of treatment. Hypnosis has been used diagnostically and therapeutically in patients with conversion disorder (see review by Van Dyck and Hoogduin 1989), and it showed sustained benefits for 6 months in a randomized, controlled trial (Moene et al. 2003). Hypnotherapy may be combined with intravenous sedation (Toone 1990) and eclectic behavioral treatment programs (Moene et al. 2003). Although abreaction or catharsis under hypnosis or sedation has had dramatic anecdotal effects in some individuals in whom the conversion was precipitated by extreme trauma, such interventions are not helpful for most patients (Toone 1990).

## Behavioral Treatment

Learning theory models have been proposed for the treatment of several somatoform disorders. Hypochondriasis has been treated with exposure and response prevention individually tailored to the patient's specific problem behaviors (Visser and Bouman 1992, 2001; Warwick and Marks 1988). Prevention of reassurance seeking was a key component of treatment because it is conceptualized as an anxiety-reducing ritual that is reinforced by the reassurance received (Warwick 1992). This program, which required a median of seven treatment sessions and 11 therapist hours, was associated with improvement that was maintained in half of the patients at follow-up (mean duration, 5 years; range, 1–8 years). Exposure therapy may decrease hypochondriacal fears and beliefs in agoraphobic patients (Fava et al. 1988). Exposure plus response prevention for hypochondriasis was found to be as effective as cognitive therapy, and both treatments demonstrated results that were superior to a waiting-list control group (Visser and Bouman 2001). Behavioral stress management is helpful in treating hypochondriasis (Clark et al. 1998). In some patients BDD has been successfully treated with behavioral techniques such as desensitization, live and fantasy exposure, and assertiveness training (Marks and Mishan 1988), although behavioral and cognitive-behavioral approaches remain poorly studied in BDD (Phillips 2001).

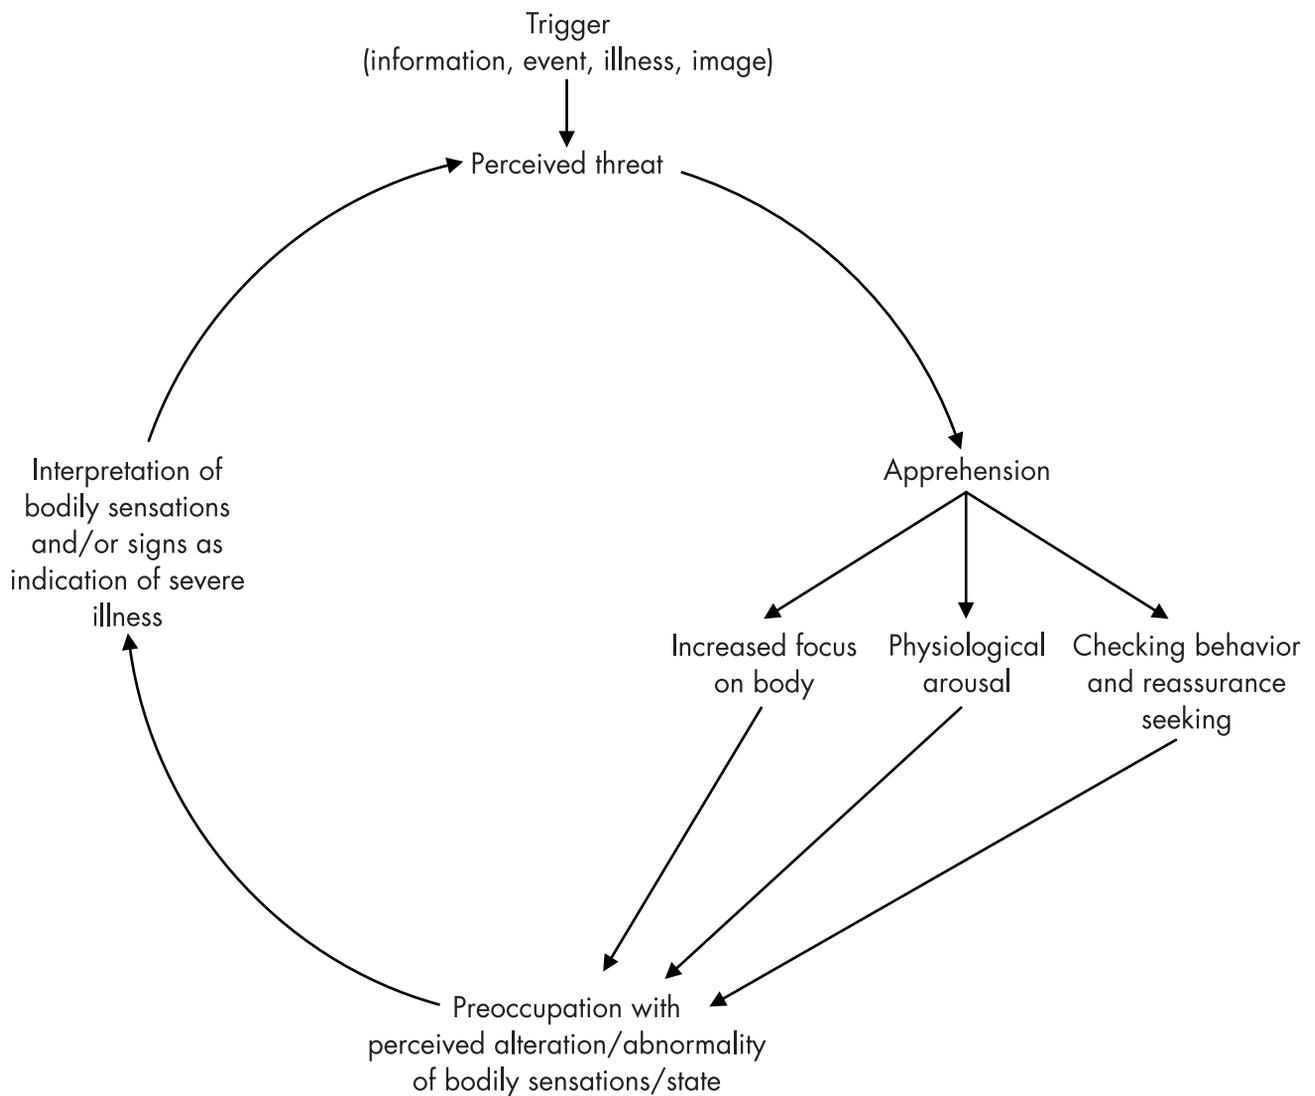

## Suggestion and Reassurance

The use of suggestion or reassurance requires clinical acumen in framing the intervention and ensuring that one does not give an explanation that is heard as "It's all in your head." Explanations should empower patients, reframe the symptoms, and emphasize the possibility of improvement over time, particularly with active involvement from the patient. For example, the psychiatrist may tell the patient, "The sudden weakness in your legs really laid you up. The good news is that you don't have multiple sclerosis, a stroke, a tumor, or anything else like that. This sort of weakness typically disappears as mysteriously as it initially appears, but our experience is that you can speed up your recovery through physical therapy."

## Cognitive Therapy

Cognitive therapy has been used in both individual and group formats for functional somatic symptoms and several somatoform disorders (see critical review of controlled trials by Kroenke and Swindle 2000). It may be the preferred form of treatment for patients with hypochondriasis (Walker et al. 1999). The use of cognitive therapy is predicated on cognitive models such as the one shown in Figure 13–3 for hypochondriasis. A cognitive model directs attention to factors that maintain preoccupation with worries about health, including attentional factors, avoidant behaviors, beliefs, and misinterpretation of symptoms, signs, and medical communications (Salkovskis 1989). Cognitive therapy has been helpful in decreasing health care visits and physical complaints in patients with multiple unexplained physical symptoms (Sumathipala et al. 2000). In an 8-week randomized, controlled study of a group cognitive-behavioral treatment, primary care patients with somatization disorder showed improvements in somatization, bodily preoccupation, and medication use at 6-month (Lidbeck 1997) and 18-month follow-up visits (Lidbeck 2003). A controlled treatment study using both individual and group CBT demonstrated cost-effectiveness and decreased health care utilization in a mixed group of patients with somatoform disorder (Hiller et al. 2003).

Cognitive therapy programs for hypochondriasis have been described in considerable detail (Salkovskis 1989) and are based on a model of hypochondriasis as a disorder of perception and cognition in which somatic sensations are perceived as abnormally intense and are attributed to serious medical disease. Barsky and colleagues (1988a) described a 6-week group program for patients with hypochondriasis. A recent randomized usual-care control trial of a 6-session individual CBT intervention demonstrated significant, persistent reductions at 12-month follow-up of

**FIGURE 13-3. A cognitive model for hypochondriasis.**

hypochondriacal symptoms, beliefs, and attitudes and health-related anxiety, as well as less impairment in social role functioning and activities of daily living, but no improvement in hypochondriacal somatic symptoms (Barsky and Ahern 2004). In a randomized, controlled trial, Clark et al. (1998) demonstrated that cognitive therapy (up to 16 weekly 1-hour sessions and up to 3 booster sessions over the next 3 months) is an effective specific treatment for hypochondriasis. Cognitive therapy was as effective as exposure plus response prevention in treating hypochondriasis (Visser and Bouman 2001). Cognitive therapy may also be helpful in treating BDD (Phillips 2001; Veale et al. 1996b).

### Dynamic Psychotherapy

Psychotherapy has a role in the management of some somatoform disorders. In general, psychoeducational and supportive techniques predominate, although insight-oriented therapy may be indicated in some patients. Explanatory therapy for hypochondriasis has been described (Kellner 1986) and showed an impact superior to the waiting-list control condition (Fava et al. 2000). Explanatory therapy has been described as "providing accurate information, teaching the principles of selective perception (attention to one part of the body makes the patient more

aware of sensations in that part of the body than in other parts), reassurance, clarification and repetition” (Fava et al. 2000). Unlike CBT, explanatory therapy is simpler, uses fewer therapeutic components, does not introduce specific behavioral techniques, and is not based on a specific theoretical framework (Fava et al. 2000). Insight-oriented psychotherapy for somatizing patients has been advocated (McDougall 1989; Rodin 1984), but there is no empirical evidence supporting it, and it will appeal to only a minority of patients.

## Group Psychotherapy

Group therapy may be particularly useful in the management of somatoform disorders. When social and affiliative needs are gratified via the group, patients’ need to somatize to establish or maintain relationships may be reduced (Ford 1984). Confrontation by fellow group members about secondary gain is usually better tolerated than that by an individual therapist or primary physician. Anger at physicians and family and dependence needs may be better tolerated in the group setting, which tends to diffuse intense affects. Group therapy also may be useful in increasing interpersonal skills and in enhancing more direct forms of communication regarding thoughts, feelings, and desires (Ford 1984). Helplessness has been identified as a central psychotherapeutic issue that can be effectively addressed in group therapy for patients with somatoform disorder (Levine et al. 1993). Various forms of group therapy have been reported for patients with somatoform disorder (see review by Levine et al. 1993). Short-term group therapy appears to be effective in primary care patients with somatization disorder (Kashner et al. 1995).

## Marital and Family Therapy

Most families will benefit from information and psychoeducational approaches. More intensive forms of therapy are required when patients have significant marital or family pathology and when somatic symptoms are an important form of social communication within the family. It is important to identify the family’s attitude and response because they may have a conscious or unconscious interest in maintaining a symptom in a patient.

# 14 Deception Syndromes: Factitious Disorders and Malingering

---

Charles V. Ford, M.D.

Disease has been simulated in every age, and by all classes of society. The monarch, the mendicant, the unhappy slave, the proud warrior, the lofty statesman, even the minister of religion as well as the condemned malefactor and boy “creeping like snail unwillingly to school,” have sought to disguise their purposes, or obtain their desires, by feigning mental or bodily infirmities (Gavin 1838, p. i)

The above introductory paragraph to Hector Gavin’s 1838 book *On the Feigned and Factitious Diseases of Soldiers and Seamen*, in which he described clinical features of factitious disorders and malingering, indicates the pervasiveness of simulated disease. Also noteworthy is that in the second century A.D., the Roman physician Galen devoted a chapter to simulated disease in one of his medical texts (Adams 1846).

In the current diagnostic classification, that of DSM-IV-TR (American Psychiatric Association 2000), simulated diseases such as somatization disorder are placed within the category of *somatoform disorders*. These disorders are considered to be of unconscious etiology. *Factitious disorders*, considered to be of conscious production but of unconscious motivation, are included among Axis I diagnoses in a separate category. *Malingering*, considered to be of both conscious production and motivation, is assigned a V code. Imprecise criteria (e.g., conscious vs. unconscious motivation) are bound to result in imprecise diagnoses, and in fact illness behavior is frequently motivated by a variety of conscious and unconscious objectives. Furthermore, a person may feign illness to achieve different goals at different times (Eisendrath 1996). Thus, an originally unconsciously motivated symptom may evolve

into a consciously driven symptom so that the patient may achieve secondary gains.

Illness behavior includes a wide continuum of symptoms and motivations. At one extreme are behaviors that might be considered normal in view of their commonality, such as using a complaint of a physical symptom (e.g., a headache) to avoid some undesired social obligation. This chapter focuses on the other extreme of consciously motivated illness behavior: factitious disorders and malingering. As noted above, the primary difference between these two forms of illness behavior is the perceived role of conscious versus unconscious motivation. Such a distinction is useful for textbook descriptions, but unfortunately in actual clinical situations the determination of motivation becomes a highly subjective process. A complicating factor is the unreliability of information provided by persons who are, by definition, deceptive.

There are two primary forms of factitious behavior. The first is self-induced or simulated disease, known at times by the eponym Munchausen syndrome, and the second is factitious disease behavior induced in others, also more commonly known as Munchausen syndrome by proxy. Although these two forms of factitious illness overlap at certain points, they are discussed separately here to provide clarity on various important clinical and legal issues. Malingering, not a medical diagnosis per se, is discussed separately from the factitious disorders.

Interest in factitious disorders has increased markedly since the publication of Asher’s sentinel paper in 1951. By 2003 there had been approximately 1,500 publications in the medical literature focusing on factitious disorders. There have been descriptions of a number of other syn-

dromes related to factitious disorder, such as factitious allegations of sexual abuse (Feldman et al. 1994; Feldman-Schorrig 1996; Gibbon 1998), the use of Internet chat rooms and support groups to create a fictional identity (Feldman 2000), the “angel of death” syndrome (Yorker 1996) (in which a nurse creates emergency situations in his or her patients), and even production of disease in one’s pets (Munro and Thrusfield 2001).

Hardie and Reed (1998) described the overlaps in characteristics of persons who demonstrate pseudologia fantastica (Table 14–1), create factitious disorders, and engage in impostorship. They proposed the term *deception syndrome* to describe these syndromes—a concept that would provide more unity than does the current tendency to create increasing numbers of new syndromes and epynms.

## Factitious Disorders

Persons who have factitious disorders intentionally feign, exaggerate, aggravate, or self-induce symptoms or disease. They are conscious of their behaviors, although the underlying motivation may be unconscious. By convention, this diagnosis is also characterized by the surreptitious nature of the behavior. Patients who acknowledge that they have produced their own self-harm (e.g., self-mutilators) are not included in this diagnostic group. Inherent in factitious disorders is a paradox: the patient presents to a physician or other health care provider with the request for medical care but simultaneously conceals the known cause of the problem.

Risk factors for factitious disorder vary according to the subtype of the clinical syndrome. The most common subtype is common factitious disorder (or nonperegrinating factitious disorder), in which the person does not use aliases or travel from hospital to hospital. In this syndrome, female gender, unmarried status, age in the 30s, prior work or experience in the health care professions (e.g., nursing), and Cluster B personality disorders with borderline features are frequently found. For full-blown Munchausen syndrome, in which the patient uses aliases and travels from hospital to hospital (and often from state to state), risk factors include male gender, single marital status, age often in the 40s, and a personality disorder of the Cluster B type with at least some antisocial features. In their review of 93 cases of factitious disorder diagnosed at the Mayo Clinic, Krahn and colleagues (2003) found that 72% were women, of whom 65.7% had some association with health-related occupations. The mean age for women was 30.7 years, and the mean age for men was 40.0 years.

**TABLE 14–1. Pseudologia fantastica**

A form of pathological lying characterized by
Matrix of fact and fiction
An enduring repetitive quality
Presentation of the storyteller in a grandiose manner and/or as a victim
The syndrome is often associated with
Cognitive dysfunction
Learning disabilities
Factitious disorders
Childhood traumatic experiences

Epidemiological features of factitious disorder are largely determined by inference rather than any specific research data. One mechanism for estimating frequency is the use of the findings of Gault and colleagues (1988), who analyzed material submitted by patients as kidney stones. Of these stones, 3.5% were obviously nonphysiological and artifactitious. Even when false stones that might have been presented innocently were eliminated, 2.6% remained as representing probable attempts to deceive physicians. This number of 2.6% obviously represents an extremely high estimate, and most investigators believe that factitious disorder is a relatively uncommon but not extremely rare disorder. For example, Sutherland and Rodin (1990) noted that 10 of 1,288 psychiatric consultations at a large teaching hospital in Toronto, Ontario, included a diagnosis of factitious disorder. A similar percentage of 0.6% was reported for a German university hospital psychiatric consultation service (Kapfhammer et al. 1998). These differing methods of determining incidence reflect a very large range. If the number of diagnoses established by psychiatric consultation is used as an estimate, then—with the assumption that no more than 1 in 10 medical inpatients is seen in psychiatric consultation—the incidence would be less than 1 in 10,000 admissions to medical–surgical services. However, many patients with factitious disorder may successfully evade detection and thereby go through the system undiagnosed.

### Clinical Features: Phenomenology, Course, and Prognosis

Self-induced factitious disorders fit into two major syndromes. Unfortunately, the terminology in the general medical literature is inconsistent, and the terms *Munchausen syndrome* and *factitious disorder* are often used interchangeably (Fink and Jensen 1989). In this chapter, *Munchausen syndrome* refers specifically to the subtype of factitious disorders originally described by Richard Asher in 1951.

Classic Munchausen syndrome consists of three essential components: the simulation or self-induction of disease, pseudologia fantastica, and travel from hospital to hospital, often using aliases to disguise identity. These patients frequently present in the emergency room with dramatic symptoms such as hemoptysis, acute chest pain suggesting a myocardial infarction, or coma from self-induced hypoglycemia. Munchausen patients may make a career out of illness and hospitalizations; as many as 423 separate hospitalizations for an individual patient have been reported (von Maurer et al. 1973).

The types of symptoms and different diseases that have been simulated defy the imagination (Table 14–2). Essentially every subspecialty journal has published case reports of self-induced illness related to that particular subspecialty. Among the most common presentations have been chest pain, endocrine disorders such as hyperthyroidism, coagulopathies, infections, and neurological symptoms. The Munchausen patient often presents during evening or weekend hours, presumably in order to be evaluated by less senior or experienced clinicians. The patient is frequently admitted to an inpatient service, where he or she may become the “star patient” in view of the dramatic nature of the symptoms or the rarity of the presumed diagnosis. In addition, the patient may call attention to himself or herself by providing false information such as claiming to be a former professional football player, a recipient of the Medal of Honor, or perhaps the president of a foreign university. Despite such reputed prominence, these patients and their physicians rarely

receive telephone calls from concerned family members or friends. The Munchausen patient is usually willing to undergo multiple diagnostic studies. When inconsistencies in history, medical findings, or laboratory examinations create suspicions, caregivers often become more confrontational. At this point the patient generally responds with irritation, new complaints, disruptive behavior, or threats to file a lawsuit. He or she may request discharge against medical advice or may simply disappear. Embarrassed and angry clinicians on the treatment team may console themselves by preparing a case presentation for grand rounds or perhaps for publication.

Munchausen syndrome is the most dramatic form of factitious behavior, and the eponym certainly has great popularity, but much more frequently seen is what has been termed *common factitious disorder*. In this syndrome, the patient does not use aliases and tends to repetitively seek treatment with the same physician or within the same health system. She may carry a diagnosis—which, on careful reflection, was made with imprecise criteria—such as bleeding coagulopathy or a collagen disease. These patients, usually young women, are often well known to care providers because of their frequent hospital admissions. They may even come to the hospital bringing stuffed animals or special sheets (e.g., Mickey Mouse) for their hospital beds. In retrospect, when the true diagnosis is discovered, it can be determined that their history, both medical and personal, was inaccurate. They are not, however, as inclined to pseudologia fantastica as are patients with full-blown Munchausen syndrome.

**TABLE 14–2. Examples of factitious diseases**

Symptom/disease	Method of production	Diagnostic clue
Infections	Injections of saliva or feces	Polymicrobial cultures
Hypoglycemic coma	Self-injection of insulin Oral hypoglycemic agents	Low C-peptide Glyburide in urine
Fever of unexplained etiology <sup>a</sup>	Manipulation of thermometer	Dissociation of fever/pulse
Neurological disease	Anisocoria secondary to anticholinergic eyedrops	Variable reactivity of pupils
Diarrhea	Laxative abuse	Laxative in stool
Pheochromocytoma	Epinephrine in urine	Low blood chromogranin A
Electrolyte imbalance	Diuretics	High urinary potassium
Vomiting	Ipecac	Increased urinary potassium with low chloride
Coagulopathies	Warfarin	Serum assay
Anemia	Self-bloodletting	No bleeding site or iron malabsorption
Pancytopenia	Methotrexate	Serum assay
Proteinuria	Egg white in urine	Large daily variations of urine protein
Purpura	Quinidine	Serum or urinary assay
Hyperthyroidism	Exogenous thyroid	Low serum thyroglobulin
Hematuria	Finger prick blood to urine	

<sup>a</sup>Now uncommon because of the use of instantaneous electronic thermometers.

Source. Adapted from Wallach 1994.

Symptoms and signs for patients with common factitious disorder tend to be less dramatic, and their complaints are often more chronic or subjective. Some common symptoms include joint pain, recurrent abscesses, failure to heal from surgical operations, hypoglycemic episodes, simulated renal colic, and blood dyscrasias. Factitious disorder as a cause for these patients' symptoms may not be suspected for months or even years. When the diagnosis is finally established, there may be disbelief among the medical care providers. "Splitting" behavior, in which the patient plays one group of providers against another group, is frequently seen.

### Factitious Disorder With Psychological Symptoms

The large majority of published cases of factitious disorder describe physical symptoms alone. When factitious psychological symptoms are recognized, they are generally in association with either authentic or fabricated physical complaints. The reason for this may be that subspecialists in psychosomatic medicine are more likely to encounter patients with factitious psychological symptoms who are hospitalized on medical–surgical wards, or in the emergency room, than to see such patients on psychiatric units. Patients with factitious psychological symptoms fabricate a wide range of symptoms. The most commonly reported include depression and suicidal thinking tied to claims of bereavement (Phillips et al. 1983; Snowden et al. 1978). The patient reports that his or her emotional distress is due to the death of someone close such as a parent or child. Distress appears genuine, is often accompanied by tears, and characteristically elicits sympathy from medical personnel. Later, staff members may discover that the mourned person is very much alive, that the circumstances of the death were less dramatic than the patient reported, or that the death was many years in the past. Case reports of the factitious psychological symptoms also describe feigned multiple personality disorder, substance dependence, dissociative and conversion reactions, memory loss, and posttraumatic stress disorder. Multiple feigned psychological symptoms may be present in the same patient (Parker 1993). Some authors urge caution in diagnosing factitious disorder with predominantly psychological symptoms, especially factitious psychosis, because some patients with these symptoms eventually manifest clear-cut severe mental illness (Nicholson and Roberts 1994; Rogers et al. 1989).

*Ganser's syndrome* is closely related to factitious disorder, with predominantly psychological symptoms. This syndrome is characterized by the provision of approximate answers (*Vorbeireden*) to questions (e.g., the exam-

iner asks, "What is the color of snow," and the patient answers, "Green"). Complaints of amnesia, disorientation, and perceptual disturbance are generally present as well. This syndrome was originally described by the nineteenth-century German psychiatrist Sigbert Ganser (1965) as a form of malingering seen in prisoners, but it has also been described in other settings, including general hospital units (Dalfen and Anthony 2000; Weiner and Braiman 1955). Ganser's syndrome was described in one patient who also had clear-cut factitious physical and psychological symptoms (Parker 1993). The etiology of this syndrome remains in question, and malingering, dissociation, and organic brain disease (Sigal et al. 1992) have been proposed as contributing factors.

When the patient presents with both physical and psychological factitious symptoms and neither predominates, the appropriate diagnosis is factitious disorder with combined physical and psychological symptoms. The aforementioned case reported by Parker (1993) included pseudodementia (Ganser's syndrome), feigned bereavement, factitious rape, pseudoseizures, and simulated renal failure.

The prognosis of patients with factitious symptoms is unclear. Some patients may, at some point in their life, abandon their behavior. Death, probably as a result of the patient's miscalculations of the risk of the behavior, has also been reported (Nichols et al. 1990).

### Diagnosis and Assessment

The diagnosis of factitious disorder may be suggested by inconsistent laboratory results, physical findings that do not conform with reported symptoms, failure to respond as predicted to effective treatment for the disorder in question, or, most frequently, the accidental discovery of medical paraphernalia on the patient's person or in the room. For example, a syringe may be found taped onto the inside portion of a toilet lid or a nurse may come into a patient's room unannounced and find the patient digging in a surgical wound with a foreign body. Ultimately, the diagnosis of factitious disorder is made via detective work by health care providers based on a high index of suspicion. A review of past medical records from other institutions may be essential to establish the diagnosis (Krahn et al. 2003). On the surface the patient may appear normal, and a psychiatric interview per se cannot establish the diagnosis unless there is a "confession." The patient, even when confronted with irrefutable evidence of factitious behavior, typically denies that the illness was self-induced.

The differential diagnoses of factitious disorder include unusual, rare, or as-yet undescribed and unknown diseases, somatoform disorders, and overt malingering.

## Etiology

The reasons why a person might engage in factitious illness behavior are to a large extent speculative. Even when seen in long-term treatment, these patients are resistant to articulating their motivations. Proposed underlying motivations are outlined in Table 14–3.

The large majority of patients with factitious disorder have an underlying severe personality disorder, usually of the Cluster B type. Factitious behavior can be seen as a form of acting out, similar to other acting-out behaviors seen in Cluster B personality disorders. Axis I comorbidity, including major depression and schizophrenia, has been described but is not common. However, it must be kept in mind that psychiatric symptoms may also be simulated.

Few patients have been extensively studied with regard to developmental history because very few will agree to see a psychotherapist and even fewer open up honestly. In the very select few who have, a childhood history of parental illness, death, or abandonment or issues of personal illness or institutionalization are common (Ford 1973). As a result of these childhood issues, factitious behavior may be viewed, at least in some circumstances, as a learned coping mechanism.

The possible role of cerebral dysfunction for at least some patients has been proposed. Pankratz and Lezak (1987) reported that approximately one-third of the Munchausen patients in their series had deficits in conceptual organization. Abnormal findings on brain imaging have also been reported (Babe et al. 1992; Fenelon et al. 1991). Brain dysfunction has also been reported in approximately 20%–25% of persons with pseudologia fantastica and/or Munchausen syndrome (Ford 1996b; King and Ford 1988).

## Management and Treatment

In the past it was suggested that blacklists should be created, disseminated, and maintained at various hospitals to identify Munchausen patients when they present for care (Mohammed et al. 1985). A variant of this concept for an individual hospital is to mark the old chart in some conspicuous manner to identify the patient when he or she presents to an emergency room. Such blacklists have found disfavor in the United States largely because of legal and ethical concerns and would be considered a violation of regulations under the Health Insurance Portability and Accountability Act of 1996 (P.L. 104-191).

A major question in management is how to deal with a patient once a definitive diagnosis of factitious disorder has been established. No matter how understandable the

**TABLE 14–3. Proposed motivations for factitious disorder**

---

Need to be the center of attention
Longing to be cared for
Maladaptive reaction to loss or separation
Anger at physicians or displaced onto physicians
Pleasure derived from deceiving others (“duping delight”)

---

anger at these deceptive patients might be, the temptation to “let them have it” must be resisted. To act out in an angry way only plays into the patient’s pathology by drawing the physician into a dramatized scene. A direct, accusative confrontation is likely to result in anger from the patient and in his or her subsequent departure from the hospital, often against medical advice, or with threats to bring a lawsuit for defamation. It has been suggested that the confrontation be more indirect, in a manner that allows face-saving for the patient or an opportunity for therapy. For example, a patient may be told, “When some patients are very upset, they often do something to themselves to create illness as a way of seeking help. We believe that something such as this must be going on, and we would like to help you focus on the true nature of your problem, which is emotional distress.” Unfortunately, such an approach, although logical and humane, does not usually result in the patient’s acknowledgment of factitious illness behavior and acceptance of psychological treatment. Another approach is to provide the patient with a paradoxical confrontation. In this technique, the patient is told that there is some question as to whether or not the illness is factitious in nature but that definitive treatment for the physical symptoms has been administered and if the patient fails to respond within a set time period then that would indicate that the problem is factitious in nature. This technique has the obvious clinical and ethical drawbacks of dishonestly treating a dishonest patient, which may be self-defeating.

When present, comorbid psychiatric disorders such as depression (if not believed to be also factitious) should be appropriately treated; in at least one case in the literature, remission of factitious behavior with antidepressant medication was reported (Earle and Folks 1986). Psychotherapy with the patient who engages in factitious behavior is, at best, extremely difficult. Treatment for these patients should be conceptualized essentially as being for a severe underlying personality disorder manifested by acting-out defenses. Stone (1977) proposed vigorous persistent confrontation of the behavior, but most clinicians who have had experience with these patients find that such confrontation results in abandonment of treatment or increase in

acting-out behaviors. Instead of direct confrontation, the patient may be provided with indirect confrontation or interpretation in ongoing supportive psychotherapy (Eisendrath 2001). This technique is based on the premise that if the patient can maintain a relationship with a physician that is not contingent on development of new physical symptoms, factitious behavior may be reduced. Such a treatment approach must be viewed as primarily symptomatic with no expectation of changes in the basic personality structure that predisposes a person to factitious illness behavior. Experience with this type of treatment indicates that there may be remissions that last a few months but that they are often followed by the patient leaving treatment without warning and reengaging in factitious illness behavior elsewhere.

In the medical care of patients with any somatizing disorder (including factitious illness and malingering), the physician should proceed with invasive diagnostic and treatment procedures based only on objective evidence. Furthermore, physicians must be cautious when prescribing any potentially dangerous or habituating medication (Ford 1992).

Legal and ethical issues frequently arise in the assessment and treatment of patients with factitious disorder. In the past, the paternalistic model of medicine suggested that the physician was permitted to do essentially anything that would help establish the diagnosis. For example, patients' rooms were searched for medical paraphernalia, drugs, and so forth. In one situation, when a bottle of insulin was found during such a search, it was spiked with a radioactive compound and the diagnosis proved by later finding radioactivity in the patient (Berkowitz et al. 1971). More recently, particularly in the United States, medical practice has emphasized patients' rights and informed consent. This creates a dilemma. On one hand, a failure to do all that is necessary to establish the diagnosis might be regarded as abdication of medical responsibility and ultimately harmful to the patient. On the other hand, even patients suspected of factitious behavior have rights to personal privacy, including privacy in one's belongings, confidentiality, and informed consent. One approach is to tell the patient that factitious illness behavior is suspected and request permission to rule this out. This has the risk of alienating a patient who does not have factitious illness. It may result in the patient with factitious disorder refusing permission, leaving the hospital, and perpetuating the same behavior at another medical facility.

Physicians may believe that the patient's outrageous behavior of factitious disease production would leave them free from the risk of malpractice suits. This is untrue, and there have been numerous reports of lawsuits initiated by these patients (Eisendrath 1996; Ford 1996a;

Janofsky 1994; Lipsitt 1986). The reasons for lawsuits may include overt greed, rage at a physician who was previously idealized (borderline behavior), or perhaps the opportunity to change one's highly dramatized role as a patient in a hospital to an equally dramatized role as a plaintiff in a courtroom. In one case in which I was an expert witness, it became obvious during the malpractice trial that the patient had produced her postsurgical wound infections. The patient and her attorney then took a new tack, claiming malpractice on the part of the surgeon for failure to recognize that the patient had a factitious disorder!

Because patients with factitious disorder do create legal and ethical problems, it is prudent for the psychiatric consultant to suggest that the management plan require careful multidisciplinary collaboration and appropriate consultation with hospital administrators, hospital and personal attorneys, and the hospital ethics committee. It cannot be overemphasized that any decision to deviate from usual medical practice with such patients should not be made by a solitary individual. Such decisions should be carried out and their rationale noted with the patient's best interests at heart and should be documented in the chart. When factitious disorder is suspected, chart documentation in a factual, nonspeculative manner is highly recommended.

In view of these patients' self-destructive nature, many physicians, including psychiatrists, may question whether involuntary psychiatric hospitalization is indicated. Thresholds for involuntary commitment vary from state to state and from country to country. In the United States, because factitious disorder represents chronic behavior, which is not immediately suicidal, these patients usually do not meet the criteria for involuntary psychiatric hospitalization. In one case in Oregon, outpatient commitment resulted in lower medical costs and less iatrogenic morbidity for a patient with factitious disorder (McFarland et al. 1983).

## **Factitious Disorders by Proxy (Factitious Disorder Not Otherwise Specified)**

---

In DSM-IV-TR the diagnostic code *factitious disorder not otherwise specified* includes a variety of factitious diseases and symptoms described or induced by another person. This particular syndrome is far better known by the eponym Munchausen syndrome by proxy, and most case reports describe parents (particularly mothers) who have induced disease in their children. There are, however, some

reports of adults inducing disease in other adults, particularly when in a caretaker setting, for example, a nurse caring for a bedridden patient (Meadow 1998; Yorker 1996).

Munchausen syndrome by proxy is an invidious behavior that, when it involves children, should be considered a form of child abuse. The syndrome was initially described by Meadow (1977), who coined the term; subsequent to his initial report there have been numerous reports from around the world, including non-Western cultures (Bappal et al. 2001).

The incidence of Munchausen syndrome by proxy is sufficiently high that children's hospitals see several cases per year. Denny et al. (2001) found the incidence in New Zealand to be 2.0/100,000 in children under age 16 years. McClure et al. (1996) computed the annual incidence in the United Kingdom to be at least 2.8/100,000 for children younger than 1 year and 0.5/100,000 for those between 1 and 16. Meadow (1999) reviewed cases of sudden infant death and was of the opinion that many of these deaths fit the phenomenological pattern of Munchausen syndrome by proxy. It is possible that many cases of Munchausen syndrome by proxy are misdiagnosed as spontaneous illness.

### Clinical Features: Phenomenology, Course, and Prognosis

The typical presentation of Munchausen syndrome by proxy is that of a child admitted to a hospital with symptoms such as seizures, bleeding, diarrhea, or respiratory or apneic difficulties. The mother, who often has a history of some medical training, characteristically assists the nurses and readily consents to any invasive diagnostic procedures proposed for the child. Discovery of the mother's role in the production of the child's symptoms may occur accidentally, such as by finding her smothering the child with a pillow or introducing a toxic substance into the child's mouth or intravenous tubing. Suspicions also may arise if symptoms or episodes of the illness occur only when the mother is alone with the child, if another child in the family has had unexplained illnesses, or if the child's medical problems do not have a predictable response to appropriate treatment.

Sheridan (2003) reviewed and summarized published data from 451 cases of Munchausen syndrome by proxy. Her findings indicate no gender bias of the child victims, who were usually age 4 years or younger. In the majority of situations the perpetrator actively produced symptoms by smothering or poisoning the child, although in some instances there was exaggeration or lying about symptoms. The most frequently noted symptoms of the child victims were, in order, apnea, anorexia, feeding problems,

diarrhea, seizures, and cyanosis. The mortality rate for identified children victims was 6.0%, but 25% of known siblings were known to be dead! This implies a much higher mortality rate (than 6.0%) when the diagnosis is unrecognized. Other reports have also emphasized the high mortality rate associated with Munchausen syndrome by proxy (Bools et al. 1993; Rosenberg 1987).

### Diagnosis and Assessment

As noted in the previous subsection, the diagnosis may become apparent by fortuitous findings such as the discovery of secret paraphernalia or drugs or the accidental observation of the mother smothering the child. However, when Munchausen syndrome by proxy is suspected but not confirmed, several procedures to confirm the diagnosis have been proposed. These include 1) a review of medical records of other siblings, looking for a pattern of chronic illness or unexplained death; 2) separation of the child from the parent to determine whether or not there is a change in the child's course of illness (e.g., many children suddenly recover when separated from the parent for several days or weeks); and 3) the controversial technique of video surveillance using a hidden camera. Ethical and legal questions may arise as to whether video surveillance involves an invasion of privacy. Such a procedure should be undertaken only after appropriate consultation with hospital legal staff, administration, and child protective services. Rules for privacy may be somewhat different to protect a helpless child rather than for an adult. In this situation it is the child who is the patient, not the parents. Hall and colleagues (2000) reported that a diagnosis of Munchausen syndrome by proxy was made in 23 of 41 patients monitored by covert video surveillance. In another 4 patients, surveillance was instrumental in establishing the innocence of the parents. It must be kept in mind that such techniques actually place the child at risk, and there should be continuous monitoring of the video screen and preestablished plans for intervention as soon as any danger to the child is detected (Southall et al. 1997).

Ayoub et al. (2002) state that perpetrators of factitious disorder by proxy should be diagnosed with factitious disorder not otherwise specified, DSM-IV-TR code 300.19. However, providing a DSM-IV-TR diagnosis to any person who perpetuates factitious behavior is controversial, because an official diagnosis might imply mitigation for misbehavior—criminal behavior in the case of Munchausen syndrome by proxy. Ford and Zaner (1987) questioned whether persons perpetuating factitious behavior should be entitled to the status and rights of patienthood.

The differential diagnosis of Munchausen syndrome by proxy, of course, always includes the possibility of un-

derlying genuine physical disease and the fact that at times an older child may produce illness in himself or herself (Libow 2000) (Table 14-4). There also may be “blended cases” in which the child or adolescent self-produces symptoms but with the active help of the parent, who may coach the behavior (Libow 2002). At present most pediatricians and child protection caseworkers are well aware of Munchausen syndrome by proxy, and there is a risk of becoming overly zealous in making the diagnosis. Rand and Feldman (1999) reported 4 cases of misdiagnosed Munchausen syndrome by proxy and identified another 11 cases in their review of more than 200 articles and books.

## Etiology

In Munchausen syndrome by proxy, the identified patient is the victim of misbehavior by another. Adults who perpetrate this disorder may superficially seem quite normal, and frequently evaluation of them does not result in a psychiatric diagnosis. Others may meet criteria for a somatoform disorder or a personality disorder or have previously produced factitious disease in themselves (Bools et al. 1994). Most explanations for perpetrating this behavior revolve around the idea that the perpetrator is motivated by the need to become the center of attention by playing the role of concerned parent in the high drama of life and death in a hospital.

Characteristics of perpetrators as computed by Sheridan (2003) include motherhood (76.5%); some features of personal Munchausen syndrome (29.3%); a psychiatric diagnosis (22.8%), usually depression or personality disorder; and a personal history of abuse (21.0%).

Family dynamics and the individual psychodynamics of the perpetrator are believed to be important, but there has not been any large-scale systematic study (Mercer and Perdue 1993). Griffith (1988) studied some families with Munchausen syndrome by proxy and proposed several commonly observed features: 1) enmeshment of parent-child relationships; 2) multigenerational themes of dominance and submission in parent-child relationships; 3) intense family-group loyalty with little protective concern for the needs of the developing child; 4) multigenerational pattern of abnormal illness behavior on the maternal side of the family; and 5) a gender reversal of typical sex roles for power and caretaking within the parental couple such that the wife is more dominant and aggressive and the husband is more caretaking and supportive. In their view of family dynamics, Mercer and Perdue (1993) suggest that the mother may be both victim and perpetrator, and her behavior is an attempt to gain power and control in a powerless existence.

**TABLE 14-4. Differential diagnosis of Munchausen syndrome by proxy**

Pediatric somatization syndromes
Somatoform disorder by proxy (parent's anxiety projected/ displaced onto child)
Infanticide/murder
Psychosis in parent
Child abuse (garden variety)
Factitious behavior initiated by child
Malingering by child (e.g., school rejection)
Unrecognized physical disease

## Management and Treatment

### *Ethical and Legal Issues*

The primary and immediate goal in treatment of Munchausen syndrome by proxy is cessation of the behavior that perpetrates symptoms. Separation between the perpetrator and the victim is usually necessary to accomplish cessation of the behavior. In the most common form of factitious disorder by proxy (parent-perpetrated), it is necessary to place the child into some type of foster care. Such placement requires a legal hearing and involvement of the agencies that have responsibility for protecting child welfare. It is amazing to see how a chronically sick child blooms when separated from the perpetrating parent. Permanent separation of parent and child is a major legal and ethical issue; courts are understandably reluctant to act in such a manner without very serious consideration. The key question is whether the parent has been sufficiently rehabilitated to reduce risk to the child, but the nature of the support system (other parent, other family members, availability of caseworkers) is also crucial.

### *Therapy for the Perpetrator*

The perpetrator, who is usually the mother, should receive psychological treatment. The effectiveness of such intervention is dependent on the perpetrator's open and honest acknowledgment of his or her behavior. Unfortunately, this does not usually occur.

### *Treatment of the Victim*

It is recognized that victims of factitious disorder by proxy experience a high incidence of varied psychiatric disorders (Bools et al. 1993; Bryk and Siegel 1997). To date there are no systematic studies of treatment. The specifics of treatment are dependent on the nature of the problem. One role of psychotherapy is to help the victim deal with feelings about an abusive parent.

## Hospital Epidemics of Factitious Disorder by Proxy

The term *angel of death syndrome* was first used in newspaper reports (later proven to be inaccurate) in which a Las Vegas, Nevada, nurse was accused of tampering with patients' life-support equipment. The motivation was allegedly to help friends win a betting pool dealing with times of patients' deaths (Kalisch et al. 1980).

Although the case against the Las Vegas nurse was disproved, there have been multiple subsequent reports in which health care providers have been accused of causing epidemics of acute cardiac/pulmonary arrests and unusual patterns of deaths (Yorker 1996). Tragically, many of these epidemics have been shown to be caused by the very persons entrusted with the patients' care. In her detailed review of multiple hospital epidemics, Yorker (1996) concludes that the perpetrators are usually nurses or nurse's aides and that the victims were physically compromised: critically ill, elderly, or very young.

The epidemics tended to cluster on evening and night shifts and also involved a large number of—often successful—resuscitations. Yorker proposed that one motive of the perpetrators is the excitement and exhilaration derived from participating in codes.

This kind of behavior constitutes serial murder, and prosecution has resulted in a number of convictions. Epidemiological techniques have been used to identify probable perpetrators, but such evidence is circumstantial and cannot be used alone to establish guilt (Sacks et al. 1988).

## Malingering

---

By definition, individuals with malingering are motivated by specific, recognizable external incentives to produce, exaggerate, or simulate physical or psychological illness (American Psychiatric Association 2000; Gorman 1982). Such incentives may be deferment for military service, avoidance of hazardous work assignments, escape from incarceration (e.g., being judged not guilty by reason of insanity), or procurement of controlled substances. Perhaps the most common incentive is financial gain, such as the receipt of disability payments or the hope of damages to be awarded in a lawsuit. It must be kept in mind that malingering is less a diagnosis than a socially unacceptable behavior with legal ramifications (Szasz 1956). Malingering often must be considered in a differential diagnosis, but much caution must be exercised in making such a "diagnosis."

Malingering is most common in settings where there are external and tangible gains accrued by illness. Among

these settings are prisons, military service, courtroom settings that involve personal or industrial injury, and the offices of physicians who perform disability evaluations. Flicken (1956) estimated that approximately 5% of persons who are conscripted for military service attempt to avoid it by feigning or manufacturing symptoms. Kay and Morris-Jones (1998) found clear-cut surveillance videotape evidence that at least 20% of the litigants registered in a pain clinic were overtly malingering their symptoms. Financial incentives *do* make a difference in symptoms and disability. In their meta-analysis of 2,353 subjects, Binder and Rohling (1996) found more abnormality and disability in patients with mild closed head injury who had financial incentives than in those who did not have such an incentive. Similarly, Paniak and colleagues (2002) found that when financial compensation was at issue, patients with mild traumatic brain injury had significantly increased symptoms. In contrast, Mayou (1995) conducted a prospective study in the United Kingdom on the outcome of persons involved in motor vehicle accidents and found that malingering to gain compensation was remarkably uncommon. He suggested that the high rates found in some tertiary care centers represent atypical and selected samples. The legal climate regarding lawsuits varies widely from country to country.

## Clinical Features: Phenomenology, Course, and Prognosis

Malingering symptoms fall into four major categories: production or simulation of an illness, exacerbation of a previous illness, exaggeration of symptoms, and falsification of laboratory samples or laboratory reports. Embellishment of previous or concurrent illness is probably the form of malingering most frequently encountered by psychosomatic subspecialists. Symptoms are usually subjective and difficult to quantify and include feigned dizziness, weakness, seizures or spells, and features of posttraumatic stress disorder (Sparr and Pankratz 1983). Patients may intensify their complaints when they are asked directly about their symptoms or when they think they are being observed. When distracted, they become physically more relaxed and at times may be seen to engage in physical activities incompatible with their symptom reports.

The malingered symptom generally disappears when the person either obtains the desired goal or is confronted with irrefutable evidence of malingering. However, it has been noted that some malingered symptoms persist even after these occurrences. It may be that the person maintains symptoms as a face-saving mechanism, or perhaps the symptom has in some way been incorporated as a habit into the individual's lifestyle.

## Diagnosis and Assessment

As noted above, identification of malingering is more an issue of socially unacceptable behavior, an accusation of a person's external motives, than a psychiatric diagnosis. The clinician should consider malingering when symptom complaints and objective data are incongruent. However, the presence of secondary gains, concurrent litigation, and seeking disability are *not* evidence of malingering per se. Thus, there must be not only verification of an external motivation but also objective evidence to demonstrate the probability of malingering. For example, a patient who cannot walk independently when seen in the consultation suite might later be seen walking normally on a sidewalk outside the hospital. Insurance companies at times engage private investigators who use video surveillance to obtain objective evidence of malingering. For example, a man who claimed an inability to raise his arms above his shoulder was videotaped climbing a ladder onto his roof and installing a television antenna.

Psychological testing is often helpful in identifying malingering patients. The Minnesota Multiphasic Personality Inventory-2 is a useful test for patients who distort their presentations (Lees-Haley and Fox 1990; McCaffrey and Bellamy-Campbell 1989; Wetzler and Marlowe 1990). This test and others have diagnostic value in assessing those who exaggerate physical and psychological symptoms (Cliffe 1992; Rawling 1992). Screening instruments with face validity such as the Beck Depression Inventory and the Hopkins Symptom Checklist-90 are easily distorted by patients who embellish their symptoms (Lees-Haley 1989a, 1989b), and these instruments have very limited value in the determination of malingering. Forced-choice psychological tests may be valuable in detecting malingering. If a person makes more errors than would be expected by chance, a statistical probability can be determined as to whether the person actually knew the correct answers.

No single evaluation technique will unequivocally identify malingerers. This is particularly true when the examiner makes a subjective assessment of a feature such as sincerity of effort (Lechner et al. 1998; Main and Waddell 1998). Rather, patients must be evaluated from a complete physical and psychosocial perspective that includes various other possibilities, such as "pseudomalingering" (Ford 1983). Pseudomalingering arises when the patient uses an external incentive as a rationalization for malingered symptoms, thereby shielding himself or herself from awareness of unconscious determinants (Ford 1983; Schneck 1962). For example, a genuinely psychotic person may believe he or she is feigning psychosis to escape punishment for a crime. By believing that one is

feigning the psychosis, the person is defensively shielded from conscious awareness of actual mental illness and thus incorrectly believes that he or she is in control of his or her thought processes. Another form of pseudomalingering may exist when a person consciously exaggerates a symptom because he or she truly believes that there is an underlying problem. An underlying problem may exist, but the examiner who picks up on the malingering may mistakenly attribute the entire problem to malingering.

The differential diagnosis of malingering includes somatoform disorders as well as factitious disorders. These clinical syndromes have indistinct boundaries, and a person may meet criteria for different disorders at different times (Ford 1992; Jonas and Pope 1985; Nadelson 1985). Furthermore, conversion disorder and malingering are on a continuum (Cameron 1947), representing opposite poles of purely unconscious and purely conscious motivation. At any one moment it is difficult for the diagnostician to know the patient's location on this continuum. Relevant factors that may play a role in assessment include evidence of past somatization as well as coexistence of anxiety, mood, substance, or personality disorders. Patients with unconsciously determined somatoform disorders (e.g., conversion) are usually consistent in their symptom presentation irrespective of their audience or whether they believe they are being observed.

## Etiology

By definition, the etiology of malingering is to obtain external gain as a result of the symptoms. However, malingering does tend to be more common in persons who may have hysteroid features. Because of personality characteristics (e.g., histrionic or sociopathic) or cognitive style, some persons may be more inclined toward simulated illness.

## Management and Treatment

Malingering is more a management problem than a therapeutic issue. With this in mind, the primary physician and psychosomatic subspecialist must be circumspect in their approach to the patient. Every note must be written with the thought in mind that it may become a courtroom exhibit. Malingering is often listed among diagnostic possibilities but is rarely proved conclusively in medical settings.

The person who is suspected of malingering, as a rule, should not be confronted with a direct accusation. Instead, subtle communication can indicate that the physician is "on to the game" (Kramer et al. 1979). One technique is to mention, almost in passing, that diagnostic

tests indicate no "serious" basis for the symptoms. The malingeringer may feel freer to discard the symptom if the physician suggests that patients with similar problems usually recover after a certain procedure is performed or a particular length of time has passed. Such suggestions are often followed by perceptible improvement, if not recovery. This technique provides face-saving mechanisms for the patient to discard the symptom. Still, some patients, particularly those seeking drugs, will leave treatment and seek medical care elsewhere. Others, in an effort to prove the existence of their disease, may vastly intensify their symptoms. In doing so, they may create such caricatures of illness that their efforts to malingering become obvious to all.

## Conclusion

Requests for psychiatric consultation on patients with suspected factitious disorder or malingering are relatively infrequent. However, when the psychosomatic medicine subspecialist does become involved with one of these cases, a disproportionate amount of time is typically required. Issues of diagnosis, legal and ethical considerations, and the need to provide liaison services for members of the medical staff may make one of these patients the primary focus of one's clinical activities for several days. Nevertheless, they are fascinating patients who demonstrate the extreme end of the continuum of abnormal illness behavior. They are rarely forgotten.

# 15 Eating Disorders

---

Michael J. Devlin, M.D.

Joel P. Jahraus, M.D.

Ilyse J. Dobrow, B.A.

**ALTHOUGH FULL-SYNDROME** eating disorders are relatively rarely diagnosed in medical settings, eating disorder symptoms—such as uncontrolled eating, excessive dieting, and marked body image distress—occur quite commonly. Two important trends may account, at least in part, for the upsurge in these symptoms: 1) the well-documented increase in the prevalence of overweight and obesity in the United States (Mokdad et al. 2001, 2003); and 2) the marked decrease in percentage of body fat of the culturally defined “ideal woman,” as exemplified by Miss America pageant winners (Rubinstein and Caballero 2000). Caught between the reality of an obesity-promoting environment and an increasingly unattainable body image ideal, it is perhaps unsurprising that growing numbers of individuals, particularly women, engage in the desperate attempts to lose weight and the dysregulated eating that characterize the eating disorders.

The mortality and morbidity rates in eating disorders are considerable. Anorexia nervosa is among the most lethal of psychiatric disorders, with mortality rates of approximately 5% per decade of illness in the longest follow-up studies (Nielsen 2001). Although the lethality of bulimia nervosa is much less than that of anorexia nervosa, the purging behaviors characteristic of this disorder can lead to significant medical and dental morbidity. Binge eating, to the degree that it contributes to the onset or maintenance of obesity, may contribute to obesity-related morbidity and death (Calle et al. 1999; Kopelman 2000). But perhaps the greater costs of eating disorders are the time and energy spent on the pursuit of thinness, often to the exclusion of interpersonal, vocational, and recreational sources of satisfaction; the shame and secrecy that often accompany these illnesses; and the ulti-

mate loss of function when the symptoms remain untreated.

Among the most puzzling of psychiatric illnesses for practitioners who regard eating as a healthy and satisfying part of life, eating disorders are also among the most difficult to treat. Yet, as summarized in this chapter, progress is being made in the conceptualization, characterization, and treatment of eating disorders.

## Definitions and Clinical Features

---

The diagnosis and treatment of disordered eating in the medical setting are among the most poorly studied and most important areas for ongoing clinical research. To fully appreciate the spectrum of eating disorders presenting in primary care and general medical settings, it is useful to apply both a categorical and a dimensional approach. The major eating disorder syndromes, including the DSM-IV-TR diagnostic categories for eating disorders (American Psychiatric Association 2000a), are discussed in the subsections that follow. Paradoxically, the most common eating disorder, eating disorder not otherwise specified (NOS), is also the most poorly defined and studied, and the dimensional approach to assessment may be of particular use in patients with this diagnosis.

### Anorexia Nervosa and Bulimia Nervosa

#### *Anorexia Nervosa*

Anorexia nervosa is first and foremost a syndrome of voluntary starvation. However, the term *voluntary* must be interpreted with caution. Although it is true that patients

with anorexia nervosa in some sense choose to restrict their eating, this choice is greatly influenced by genetic vulnerabilities, cultural forces, and life events. Patients in the late stages of anorexia nervosa will often clearly describe that any sense of free will they once may have had regarding their condition has, to a great degree, vanished.

The phenomenon of unexplained starvation, or “nervous consumption,” in an otherwise healthy individual was reported as long ago as the late seventeenth century (Morton 1689). Although the practice of extreme food restriction for reasons generally unrelated to body image occurred before the nineteenth century (Brumberg 1988), it was not until the 1870s that the modern syndrome of anorexia nervosa was recognized nearly simultaneously by Lasègue (1873) and Gull (1874), the latter of whom coined the term *anorexia nervosa*. This modern concept was further refined in the 1960s by psychiatrist Hilde Bruch (1973) and others, who recognized low self-esteem and body image distortion as core features of the disorder.

In keeping with earlier conceptions, the current definition of anorexia nervosa is centered on the behavioral feature of starvation. To be diagnosed with anorexia nervosa, patients must manifest weight loss, or the absence of expected weight gain, leading to a state of significant undernourishment, as reflected by a weight markedly (i.e., at least 15%) lower than expected for gender and height. However, to meet modern (DSM-IV-TR) criteria for anorexia nervosa, an individual must manifest the more recently identified psychological features. The diagnosis requires an overconcern with weight and shape, which may or may not take the form of an actual misperception of body fatness but must reflect an overinvestment in thinness as a central feature of one's self-worth. In addition, amenorrhea is a requirement for postmenarchal women.

Although patients with anorexia nervosa often view their illness as that which makes them unique or special, there is a surprising uniformity in the way these patients present, and there are a number of associated features that occur quite predictably. In addition to severely restricting their intake of food, many individuals with anorexia nervosa are also compulsive exercisers. Some anorexic patients engage in strict dieting without any binge eating or purging (restricting type), whereas others periodically engage in purging (e.g., vomiting, laxative abuse) or uncontrolled binge eating (binge-eating/purging type). Patients with anorexia nervosa are often rigid and perfectionistic, not only in their adherence to restrictive eating and compulsive exercise practices but also in other areas of life. Interestingly, the narrowing of interests, increasing focus on food, and peculiar food-related rituals (toying with food, consumption of unusual food combinations, possessiveness toward food) were also observed in the Minnesota

semistarvation study subjects. These subjects were male World War II conscientious objectors who volunteered to participate in a study of the physiological and psychological effects of starvation, eventually losing 25% of their body weight (Franklin et al. 1948). The fact that these men, who had no prior histories of eating disorders, exhibited behaviors so reminiscent of those seen in anorexia nervosa suggests the degree to which these features of the illness are driven by the physiological effects of starvation.

### ***Bulimia Nervosa***

The other major eating disorder currently defined in DSM-IV-TR is bulimia nervosa, popularly known as the binge-purge syndrome. This syndrome, first described as a variant of anorexia nervosa (Russell 1979) and later applied to individuals of normal weight, comprises regular uncontrolled consumption of objectively large amounts of food (binge eating), regular use of unhealthy compensatory methods intended to undo the effects of eating, and preoccupation with weight and/or shape as a central component of self-worth. Eating binges typically consist of more than 2,000 kcal and, contrary to popular belief, are not primarily composed of carbohydrate (Walsh et al. 1989). Compensatory behaviors include purging methods (i.e., elimination of food and fluids from the body by the use of vomiting, laxatives, diuretics, or enemas) and non-purging methods (such as fasting or excessive exercise) for preventing weight gain. Patients with diabetes mellitus who have bulimia nervosa may attempt to purge by reducing or omitting their insulin dosage to promote glycosuria, thereby eliminating calories from the body. Although most individuals who present for treatment for bulimia nervosa are of normal weight, the diagnosis can also be made in overweight or obese individuals. Under the current diagnostic system, individuals who simultaneously meet criteria for anorexia nervosa and bulimia nervosa are diagnosed as having anorexia nervosa, binge-eating/purging type. In fact, the progression from anorexia nervosa to bulimia nervosa is quite common, occurring in about one-half of patients with restricting anorexia nervosa (Bulik et al. 1997). Normal-weight patients with bulimia nervosa progress to anorexia nervosa much less frequently.

### ***Psychiatric Comorbidity of Anorexia Nervosa and Bulimia Nervosa***

Individuals with anorexia nervosa and bulimia nervosa often manifest comorbid symptoms of depression and anxiety. Many studies suggest that, at least in clinical samples, a majority or significant minority of individuals with eating disorders also have a lifetime diagnosis of affective or

anxiety disorder (Mitchell et al. 1991). Among affective disorders, major depressive disorder occurs most frequently. Among anxiety disorders, obsessive-compulsive disorder (OCD) has been of particular interest because eating- and exercise-related practices, particularly in individuals with anorexia nervosa, may include the repetitive, ritualized behaviors characteristic of OCD. Although in some cases anxiety or depressive symptoms may be secondary to disordered eating, it is likely that shared etiological factors largely account for the observed comorbidity (Bulik 2002). In any case, a diagnosis of depression or anxiety disorder, particularly in an individual at risk for an eating disorder (i.e., adolescent and young adult women) should raise the clinician's level of suspicion that an eating disorder may also be present. In addition, the comorbid diagnosis must of course be taken into account in devising the treatment plan. In general, treatment can proceed simultaneously with the emphasis, for individuals with anorexia nervosa, on weight restoration as a precondition for successful treatment of comorbid conditions.

The relationship between eating disorders and substance use disorders is of great theoretical as well as practical interest, because the idea of "food addiction" suggests the possibility of common underlying pathophysiological mechanisms (Del Parigi et al. 2003). It is certainly the case that eating and substance abuse disorders co-occur at a rate significantly higher than that explainable by chance (Holderness et al. 1994). However, in contrast to the data on the overlap between eating, affective, and anxiety disorders, the available data on familial transmission of eating and substance abuse disorders fail to support the existence of common genetic risk factors (Wilson 2002). Nonetheless, the experience of patients with eating disorders, and even the terminology patients use (e.g., "compulsive" exercise, "going on a binge") can often mimic the argot of substance abuse. Of course, the one major difference is that, to the degree that food is considered the abused substance, abstinence is not a therapeutic option. For patients with comorbid eating and substance use disorders, it is recommended that the substance abuse problem be prioritized. For patients in whom substance abuse is not severe, treatment for the two disorders may proceed simultaneously (Wilson 2002). Substance use disorders may significantly affect the outcome of eating disorders. In a recent large-scale study, severity of alcohol use disorder was a significant predictor of death in anorexia nervosa, with a significant minority of patients apparently developing alcoholism subsequent to the onset of their eating disorder. This finding suggests that patients with eating disorders should be carefully assessed over time for the emergence or worsening of a substance use disorder (Keel et al. 2003).

## Eating Disorders and Obesity

Although obesity is not, in and of itself, an eating disorder (Devlin et al. 2000), obese individuals may have eating disorders such as binge-eating disorder (BED) and night-eating syndrome (Stunkard and Allison 2003). BED (uncontrolled binge eating in the absence of regular compensatory behavior) has been a particular focus of research since it was identified in Appendix B of DSM-IV (American Psychiatric Association 1994) as a criteria set requiring further study. Although the status of BED is uncertain (Devlin et al. 2003), the phenomenon of binge eating among the obese has been clearly identified, and its associated features have been studied (Dingemans et al. 2002). In particular, binge eating in the obese has been found to be associated with higher rates of major medical disorders, greater health dissatisfaction, and a higher lifetime prevalence of depression, panic, phobias, and alcohol dependence (Bulik et al. 2002).

Night-eating syndrome—characterized by morning anorexia, evening hyperphagia, and insomnia—has been much less thoroughly studied, but preliminary studies suggest that it has distinct behavioral/psychological (Gluck et al. 2001) and physiological (Birketvedt et al. 1999) features. Nocturnal sleep-related eating disorders among the obese represent a similar phenomenon but are often characterized by partial or complete amnesia for the nighttime eating episode and by associated sleep disorders (Schenk and Mahowald 1994). Although the best methods for sequencing or combining treatments for obesity and eating disorders have not yet been fully worked out, approaches for simultaneously treating eating disorders and obesity have been described (Devlin 2001).

## Atypical Eating Disorders

A final category of eating disorders in DSM-IV-TR is eating disorder NOS, defined as a clinically significant eating disorder that does not meet diagnostic criteria for any defined eating disorder diagnosis. Examples are 1) regular occurrence of subjective binge episodes (i.e., uncontrolled consumption of amounts of food not deemed large) followed by purging, 2) strict dieting and weight loss without amenorrhea, or 3) continuous uncontrolled snacking throughout the day with no discrete binge episodes. In addition, patients with behaviors typical of eating disorders, such as food avoidance or vomiting, but who deny body image concern—attributing their symptoms instead to somatic symptoms like bloating, nausea, intolerable fullness, or extreme discomfort after eating—may be diagnosed as having eating disorder NOS once medical etiolo-

ogies have been ruled out. Community-based studies have typically found that these atypical eating disorders are more common than anorexia nervosa and bulimia nervosa. Nonetheless, they have received relatively little attention in the literature and are poorly understood at this point. Although much of the literature is based on samples seen in eating disorder clinics that are geared toward treating patients with full-blown anorexia nervosa and bulimia nervosa, individuals seen in the medical setting who are not specifically presenting for treatment of an eating disorder may be particularly likely to manifest eating disorder NOS.

Given this state of affairs, it is perhaps useful to consider a transdiagnostic or dimensional approach to the eating disorders (Fairburn et al. 2003). One dimension of the patient's condition is *nutritional*, with the spectrum ranging from undernourished to severely obese. A second dimension is *behavioral*, with behaviors of interest including binge eating, nighttime eating, uncontrolled eating of some other variety, extreme dieting, purging, and so forth. A third dimension is *psychological*. This dimension includes body image distress—perhaps the most unifying feature of individuals with eating disorders, be they emaciated, of normal weight, or obese—and psychiatric comorbidity. In addition to assessing the psychological dimension, it is important to assess the patient's *motivation for change*. In contrast to anorexia nervosa, which is often embraced by patients as a lifestyle choice that they are ambivalent about relinquishing, patients with bulimia nervosa are generally more motivated to break the binge-purge cycle, although they may be less enthusiastic about confronting the dieting and body obsession that underlie the behavior. Obese patients with eating disorders may be highly motivated to lose weight but may have unrealistic expectations of thinness that continually undermine their weight-control attempts. A consideration of the various dimensions of a given patient's eating disorder syndrome and the particular history of the patient (e.g., chronicity, rapidity of change, and functional impairment) may assist the practitioner in the difficult task of applying findings from clinical studies of typical eating disorders to the atypical eating disorders more commonly observed in the medical setting.

## Eating Disorders in Children

Eating disorders in children and adolescents represent a particular concern because, if not diagnosed and treated, they may have life-long psychological and medical consequences (see also Chapter 34, "Pediatrics"). Disordered eating patterns occurring before puberty include food avoidance emotional disorder, selective eating, pervasive

refusal syndrome, functional dysphagia, and full-syndrome anorexia nervosa (Lask and Bryant-Waugh 1997; Rosen 2003). *Food avoidance emotional disorder* is similar to but less severe than anorexia nervosa and carries a better prognosis. *Selective eating* is diagnosed in children who eat only a small number of foods but whose growth and development are generally normal. *Pervasive refusal syndrome* is a severe disorder in which refusal to eat is accompanied by refusal to function in other spheres (e.g., walking, talking, self-care) and is probably not best viewed as an eating disorder. Children with *functional dysphagia* avoid food due to a fear of swallowing, choking, or vomiting for which no organic etiology can be identified. Bulimia nervosa is thought to occur quite rarely before puberty. Problems of food refusal, selective eating, phobias, failure to thrive, pica, and rumination in children are discussed in detail in Chapter 34, "Pediatrics." However, it is notable that symptoms such as eating conflicts, struggles with food, and unpleasant meals in early childhood have been found to be associated with the later development of eating disorders (Kotler et al. 2001) and therefore should be followed closely.

As reviewed in a recent position paper from the Society for Adolescent Medicine (Rome et al. 2003), dieting among school-age girls is increasingly common, and prevention and screening for eating disorders may avert the progression from pathological dieting to clinically significant eating disorders. Thus, the identification of a significant eating disorder symptom, even in the absence of a formal diagnosis, should trigger some form of intervention to address the problem rather than a "wait-and-see" approach, which may allow the problem to become more entrenched. Pathological dieting is in some cases difficult to differentiate from normative dieting, but extreme distress about weight or shape, rapid weight loss, frequent weight or size checking, rigid adherence to dietary or exercise regimens, and use of unhealthy dietary practices are all worrisome signs. From a prevention standpoint, eating disorder NOS should probably be the most commonly diagnosed eating disorder in this group.

## Feeding Disorders of Infancy or Early Childhood

Quite distinct from the eating disorders described in the preceding subsections are the feeding disorders seen in infants and children, including pica, rumination disorder, and feeding disorder of infancy or early childhood. *Pica* refers to the consumption of nonnutritive substances such as hair, dirt, pebbles, or clay, sometimes but not always occurring in individuals with mental retardation, but meriting a separate diagnosis only if it is sufficiently se-

vere to warrant independent clinical attention. Pica may be associated with poisoning (e.g., from lead paint) or mechanical obstruction. *Rumination* refers to the regurgitation, rechewing, and reswallowing of ingested food. Although most commonly seen in infants, rumination may also be seen in older children with mental retardation. Interestingly, a small proportion of adolescent and adult patients with anorexia nervosa and bulimia nervosa report rumination.

Finally, feeding disorder of infancy or early childhood is usually diagnosed in the first year of life but sometimes in children up to 3 years of age, for whom food intake is inadequate to support normal growth and development. As recently reviewed by Rudolph and Link (2002), the early recognition of feeding problems and diagnostic workup to exclude gastrointestinal, metabolic, sensory, or other general medical etiologies can lead to more appropriate management of affected children and their families.

## Epidemiology

---

A number of researchers have attempted to establish incidence and prevalence rates for anorexia nervosa, bulimia nervosa, and (to a lesser extent) BED, and findings have been well summarized in recent reviews (Fairburn and Harrison 2003; Nielsen 2001). Anorexia nervosa is thought to have a prevalence of approximately 0.7% among teenage girls and to be approximately one-tenth as common in males as in females. Incidence estimates in Western countries are roughly 10 females and 1 male per 100,000 population per year, with the risk of new onset greatest in white adolescents. It has been suggested, although it has not yet been conclusively proved, that anorexia nervosa has become a more common illness in recent years. Alternative explanations for an apparent increase include greater recognition among patients and clinicians and increased help seeking.

Bulimia nervosa is a more prevalent illness than anorexia nervosa, with a prevalence of 1%–2% in teenage and young adult women. Incidence is roughly 15 females and 0.5 male per 100,000 population per year. Like anorexia nervosa, bulimia nervosa is much less common in men than in women and most often affects Western Caucasian adolescents and young adults. Evidence of an increase in cases of bulimia nervosa over the past few decades is considerably stronger than evidence of an increase in anorexia nervosa. Some research has suggested that certain segments of the population, such as elite athletes (Smolak et al. 2000) and dancers (Dotti et al. 2002), are at particular risk for developing symptoms of bulimia nervosa or anorexia nervosa.

There have been few studies of the epidemiology of BED. The limited data that have been collected suggest that BED has a lifetime prevalence similar to that of bulimia nervosa. Roughly 5%–10% of those seeking treatment for obesity have BED. Unlike anorexia nervosa and bulimia nervosa, approximately a quarter of those with BED are male, and most patients with BED present with the illness in their 40s.

In establishing epidemiological data for eating disorders, it is important to consider not only individuals who meet diagnostic criteria for anorexia nervosa, bulimia nervosa, and BED but also the large numbers of individuals who are diagnosed with eating disorder NOS or who do not fulfill all DSM-IV-TR criteria for an eating disorder but nonetheless have serious eating pathology. In terms of eating disorder NOS, Fairburn and Harrison (2003) cited three community-based case series studies that all found eating disorder NOS to be a more common diagnosis than anorexia nervosa or bulimia nervosa. In addition, studies of subsyndromal anorexia nervosa, bulimia nervosa, and BED indicate that these subthreshold diagnoses are strikingly similar to their diagnostic counterparts in terms of distress and functional impairment. Therefore, to make a truly accurate assessment of the degree of eating pathology in the general population, epidemiologists must consider both eating disorder NOS and subthreshold eating disorders in addition to anorexia nervosa, bulimia nervosa, and BED.

## Course and Outcome

---

Studies of the long-term course of anorexia nervosa suggest that there is no one typical outcome. Rather, the illness tends to require long-term treatment, with some patients achieving full recovery, others experiencing a longer course of partially remitted or unremitted illness, and some dying as a direct or indirect result of the illness (Pike 1998). Mortality rates are as high as 5% per decade of illness in the longest follow-up studies (Nielsen 2001); of surviving patients, fewer than half recover fully, one-third recover partially, and one-fifth remain chronically ill (Steinhausen 2002). The outcome of patients treated as adolescents appears to be more favorable (Strober et al. 1997), underscoring the importance of early intervention or, ideally, prevention. Bulimia nervosa generally has a more favorable course than anorexia nervosa. However, long-term follow-up studies suggest that 10 years after presentation, nearly one-third of patients continue to binge and purge regularly (Keel et al. 1999). The outcome of eating disorder NOS is less well defined. However, it is clear that these atypical eating disorders often represent

partial recovery from full-syndrome eating disorders or evolve into fully developed anorexia nervosa and bulimia nervosa (Fairburn and Harrison 2003); careful diagnosis and aggressive treatment are therefore warranted. Several studies have identified specific historical and medical factors that predict good versus poor outcome in eating disorders (Table 15–1).

## Assessment and Diagnosis

### Assessment

The assessment of patients with symptoms suggestive of eating disorders presents several challenges. The clinical presentation may be confusing in that it may be difficult to determine whether behaviors such as food restriction or vomiting are driven by psychological or somatic distress, and the medical history is often vague and nonspecific. Moreover, as summarized above under “Psychiatric Comorbidity of Anorexia Nervosa and Bulimia Nervosa,” comorbid psychiatric conditions frequently occur and may further complicate the presentation. It is often difficult to ascertain whether the comorbid psychiatric illness

is causally related to the eating disorder or is more indirectly involved in the manifestation of the eating disorder. As an illustration of the latter, an individual with comorbid social phobia may experience a flare-up of eating disorder symptoms in social situations.

Probably the single most important component of the workup for eating disorders is a thorough history, covering the nutritional, behavioral, psychological, and motivational features discussed above under “Atypical Eating Disorders.” The history should include past and recent patterns of eating, abnormal weight control behavior, associated beliefs and attitudes, timing of emergence of issues with eating and weight, lifetime weight course, and attitudes toward body image. Although obesity and extreme emaciation are readily apparent, the behaviors associated with these bodily states are not. Normal-weight patients with eating disorders may appear entirely healthy, and patients with anorexia nervosa may attempt to persuade the clinician that they are “naturally thin.” Patients with eating disorders may hide their symptoms for several reasons. Behaviors such as binge eating and purging are often experienced by patients as shameful or disgusting. Patients with anorexia nervosa often feel that they must

**TABLE 15–1. Prognostic factors in eating disorders**

<b>Factors predicting negative outcome</b>	<b>Factors predicting favorable outcome</b>
<b>Anorexia nervosa</b>	
History of premorbid development or clinical abnormalities	Early age at onset
Binge eating and/or purging	Hospitalization for an affective disorder before baseline assessment
Long duration of illness	Short interval between symptom onset and beginning of treatment
Weight $\leq 60\%$ ideal body weight or body mass index $< 13 \text{ kg/m}^2$	Conflict-free child-parent relationships
High serum uric acid level	Histrionic personality traits
High serum creatinine level	
Low serum albumin level	
Obsessive-compulsive personality traits	
Comorbid affective disorder	
Comorbid substance abuse	
Severity of alcohol use disorder during follow-up	
<b>Bulimia nervosa</b>	
Poor pretreatment global functioning	Younger age
Premorbid parental obesity	Shorter duration of symptoms
History of substance abuse	Less severe symptoms
History of obesity	Absence of concurrent disruptive pathology
Comorbid major depression	Strong motivation for treatment
High self-directedness	
Comorbid personality disorders (particularly borderline)	
Posttreatment food restriction	

*Source.* Adapted from Bulik et al. 1998; Hebebrand et al. 1997; D.B. Herzog et al. 2000; W. Herzog et al. 1997; Keel et al. 2003; Richards et al. 2000; Steinhausen 2002.

hide their restrictive dieting and compulsive exercise to avoid being prevented from continuing them. Obese patients with eating disorders may be particularly likely to minimize contact with health care providers because they fear being blamed or because they blame themselves for their obesity. Bearing this in mind, clinicians should employ a nonjudgmental assessment style that recognizes the patient's ambivalence and engages the patient in a medically informed discussion of the nature of the illness and the options for treatment. A useful approach to the assessment of eating disorder symptoms in a primary care setting was described by Kreipe and Yussman (2003).

Of particular importance to psychosomatic medicine specialists is the medical evaluation of patients with eating disorders. When the patient displays behaviors and attitudes characteristic of eating disorders (e.g., a classic binge-purge pattern, an unhealthy and excessive dieting regimen, or a lack of concern about weight loss or abnormal eating behaviors), the workup to establish a diagnosis of an eating disorder need not be exhaustive in ruling out primary organic disorders. No laboratory testing is required to make the diagnosis of an eating disorder unless the historical or physical evidence suggests the possibility of an organic etiology. However, for patients with an atypical presentation or those in whom an eating disorder is essentially a diagnosis of exclusion, the workup should be more extensive and the level of suspicion for an underlying organic etiology should remain high. In patients known to have an eating disorder, physical examination and laboratory testing are key in evaluating any medical complications (see below) or comorbid medical illnesses and in guiding treatment.

When the medical provider is seeing the patient for the first time, he or she must, in collaboration with the mental health provider, determine the level of care that is needed and the urgency of intervention. As outlined in the American Psychiatric Association (2000b) "Practice Guideline for the Treatment of Patients With Eating Disorders," the physical assessment of the patient should include 1) a complete physical examination, with attention to evidence of dehydration, acrocyanosis, lanugo, salivary gland enlargement, and scarring on the dorsum of the hands (Russell's sign); 2) vital signs with orthostatic determination of blood pressure and pulse; 3) assessment of physical and sexual growth and development, including height and weight (for pediatric patients a review of the patient's growth chart may be helpful); and 4) dental examination.

Laboratory evaluation should be individualized for the particular patient. In accordance with the American Psychiatric Association (2000b) "Practice Guideline for the Treatment of Patients With Eating Disorders," the

routine workup should include serum electrolytes, blood urea nitrogen and creatinine, liver enzymes, serum albumin, thyroid function tests, complete blood cell count, and urinalysis. Severely malnourished patients should receive additional blood chemistry assessments—including calcium, magnesium, and phosphate levels—and an electrocardiogram. Patients who are chronically underweight should be assessed for osteopenia and osteoporosis using dual-energy X-ray absorptiometry, and serum estradiol (or testosterone in males) may be assessed. Other tests that are not performed routinely but may be indicated in particular clinical situations include serum amylase, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels; computed tomography or magnetic resonance imaging (MRI) of the brain; and screening stool for blood. Although elevated serum amylase concentration is a frequent concomitant of vomiting, this test is not sufficiently sensitive or specific to serve as a useful screening tool for unreported vomiting (Walsh et al. 1990).

Large-scale screening for eating disorders may be a priority in some settings, particularly those in which the prevalence is known to be relatively high, such as high school or university health services. Although a variety of self-report and interview-based assessment tools are frequently used in research settings, one well-established instrument that can be recommended for its brevity and ease of use is the Eating Attitudes Test (EAT-26), originally developed to assess attitudes and behaviors characteristic of anorexia nervosa and also useful in detecting bulimia nervosa (Garner et al. 1982). Another more recently developed screening tool is the SCOFF, a five-item scale that, in initial studies, has good sensitivity and specificity for detecting anorexia nervosa and bulimia nervosa (Morgan et al. 1999). The SCOFF questions are 1) Do you make yourself Sick because you feel uncomfortably full?; 2) Do you worry you have lost Control over how much you eat?; 3) Have you recently lost more than One stone (14 lb) in a 3-month period?; 4) Do you believe yourself to be Fat when others believe you are too thin?; and 5) Would you say Food dominates your life?

## Differential Diagnosis

Hyperphagia, hypophagia, and altered eating patterns occur as features of a variety of medical and psychiatric illnesses and do not, in and of themselves, constitute formal eating disorders according to the standard of DSM-IV-TR. Table 15-2 lists some medical and psychiatric illnesses to consider in the differential diagnosis of an eating disorder. Two conditions of particular interest are Prader-Willi syndrome and Kleine-Levin syndrome.

**TABLE 15–2. Medical and psychiatric differential diagnosis of eating disorders**

System	Diagnosis
Endocrine	Diabetes mellitus, hyperthyroidism, Addison's disease, Sheehan's syndrome (postpartum pituitary necrosis), panhypopituitarism
Gastrointestinal	Malabsorption, pancreatitis, cystic fibrosis, inflammatory bowel disease, peptic ulcer disease, superior mesenteric artery syndrome, Zenker's diverticulum, dysmotility disorders
Neurologic	Psychomotor or limbic seizures, degenerative neurological conditions (Pick's disease, Alzheimer's disease, Huntington's disease, Parkinson's disease), hypothalamic or diencephalic tumor
Other medical	Malignancies (especially lymphoma and gastrointestinal cancers), collagen vascular disorders, chronic infections (especially tuberculosis, human immunodeficiency virus, fungal disease), parasitic infections, chronic renal failure, drug-induced appetite/weight change (e.g., corticosteroids, novel antipsychotics)
Psychiatric	Body dysmorphic disorder, melancholic major depression, atypical depression, obsessive-compulsive disorder, substance use disorder, dementia, factitious disorder, somatization disorder, psychotic disorder

*Prader-Willi syndrome* (PWS) is a multisystem disorder characterized by neonatal hypotonia, later obesity, hyperphagia, hypogonadotropic hypogonadism, and mental retardation. It has recently been reported that, in contrast to most obese individuals, those with PWS have markedly elevated levels of ghrelin, an enteric hormone that stimulates growth hormone secretion and food intake (Haqq et al. 2003). PWS occurs sporadically, as a result of either microdeletion of chromosome 15p (70%) or maternal disomy of chromosome 15 (30%). Care of individuals with PWS can be challenging, primarily due to hyperphagia, food seeking and obesity, and conduct disorder, particularly manifested as tantrums or oppositional behavior (Couper 1999).

*Kleine-Levin syndrome* is a rare self-limited disorder of unknown origin that usually affects adolescent males and is characterized by episodic hypersomnia, increased appetite, and behavioral and psychiatric disturbances. Individuals typically function normally between episodes (Papacostas and Hadjivasilis 2000).

The presence of body image disturbance or intentional weight manipulation is usually quite useful in differentiating true eating disorders from other eating-related disorders. In the absence of these features, the diagnosis of an eating disorder should be regarded as provisional, and medical disorders such as those listed in Table 15–2 should be thoroughly considered in the differential diagnosis.

## Etiology and Risk Factors

As research on the etiology of eating disorders has progressed, it has become clear that the onset of an eating disorder results from a confluence of factors: sociocultural, biological, and genetic. Most of what is currently known about the etiology of eating disorders focuses on anorexia nervosa and bulimia nervosa. Risk factors for BED may overlap with—but are not the same as—those for anorexia

nervosa and bulimia nervosa and are considered briefly below under “Etiology of Binge-Eating Disorder.”

## Culture

Although eating disorders were once thought to affect mainly upper-class, Western women from majority cultures, they are increasingly prevalent among individuals from lower socioeconomic sectors and minority ethnic groups, both in the United States and in other countries (Gard and Freeman 1996; Striegel-Moore 1997). The one factor that seems to unite all the cultures in which eating disorders are prevalent is a relative abundance of food. In such cultures, thinness becomes an ideal, presented by the media as a quality for which everyone, particularly women, should strive.

Clearly, however, not everyone who lives in a culture of abundance develops an eating disorder. As Polivy and Herman (2002) explain, the “idealization of thinness” in cultures of abundance may trigger for some an intense focus on their body shape and weight. This intense focus, in turn, may precipitate the development of eating disorder pathology. Thus, a culture of abundance (and the thin ideal that comes with that culture) may be a necessary, but not sufficient, precursor to the development of eating disorders.

Some have suggested that the process of cultural change may be associated with increased vulnerability to eating disorders, especially as developing cultures embrace the modern Western body ideal of thinness. Such change may occur across time within a given society or on an individual level (Miller and Pumariega 2001).

## Family and Individual Environment

Along with cultural pressures toward thinness, familial and peer pressures to uphold the thin ideal have been cited

as potential contributors to eating disorder pathology (Branch and Eurman 1980; Levine et al. 1994; Shisslak et al. 1998; Stice 1998; Wertheim et al. 1997). Furthermore, it has been argued that certain types of familial environments—namely, those in which parents are overly critical, hostile, and coercive and are overly enmeshed in their children's lives (e.g., Haworth-Hoepfner 2000; Minuchin et al. 1978)—may more readily breed eating disorder behaviors. However, none of these assertions concerning the role of peers and family in the development of eating disorders have been proved conclusively, and therefore further study is necessary (Stice 2002). A predisposition to eating disorders has also been noted among individuals who participate in certain activities that promote thinness, such as ballet dancing, modeling, and some sports that emphasize weight and body shape (Kann et al. 2000). Although a history of sexual abuse or trauma appears to be a risk factor for developing eating problems (Everill and Waller 1995; Kendler et al. 2000; Kent and Waller 2000), there is currently not enough consistent evidence to support such a history as a specific risk factor for eating disorders (Stice 2002).

## Genetics

Although the research discussed above under “Culture” implicates culture as an important risk factor for the development of eating disorders, it is clear that individual vulnerabilities play a substantial role. Specifically, such traits as perfectionism, impulsivity, negative affect, and low self-esteem have all been cited as potential risk factors (Fairburn et al. 1999; Polivy and Herman 2002; Stice 2002) and may account for the fact that only a minority of young women in a high-risk cultural environment actually develop clinical eating disorders. In addition, a vulnerability to obesity appears to increase risk for bulimia nervosa and BED (Fairburn et al. 1997, 1998), possibly by promoting dieting. Many such trait vulnerabilities may be largely genetically determined, and the genetics of eating disorders is a rapidly developing area of interest (Collier 2002).

Results of some genetic studies have suggested that anorexia nervosa, bulimia nervosa, and atypical eating disorders aggregate in families, and it appears that at least some of the risk factors are common to both anorexia nervosa and bulimia nervosa. In other words, relatives of persons with an eating disorder are significantly more likely than members of the general population to develop either the same or an alternative eating disorder. Twin studies have also suggested that genetic factors contribute substantially to the development of eating disorders (Bulik et

al. 2000). In light of the evidence supporting the importance of genetic risk factors for eating disorders, the challenge of identifying biological abnormalities that reflect the expression of the particular genes associated with eating disorders has become an important part of the research agenda. A reported association between a polymorphism in the promoter region of the serotonin<sub>2A</sub> receptor gene and risk for anorexia nervosa has not been consistently confirmed, and the current status of this research is uncertain (Collier 2002). In addition, a report (Branson et al. 2003) of an association between BED and a mutation in the melanocortin<sub>4</sub> receptor gene, a candidate gene for appetite and weight regulation, represents a potentially important clue to the means by which genetic risk contributes to binge eating. A recent study, however, failed to replicate this finding (Helebrand et al. 2004). Finally, a polymorphism in the gene for agouti-related peptide, a melanocortin receptor inverse agonist, has also been reported to be associated with anorexia nervosa (Adan et al. 2003). Clearly, the clarification of the particular genetic risks for eating disorders awaits further study and replication.

## Neurotransmitters, Neuropeptides, and Neuroanatomy

A great deal of research has focused on abnormalities in the functioning of neurotransmitters, particularly serotonin, in the development and maintenance of eating pathology (Kaye and Strober 1999). A confluence of evidence suggests that serotonergic activity is increased in women who have recovered from anorexia nervosa and bulimia nervosa but is decreased in underweight individuals with anorexia nervosa and actively symptomatic women with bulimia nervosa. These findings are consistent with the idea that at baseline these patients are characterized by perfectionism and behavioral overcontrol, but that when symptomatic, they may be more impulsive and undercontrolled (Kaye 2002).

More recently, researchers have been interested in the role of appetite- and weight-regulating peptides, including those that stimulate appetite (such as neuropeptide Y, peptide YY, and galanin) and those that reduce appetite (such as leptin and corticotropin-releasing hormone). Most, but not all, of the reported abnormalities normalize after recovery, suggesting that they may reflect the operation of physiological mechanisms triggered by malnutrition or weight loss. However, increased cerebrospinal fluid concentrations of peptide YY in women who have recovered from bulimia nervosa and reduced cerebrospinal fluid concentrations of galanin in women

with anorexia nervosa who have had long-term weight restoration may represent trait abnormalities rather than transient states resulting from eating disorder symptoms. The role of these peptides in the etiology of eating disorders requires further study (Kaye 2002).

One relatively new avenue of research into the biological underpinnings of eating disorders is brain imaging, recently reviewed by Chowdhury and Lask (2001). Computed tomographic and MRI studies have consistently detected ventricular enlargement and diffuse atrophy in underweight patients with anorexia nervosa. Most reported abnormalities appear to reverse with weight restoration, suggesting that they represent secondary effects of malnutrition, although one study reported gray matter volume reduction that persisted even after weight regain (Lambe et al. 1997). Although it is unlikely to be etiological, this persistent abnormality may reflect the effect of long-term malnutrition on the brain and may be related to the high rate of relapse in recovered anorexia nervosa patients.

Functional imaging studies have not yet provided a consistent picture of the relationship between abnormal functioning in particular brain regions and eating disorder symptoms, but provocative findings are beginning to emerge. For example, one recent study of early-onset anorexia nervosa in children and adolescents used single photon emission computed tomography to assess regional cerebral blood flow. The researchers found that most patients in the study had abnormally low cerebral blood flow, predominantly affecting the temporal lobe. The authors concluded that these abnormalities may affect limbic-system function and may be associated with eating disorder psychopathology in these patients (Chowdhury et al. 2003).

## Etiology of Binge-Eating Disorder

It should be noted that risk factors for BED may differ in degree and kind from those for anorexia nervosa and bulimia nervosa. A case-control community study found that risk factors for the development of BED were less numerous and weaker than those for anorexia nervosa and bulimia nervosa. Specific risk factors for BED include parental depression, vulnerability to obesity, and repeated exposure to negative comments about shape, weight, and eating (Fairburn et al. 1998). Genetic and environmental factors appear to interact in determining whether an individual progresses toward bulimia nervosa or BED. Genetic risk factors for binge eating and bulimia nervosa may be similar, whereas nonshared environment may be important in influencing the risk for bulimia nervosa once binge eating is initiated (Wade et al. 2000).

## Medical Complications

---

The pathological processes associated with eating disorders are multisystemic in nature and result from the altered eating and compensatory behaviors that characterize these disorders. Medical morbidity in eating disorders results from severe restriction with extensive weight loss; self-induced vomiting; use of laxatives, diuretics, or appetite suppressants; or binge eating with excessive weight gain. These symptoms and the resultant pathological processes may occur singly, as in patients with restricting anorexia nervosa or normal-weight bulimia nervosa, or may co-occur, as in patients with anorexia nervosa purging subtype or eating disorder NOS. It is important to note that individuals with normal or above-normal body weight who lose an excessive amount of weight may manifest similar changes in medical status as those who start at normal or low body weight and lose even more. Eating-disorder symptoms and their effects on medical status are summarized in Table 15-3. Medical morbidity related to obesity has been extensively reviewed elsewhere (Pi-Sunyer 2002) and is beyond the scope of this chapter.

## System-Focused Review of Medical Complications

### *Metabolic/Endocrine*

The primary pathophysiological response to starvation is reduced energy expenditure as a physiological adaptation (Dulloo and Jacquet 1998) (see also Chapter 23, "Endocrine and Metabolic Disorders"). This reduction in energy expenditure has been clearly demonstrated in anorexia nervosa. Underlying the reduced metabolic rate is a change in thyroid hormone synthesis characterized by normal thyroid-stimulating hormone level, low or normal thyroxine ( $T_4$ ) concentration, low or normal levels of triiodothyronine ( $T_3$ ), and elevated concentration of reverse  $T_3$ —a pattern known as the euthyroid sick syndrome. The concept of bulimia nervosa and BED as states of intermittent starvation is controversial, and the data on energy expenditure in these conditions are inconsistent (de Zwaan et al. 2002). The typical endocrine features of starvation (increased cortisol and growth hormone levels; decreased estrogen, LH, and FSH levels in women; decreased testosterone level in men) are also seen in anorexia nervosa and resolve with weight restoration (Devlin and Walsh 1988).

Starvation is also associated with a reduction in noradrenergic activity in the central and peripheral nervous systems of patients with eating disorders. This reduction can

**TABLE 15–3. Eating disorder symptoms and medical effects**

Symptom	Medical effect
Restrictive eating	Cognitive dysfunction, fatigue, cold intolerance, constipation, dizziness, hypoglycemia, acrocyanosis, orthostatic pulse and blood pressure, edema, amenorrhea
Vomiting	Dehydration, metabolic alkalosis, hypokalemia, arrhythmias, esophagitis/gastritis, esophageal tears, dental caries, parotid/submandibular gland hypertrophy, gastroesophageal reflux disease, pharyngitis
Binge eating/overeating (with increasing weight)	Obesity, dyslipidemia, hypertension, type 2 diabetes, coronary artery disease, stroke, gallbladder disease, osteoarthritis, sleep apnea, respiratory disorders
Laxative abuse	Cathartic colon, dehydration, hypokalemia, metabolic acidosis or mild metabolic alkalosis
Diuretic abuse	Dehydration, electrolyte imbalance (hypokalemia and hypomagnesemia)
Appetite-suppressant abuse	Hypertension, tremor, arrhythmias
Ipecac abuse	Generalized myopathy, cardiomyopathy
Compulsive exercise	Bradycardia, overuse syndrome, stress fractures
Water loading	Hyponatremia, headache, nausea, dizziness, seizure

lead to hypotension, bradycardia, hypothermia, and depression (Pirke 1996). It is not uncommon for body temperature to drop to 95°F (35°C) or even lower with continued weight loss, and marked bradycardia is common in underweight patients and in those who exercise extensively. Altered autonomic control of heart rate and blood pressure appears to return to normal with refeeding and resolution of eating disorder–related symptoms (Rechlin et al. 1998).

Other metabolic concomitants of starvation include low serum albumin and high serum uric acid levels, both poor prognostic indicators in anorexia nervosa (W. Herzog et al. 1997). Hypoglycemia is often seen in underweight patients with anorexia nervosa (Bhanji and Mattingly 1988) and sometimes in normal-weight patients with bulimia nervosa (Devlin et al. 1990); symptomatic hypoglycemia is uncommon, but there are case reports of coma and death attributed to severe hypoglycemia in anorexia nervosa. Finally, the potential for zinc deficiency in patients with anorexia nervosa due to insufficient dietary intake has led to a small number of zinc supplementation trials, the results of which have been mixed (Roerig et al. 2002).

### ***Renal Failure, Loss of Fluids, and Electrolyte Imbalance***

Eating disorder–related behaviors such as vomiting, laxative or diuretic use, fluid restriction, or water loading may result in substantial fluctuations in fluid status and lead to life-threatening states such as severe dehydration with hypotension, acid–base disturbances, and electrolyte imbalances. Fluid loss, particularly from vomiting, often leads

to metabolic alkalosis. Patients who abuse laxatives often develop metabolic acidosis. The most common electrolyte imbalance is hypokalemia, which, if chronic and persistent, can lead to nephropathy and chronic renal failure requiring dialysis, as well as intestinal ileus and skeletal muscle myopathy. Cardiac arrhythmias secondary to hypokalemia can be life-threatening; patients with arrhythmias must be given supplemental potassium as soon as possible to correct the imbalance. An electrocardiogram should be obtained and the patient should be placed on cardiac monitoring with intravenous potassium replacement if there are significant electrocardiographic abnormalities. Otherwise, oral potassium replacement is usually safe and effective if retention of the medication after ingestion can be assured. Hypomagnesemia may also be present and may interfere with potassium normalization. Hypocalcemia is uncommon, but when present it may be associated with prolongation of the QTc interval (see “Cardiovascular” below).

Serum phosphate levels also must be monitored because they are frequently low in patients with eating disorders, particularly those with low body weight. Although total body phosphate can be depleted through malnutrition, refeeding can also cause a drop to dangerous levels, and oral phosphate replacement is typically needed. During the first week of refeeding in inpatients, electrolyte levels should be obtained at baseline and then monitored at least every other day for the remainder of the week. Thereafter, they can be monitored less frequently if they remain stable (P.S. Mehler and Andersen 1999). Hyponatremia can result from purging behaviors or from water loading. Significant hyponatremia is associated with increased seizure risk and therefore requires prompt detec-

tion, treatment, and close monitoring. Free water intake may need to be restricted until the sodium imbalance is corrected. Patients with normal kidney function will typically correct their fluid imbalance via spontaneous diuresis.

Fluid losses caused by vomiting or abuse of diuretics, laxatives, or caffeine stimulate the renin-angiotensin system. Particularly in laxative abusers, this stimulation results in an increase in aldosterone concentration and subsequent fluid retention that may persist for weeks, leading to significant weight gain and even frank edema that is difficult for patients to tolerate. Maintenance of proper fluid status over time will correct the fluid retention, and diuresis will eventually ensue. Erratic release of vasopressin from the posterior pituitary may result in symptoms of diabetes insipidus, including excessive urination and hypernatremia (Gold et al. 1983). Blood urea nitrogen is an unreliable indicator of hydration because it may be both reduced by inadequate protein intake and elevated by dehydration or increased protein catabolism. Renal insufficiency may occur in cases of extreme starvation.

### **Central Nervous System**

Both structural and functional changes in the brain are seen in adults and adolescents with anorexia nervosa. Studies have shown evidence of ventricular and cortical sulcal enlargement as well as functional impairment in attention and concentration, visual associative learning, visuospatial abilities, problem solving, and attentional-perceptual motor functions. Other impairments include psychomotor slowing, poor planning, and lack of insight. Some reversal of these changes have been demonstrated with weight restoration; however, it is unknown if they are completely reversible (Chowdhury and Lask 2001; Kerem and Katzman 2003; Kingston et al. 1996; Lambe et al. 1997).

### **Cardiovascular**

Individuals with very low body weight lose significant cardiac muscle over time. This loss limits their cardiac output and may lead to congestive heart failure. Undernourished individuals may also develop clinically silent pericardial effusions (Silveti et al. 1998), as well as conduction abnormalities with arrhythmias or a prolonged QTc interval. The latter has been shown to be a marker for risk of sudden death and therefore requires close monitoring (Cooke and Chambers 1995). Prolongation of the QTc interval is often associated with hypokalemia, hypocalcemia, or hypomagnesemia but may also be caused or exacerbated by medication (Al-Khatib et al. 2003; Halmi 2002). It typically normalizes within days after nutritional

restoration begins (Swenne and Larsson 1999). The most common abnormality is sinus bradycardia secondary to vagal hyperactivity. Mitral valve prolapse has also been noted, although its clinical significance is not fully known. This occurs more commonly in patients with anorexia nervosa and is perhaps secondary to physical remodeling of the heart with starvation (Cooke and Chambers 1995). The cardiovascular system is particularly vulnerable to substances used by patients with eating disorders for weight loss, including ipecac, diuretics, and appetite suppressants. The effects of these substances are noted in Table 15–3. Long-term use of ipecac is particularly dangerous, because it can be associated with the development of cardiomyopathy. In one study, chest pain was found to be a relatively common symptom in patients with eating disorders. Typical and atypical angina were surprisingly common and were thought to reflect underlying coronary artery disease. Increasing age, smoking history, and a family history of chest pain were correlated with the presence of angina (Birmingham et al. 1999).

### **Gastrointestinal**

Gastrointestinal complications of eating disorders vary according to the specific eating disorder symptoms the patient manifests. Restrictive eating with marked weight loss leads to a slowing of gastrointestinal motility, resulting in gastroparesis and constipation. Impaired gastrointestinal motility may also result from ongoing abuse of laxatives, often in escalating amounts due to the development of tolerance. This condition, known as *cathartic colon*, can be associated with hemorrhoids and rectal prolapse from chronic straining. Even in the absence of weight loss, patients with bulimia nervosa have delayed gastric emptying (Devlin et al. 1997), which may explain in part the prolonged sensation of uncomfortable fullness commonly reported by these patients. As recently summarized by Roerig et al. (2002), prokinetic agents such as cisapride (now no longer available due to cardiac conduction effects) have been shown to reduce gastrointestinal complaints but do not enhance weight gain in patients with anorexia nervosa. Elevation of hepatic transaminases is common in underweight patients with anorexia nervosa and may transiently increase during early refeeding.

Vomiting may cause complications related to acid reflux such as enlargement of salivary glands, dental caries, esophagitis, and gastritis. Gastrointestinal dysmotility, when present, is often related to hypokalemia. Forced vomiting may result in hematemesis, which may be secondary to a pharyngeal scratch from induction of vomiting but may also be secondary to gastritis, esophagitis, or (less frequently) gastric or esophageal tears. Binge eating

in bulimia or anorexia can cause acute gastric dilatation, as can rapid refeeding in anorexia nervosa. This requires decompression with a nasogastric tube and fluid and electrolyte replacement.

### *Genitourinary*

In women with anorexia nervosa, amenorrhea is due to hypothalamic amenorrhea syndrome, in which pulsatile secretion of gonadotropin-releasing hormone (GnRH) is diminished. This reduced secretion in turn causes lower levels of LH and FSH along with low blood levels of estradiol, estrone, progesterone, and testosterone, leading to a physiological return to the prepubertal state. Although weight loss is a common precipitant of amenorrhea, a minority of patients develop amenorrhea before the onset of weight loss, indicating that other factors such as caloric restriction, excessive exercise, or psychogenic stress may also be important contributors (Morgan 1999). Menstrual cycling typically resumes with weight restoration at approximately 90% of standard body weight, but there may be a delay of up to 6 months after initial weight restoration (P.S. Mehler and Andersen 1999). Except in cases in which ovulation is induced, pregnancy is rare in women with active anorexia nervosa. However, in a study of 140 women with this eating disorder, at 10-year follow-up 50 had conceived, of whom 20% appeared to have done so while actively anorectic (Brinch et al. 1988).

About half of women with bulimia nervosa become amenorrheic or oligomenorrheic despite having no apparent change in percentage body fat. As in anorexia nervosa, this condition is commonly associated with impaired follicular maturation due to reduced LH concentrations and pulse frequency. Women with abnormal menstrual cycles in bulimia nervosa appear to be underweight in relationship to their own lifetime high body weight but not to average or expected body weight for their age and height (Devlin et al. 1989; Morgan 1999). Despite the profound effects of eating disorders on reproductive function, outcome studies suggest that with full recovery, fertility may not be compromised (Crow et al. 2002; Mitchell-Gielegheim et al. 2002).

### *Musculoskeletal*

Severe protein-energy malnutrition gives rise to a metabolic myopathy with significant loss of muscle mass and function. Cases of rhabdomyolysis have been reported in anorexia nervosa. However, muscle is very responsive to refeeding. One study found that muscle performance improved long before the nutritional compromise was entirely corrected, with some improvement noted as early as the eighth day of refeeding (Rigaud et al. 1997).

Osteopenia and osteoporosis are relatively unique among complications of starvation in that they appear not to be readily reversible with weight recovery. These conditions are chronic rather than acute effects of starvation, because clinically significant bone loss does not usually begin until 12 months after onset of illness. In their study of adolescent women with anorexia nervosa, Castro et al. (2000) noted the following factors related to development of osteopenia: more than 12 months since onset of the disorder, more than 6 months of amenorrhea, body mass index less than 15 kg/m<sup>2</sup>, calcium intake less than 600 mg/day, and less than 3 hours/week of physical activity. It is estimated that osteopenia or osteoporosis occurs in more than half of adolescent and young adult females who struggle with anorexia nervosa. These conditions can result in painful fractures, disfiguring kyphosis, and loss of height. The pathophysiology of bone loss in anorexia nervosa is complex (Golden 2003; P.S. Mehler 2003; Rosenblum and Forman 2002). Estrogen deficiency has long been thought to mediate bone loss in anorexia nervosa via an increase in osteoclast function, which promotes bone resorption. However, there are other factors integral to this process as well. Insulin-like growth factor-1 (IGF-1), a nutritionally dependent bone trophic hormone that stimulates osteoblasts to increase bone formation, is decreased in anorexic females, possibly due to decreased dehydroepiandrosterone (DHEA) in adolescent and young women with anorexia nervosa. Osteopenia and osteoporosis occur in men with anorexia nervosa as well, perhaps due to a relative lack of testosterone, which is a major substrate for estrogen production (Andersen et al. 2000).

The treatment of low bone density in anorexia nervosa requires, first and foremost, refeeding. Weight restoration is found to be effective in increasing bone mass, although not to pre-illness levels. Moderate exercise has been shown to be protective, but strenuous activity is detrimental. The uncertain status of pharmacological treatment for osteoporosis in these individuals has recently been well reviewed (Golden 2003; P.S. Mehler 2003). Hormonal treatment has generally not been found to yield improvement in bone mass in anorexia nervosa, although patients with extremely low weight may derive some benefit (Klibanski et al. 1995), and the combination of IGF-1 and oral contraceptives may be useful in some cases (Grinspoon et al. 2002). The use of estrogen in adolescents should be undertaken with caution because of the potential for fusion of the epiphyses with resultant compromise in final adult height. If estrogen is given, low doses (30–35 µg) should be used. Depot medroxyprogesterone acetate (Depo-Provera) may cause further bone loss and should be avoided. The benefit of

supplemental calcium is not clear; however, the current standard practice in the treatment of anorexia nervosa is to give daily calcium (1,500 mg/day) with meals and vitamin D (400 IU/day). The efficacy of oral bisphosphonates in anorexia nervosa is not proven. Raloxifene, a selective estrogen receptor modulator, suppresses bone turnover. Although it is effective for the prevention and treatment of osteoporosis, it has not been studied specifically for use in anorexia nervosa. Likewise, there is no evidence supporting the use of calcitonin in anorexia nervosa.

### ***Integument***

The cutaneous signs of eating disorders result from malnutrition and self-induced vomiting. Findings related to malnutrition include dry, scaly skin; lanugo hair; carotenodermia; brittle nails; and hair loss. Those related to self-induced vomiting include calluses on the dorsum of the hands from constant abrasion against the front teeth with induction of vomiting (Russell's sign), and purpura and petechiae from recurrent Valsalva maneuvers to induce vomiting. Purpura and petechiae can also be seen as a result of thrombocytopenia secondary to malnutrition (Sharp and Freeman 1993).

### ***Other***

Bone marrow suppression with leukopenia, anemia, and thrombocytopenia is common in states of starvation, but these reach clinically significant levels only in the most severe cases. Pulmonary complications of eating disorders are rare but include pneumomediastinum and aspiration pneumonia from forced vomiting. Dyspnea in long-standing malnourished states is often secondary to respiratory muscle weakness, which does not always show prompt recovery with refeeding and improved nutrition (Birmingham and Tan 2003).

## **Eating Disorders and Pregnancy**

Eating disorders affect women during the period of reproductive functioning. In one study, a full 17% of female patients seen at an infertility clinic had eating disorders (Stewart et al. 1990). However, pregnant women with eating disorders rarely disclose their eating disorder to their obstetrician. Poor maternal or fetal weight gain should serve as red flags to the clinician regarding the possibility of a hidden eating disorder (Morgan 1999). The diagnosis of an eating disorder has clinical significance, and the timely identification of an eating disorder may enable the clinician to more effectively manage the patient and optimize outcome.

Although the majority of women with eating disorders have normal pregnancies resulting in healthy babies, and eating disorder symptoms may improve during pregnancy, rates of caesarean section and of postpartum depression are elevated in women with eating disorders (Franko et al. 2001). Low prepregnancy weight and low weight gain during pregnancy are associated with low infant birth weight and a higher incidence of congenital malformations. Other maternal complications include an increase in bulimic symptoms during pregnancy as well as restrictive eating. Both low and high maternal weight gain may occur, miscarriage is more common, and hypertension is reported more often among bulimic women. Considerations for hospital admission include degree of weight loss, hypokalemia and other electrolyte abnormalities, and electrocardiographic changes, as well as fetal growth and physiological profile. Birth complications for both anorexia nervosa and bulimia nervosa include stillbirth, low birth weight, low Apgar scores, and cleft lip and palate (Mitchell-Gielegheem et al. 2002).

Breast-feeding problems in women with eating disorders have been noted. These include complaints of insufficient lactation or of allergies or negative reactions to breast milk in the infant, resulting in early transition to bottle feeding. For women whose eating disorder treatment includes medication, the risks and benefits of breast-feeding should be carefully reviewed. Child-rearing practices may also be affected by the presence of an unresolved eating disorder in the mother. In a small proportion of cases, inadequate feeding of children has been reported with a secondary effect on the child's growth (Fairburn and Harrison 2003; Mitchell-Gielegheem et al. 2002).

## **Eating Disorders and Diabetes Mellitus**

Some evidence suggests that there is an increase in disordered eating in chronic medical conditions for which dietary restraint is part of the treatment plan (see also Chapter 23, "Endocrine and Metabolic Disorders"). This is particularly true of type 1 diabetes mellitus. The presence of a comorbid eating disorder is associated with markedly worse outcome. A recent study of mortality of individuals with type 1 diabetes and anorexia nervosa reported crude mortality rates of 2.5% for type 1 diabetes, 6.5% for anorexia nervosa, and 34.8% for concurrent cases (Nielsen et al. 2002). Individuals with anorexia nervosa and bulimia nervosa may withhold their daily insulin to prevent uptake of glucose and, in effect, purge. However, they may also manifest other symptoms such as restricting, laxative use, vomiting, use of appetite suppressants, and compulsive exercise. Blood glucose level is typically elevated, and there is an increased risk of keto-

acidosis and other complications (Rodin 2002). In one study (Rydall et al. 1997), disordered eating behavior was found to be associated with a threefold increase in diabetic retinopathy at follow-up. In fact, eating disorders were more predictive of retinopathy than was the duration of diabetes. Another study demonstrated that mean glycosylated hemoglobin was higher in subjects with diabetes mellitus who had an eating disorder (9.4%) compared with those without an eating disorder (8.6%) (Affenito and Adams 2001). The multidisciplinary team treatment of these individuals should include close endocrinological supervision. There is an ongoing need for frequent insulin changes with progression of the meal plan and activity level, or with symptom fluctuation.

## Treatment

---

Given the contributions of cultural, familial, environmental, and genetic factors to the development of eating disorders, it is not difficult to appreciate why a biopsychosocial approach to understanding eating disorders and a multidisciplinary approach to treatment are seen as the foundation of current practice. This approach includes, at a minimum, team members to provide psychotherapy and medication management, medical monitoring and treatment, dietary management, and social service needs. The intensity of treatment and of the setting in which treatment is delivered may vary from self-help or support groups for the least symptomatic patients to weekly outpatient treatment, intensive outpatient treatment, day hospital treatment, or inpatient treatment for the most severely compromised (Kaplan et al. 2001). Patients with anorexia nervosa who are significantly underweight often require inpatient treatment, at least in the initial phase of weight restoration. Those with bulimia nervosa and BED can most often be treated as outpatients, although medical or psychiatric instability or failure of outpatient treatment options may indicate hospitalization. The American Psychiatric Association (2000b) "Practice Guideline for the Treatment of Patients With Eating Disorders" provides a useful set of standards for determining the appropriate initial level of care.

## Nutritional Approaches

Nutritional rehabilitation is a fundamental and often extremely challenging component of treatment. Body weight may range from extremely low in patients with anorexia nervosa to high or markedly unstable in patients with bulimia nervosa and BED. Dietary history at intake may reveal various abnormalities, including avoidance of

particular foods, overconsumption of low-calorie foods such as artificial sweeteners, uncontrolled binge eating, or food rituals. The latter are common and include preferences for unusually seasoned foods or combinations of foods, prolonged mealtimes, and eating alone. Strikingly, even in patients who eat very little themselves, food obsessions and a tendency to work around food are common (Rock and Curran-Celentano 1996).

Weight restoration is of primary importance for the individual with low body weight, whereas weight stabilization may be needed in individuals with normal or above-normal body weight. For obese patients, weight loss may be a goal, but this is usually best deferred until treatment for the eating disorder is well under way. An inpatient program should be considered for the most seriously nutritionally compromised patients, including those whose weight is less than 75% of ideal body weight or for those, especially children and adolescents, whose weight loss may not be as severe but who are losing weight at a rapid rate. The initial plan calls for establishment of a healthy weight target and a plan to restore weight safely and effectively while addressing body image and related concerns. A target weight for discharge from inpatient treatment is typically set at a range greater than or equal to approximately 90% of average for age and height. It is important that patients understand that this is a *minimum acceptable* rather than a recommended weight range.

Body composition is characterized by an extremely low percentage of body fat in emaciated patients with anorexia nervosa that increases rapidly with refeeding. Measurement of skinfold thickness provides a reliable estimate of body fat in these patients (Probst et al. 2001). Studies of body composition during the process of refeeding in patients with anorexia nervosa reveal that most of the nonfluid weight regained is represented by fat, accounting for 32%–77% of total weight gained (Rock and Curran-Celentano 1996), whereas muscle mass appears to lag behind (Polito et al. 1998). The initial distribution of weight regain is often disproportionately centripetal (Grinspoon et al. 2001), with redistribution occurring in the months following achievement of target weight.

Patients with anorexia nervosa may be unwilling or unable to accept food, at least initially. According to the American Psychiatric Association (2000b) "Practice Guideline for the Treatment of Patients With Eating Disorders," intake levels should usually start at 30–40 kcal/kg/day (approximately 1,000–1,600 kcal/day) and should be advanced progressively to yield a rate of weight gain of 2–3 lb/week for inpatients and 0.5–1 lb/week for outpatients. Patients may require levels of energy intake as high as 70–100 kcal/kg/day or more to accomplish this rate of

weight gain, and nutritional supplements are often used in patients with high caloric requirements for weight regain. Although the oral feeding route is preferred, nasogastric feeding is utilized in the initial stage of treatment in some treatment centers. In particular, recent reports support progressive nocturnal nasogastric supplemental feeding for individuals with low body weight as a means of minimizing somatic and psychological distress during initial weight regain and of speeding weight restoration (Robb et al. 2002; Zuercher et al. 2003). As weight gain progresses, regular meal portion sizes are gradually increased until nasogastric supplements are no longer required. Parenteral nutrition may be utilized in extreme circumstances; however, parenteral feedings are usually not given because of the associated risks of infection and increased risk of refeeding syndrome (described below in this subsection). Although weight regain is rarely steady, a particularly erratic weight-gain pattern or inability to gain weight despite increasing caloric intake may reflect covert disposal of food, exercise, purging, or water loading to make weight, and more stringent monitoring may be in order.

Physical activity during weight restoration should be adapted to the food intake and energy expenditure of the patient, taking into account the patient's history of excessive exercise. Adherence to the refeeding protocol is often linked with greater freedom to participate in activities and other rewards. Increases in physical activity must be balanced with medical stability, weight restoration, and control of eating disorder symptoms, including excessive activity. Strict limitations are needed for individuals who struggle with compulsive exercise, and more intensive monitoring may be needed for those found to be exercising covertly. In most programs, activity is progressively advanced to include regimens of stretching, strengthening, and aerobic activity when appropriate (Rosenblum and Foreman 2002).

Careful medical monitoring is essential throughout the refeeding period and typically includes monitoring of vital signs, food and fluid intake and output, and routine electrolytes plus magnesium, calcium, and phosphate. In addition, patients should be observed for edema and rapid weight regain. If present, these may suggest fluid overload or congestive heart failure. Gastrointestinal symptoms of constipation and bloating should also be monitored. Cardiac monitoring may be indicated for severely malnourished individuals (below 70% of ideal body weight), especially children and adolescents and those individuals with severe electrolyte disturbances, arrhythmias, or prolonged QTc interval (Al-Khatib et al. 2003).

One of the most serious complications of weight restoration is the refeeding syndrome, characterized by marked

fluid and electrolyte abnormalities, including low serum phosphate levels. The combination of depletion of total body phosphate stores during catabolic starvation and increased cellular influx of phosphate during anabolic refeeding leads to severe extracellular hypophosphatemia. This well-recognized complication of refeeding, particularly in individuals with very low body weight, can lead to cardiac arrhythmias, delirium, and even sudden death (Solomon and Kirby 1990). This syndrome has most often been noted in refeeding with total parenteral nutrition but can be seen with oral and nasogastric refeeding regimens as well (Fisher et al. 2000).

Cholesterol levels in anorexia nervosa are usually normal or high despite low cholesterol intake. These levels do not result from the *de novo* synthesis of cholesterol. Rather, abnormal thyroid hormone status, low serum estrogen levels, hypercortisolism, and impaired clearance of cholesterol explain or contribute to hypercholesterolemia in this setting. Weight restoration is typically accompanied by reduction in cholesterol level and apolipoprotein B (Feillet et al. 2000), and no effort should be made to further reduce dietary fat or cholesterol (Rock and Curran-Celentano 1996). Other laboratory abnormalities that characterize starvation and early recovery such as low white blood cell count or elevated liver transaminases typically normalize with weight recovery.

As refeeding progresses, specific laboratory markers can be used to assess improvement or deterioration in nutritional status and in effect measure the transition from protein catabolism to anabolism. A number of different parameters have been used, including serum albumin, prealbumin, retinol-binding protein, transferrin, and C-reactive protein. Serum prealbumin has a short half-life and responds rapidly to low energy intake even in the presence of adequate protein intake, making it an excellent marker of nutritional response to refeeding in severely malnourished individuals. Serum prealbumin levels of 20–40 mg/dL are considered normal, levels in the range of 10–15 mg/dL indicate mild malnutrition, levels of 5–10 mg/dL indicate moderate malnutrition, and levels of less than 5 mg/dL suggest severe depletion (Mears 1996). More recently Caregaro et al. (2001) studied the use of IGF-1 as a biochemical marker of malnutrition and a sensitive index of nutritional repletion in patients with eating disorders.

For patients with binge eating and/or purging, nutritional rehabilitation is geared toward the establishment of a regular eating pattern, moderation of dietary restraint, and elimination of unhealthy dieting practices. Inpatients with bulimia nervosa may require constant observation after meals to keep them from vomiting and to help them learn to tolerate the sensation of fullness following a meal.

For obese patients with bulimia nervosa, weight loss may be medically indicated after resolution of the eating disorder. It is an important principle of treatment that cessation of binge eating/purging and simultaneous weight loss are incompatible goals (Rock and Curran-Celentano 1996). In contrast, for obese patients with BED, some have proposed treatments that concurrently target both obesity and binge eating (Devlin 2001).

## Psychopharmacological Approaches

A number of studies have evaluated the efficacy of medications in the treatment of eating disorders, and findings are thoroughly summarized in recent reviews of medication for eating disorders (Bacaltchuk et al. 2000; Wilson and Fairburn 2002). An important related area, the psychopharmacological management of obesity associated with mental disorders, is beyond the scope of this chapter but has recently been reviewed (Malhotra and McElroy 2002).

The most widely studied class of drugs for eating disorders is antidepressants, including tricyclics, monoamine oxidase inhibitors (MAOIs), and selective serotonin reuptake inhibitors (SSRIs). For patients with bulimia nervosa, antidepressants are significantly more effective than placebo in reducing binge-eating and purging behaviors. Furthermore, it appears that all antidepressants work equally effectively; however, SSRIs yield fewer side effects than MAOIs and tricyclics, and fluoxetine is the only medication approved by the U.S. Food and Drug Administration for the treatment of bulimia nervosa. However, longer-term studies of antidepressant treatment with bulimia nervosa suggest that these medications alone are not sufficient to facilitate long-term remission (Romano et al. 2002; Walsh et al. 1991). Research on pharmacotherapy for BED has suggested that antidepressants may reduce binge frequency, at least in the short term; however, this finding has not been as clearly demonstrated for BED as for bulimia nervosa. For patients with anorexia nervosa, antidepressant treatment has, for the most part, not proved effective (Attia et al. 1998).

Although they are less well studied than antidepressants, other classes of drugs have been reported to be useful in the treatment of BED and bulimia nervosa. Anticonvulsants (carbamazepine, phenytoin, valproate) and other psychotropic medications (lithium, naltrexone, methylphenidate) have been reported to be effective in reducing binge eating in bulimia nervosa or BED, but their routine use has not been clearly established. Most recently, topiramate has been found to curb binge-eating episodes in patients with BED (McElroy et al. 2003) and bulimia nervosa and also to cause weight loss in obese pa-

tients, a potentially useful side effect that has not been observed with other medications used for these disorders (Malhotra and McElroy 2002). In addition to topiramate, appetite suppressant medications have been thought to be a potentially useful treatment for BED. One study (Stunkard et al. 1996) demonstrated that D-fenfluramine, a drug that is now off the market, was effective in reducing binge eating in patients with BED. In a recently completed trial, sibutramine (Meridia) was found to be significantly more effective than placebo in reducing binge frequency in obese patients with BED. In addition, individuals taking sibutramine lost a clinically significant amount of weight (Appolinario et al. 2003).

In general, patients with anorexia nervosa have not responded favorably to pharmacotherapy (Wilson and Fairburn 2002). However, recent evidence suggests that the antipsychotic medication olanzapine may be a useful tool in the treatment of anorexia nervosa, both for its ability to target the delusions, anxiety, and obsessions that often characterize those with anorexia nervosa and its documented side effect of weight gain (C. Mehler et al. 2001; Powers et al. 2002). Double-blind, randomized trials of olanzapine are necessary before firm conclusions about its efficacy can be drawn. In addition, some studies have found that fluoxetine is a useful tool for relapse prevention in weight-restored patients with prior anorexia nervosa (Kaye et al. 1991, 2001). Again, more research is necessary to validate the use of fluoxetine for this population. Finally, a recent pilot study using recombinant human growth hormone (rhGH) in adolescent patients with anorexia nervosa reported more rapid medical stabilization and numerical but not statistically significant improvements in weight gain and length of hospitalization in the rhGH group (Hill et al. 2000).

## Psychotherapeutic Approaches

Mental health professionals employ a wide variety of therapeutic techniques in their efforts to treat the symptoms of anorexia nervosa, bulimia nervosa, and BED. However, only a few of these psychotherapies, such as cognitive-behavioral therapy (CBT) and interpersonal therapy, have been systematically studied in randomized, controlled trials. In addition, certain other types of therapy have been studied for the treatment of only one eating disorder diagnosis, such as manualized family therapy and inpatient treatment for those with anorexia nervosa and behavioral weight loss for patients with BED.

CBT, the most widely studied method of psychotherapy for eating disorders, targets the two broad areas of eating disorder symptoms: 1) cognitive and attitudinal disturbances, such as low self-esteem and overemphasis on

and distortion of weight and shape; and 2) behavioral aspects of eating and weight regulation, such as purging and food intake restriction. The goals of CBT are to challenge rigid rules about eating and weight that patients with eating disorders have imposed on themselves and to help these patients develop healthier behaviors and cognitions. CBT for bulimia nervosa was first put into manualized format in the early 1990s (Fairburn et al. 1993b) and has subsequently been modified for patients with anorexia nervosa and BED (Garner et al. 1997; Marcus 1997). CBT has been administered in an individual format, in a group setting, and via a self-help manual.

Most studies of CBT have examined patients with bulimia nervosa. In general, it has been shown that CBT is more effective than minimal treatment, supportive psychotherapy, and purely behavioral interventions in reducing both the behavioral and cognitive disturbances of patients with bulimia nervosa. Studies assessing the effectiveness of CBT alone, medication alone, and their combination in the treatment of bulimia nervosa have shown that CBT alone is more effective than medication alone and leads to more successful long-term maintenance of change. Furthermore, the combination of CBT and antidepressant medication is significantly superior to medication alone (Wilson and Fairburn 2002). Medication may confer modest additional benefits to CBT and may be most useful for targeting comorbid symptoms of depression and anxiety (Walsh et al. 1997). Studies of CBT in patients with BED have shown that CBT is significantly more effective than no treatment (American Psychiatric Association 2000b), but it appears to be no more effective than other types of treatment, such as behavioral weight-loss programs (Agras et al. 1994) or interpersonal therapy (Wilfley et al. 2002). Studies of CBT for anorexia nervosa have been too small in scope and methodologically unsound to yield firm conclusions about the use of CBT in this population.

Interpersonal therapy was originally developed as a treatment for depression (Klerman et al. 1984) and was subsequently adapted for use with bulimia nervosa and BED (Fairburn 1997; Wilfley et al. 1993). Interpersonal therapy focuses on a person's interpersonal relationships rather than on the specific behavioral or attitudinal disturbances of the eating disorder. Studies comparing CBT and interpersonal therapy for bulimia nervosa have shown that although CBT appears to exert its effects more quickly, the two treatments both lead to significant long-term symptom change (Agras et al. 2000; Fairburn et al. 1993a). In patients with BED, CBT and interpersonal therapy appear to be equally effective (Wilfley et al. 2002).

A few additional nonpharmacological forms of treatment for eating disorders deserve mention. One form of

treatment for BED is behavioral weight loss, with the goal of improving the patient's diet and exercise regimen and restricting his or her caloric intake. In general, it appears that behavioral weight loss is effective in the short term in reducing episodes of binge eating and yielding clinically significant weight loss (Agras et al. 1994; Marcus et al. 1995; Nauta et al. 2000). However, few studies have examined the long-term effects of behavioral programs, a key issue in obesity treatment. Some patients who have BED associated with obesity may also pursue weight-loss surgery, the most common procedure being the Roux-en-Y gastric bypass (see Chapter 30, "Surgery"). For these patients, the long-term prognostic significance of an eating disorder is uncertain and merits further study.

There have been few systematic studies of treatment for anorexia nervosa. Patients with anorexia nervosa can be treated either on an inpatient or an outpatient basis. Often treatment is sequenced, starting out with inpatient therapy or partial hospitalization followed by outpatient therapy aimed at relapse prevention. Inpatient therapy usually involves some combination of individual therapy, family therapy, nutritional counseling, and occupational/recreational therapy, typically with behavioral incentives in place for encouraging weight gain. Outpatient therapies used for anorexia nervosa have been eclectic, ranging from nutritional counseling to supportive psychotherapy to CBT. Recently, researchers have begun to empirically evaluate some forms of anorexia nervosa outpatient treatment. For example, a group from the Maudsley Hospital in London developed a manualized outpatient family therapy for adolescents with anorexia nervosa that seeks to empower parents to refeed their child at home (Lock et al. 2001). Results from a number of studies suggest that the Maudsley method is extremely effective for long-term weight restoration in adolescents with an early onset of anorexia nervosa and a short duration of illness (Eisler et al. 1997, 2000; Russell et al. 1987).

## Involuntary Treatment

A critical issue concerning treatment for eating disorders, particularly anorexia nervosa, is the question of involuntary hospitalization for critically ill patients. Patients with anorexia nervosa often experience their illness as an important component of their identity, and they are therefore quite reluctant to undertake treatment. Many patients are hospitalized against their will by loved ones or health care providers with serious concerns about their medical stability. Some countries (e.g., the United Kingdom) have established clear guidelines outlining the conditions under which compulsory treatment for anorexia nervosa is indicated. However, the United States has no

such guidelines, and American clinicians treating patients with anorexia nervosa must therefore consult more general standards for involuntary treatment.

The question of whether involuntary treatment for anorexia nervosa is ethical is a controversial one. Supporters of involuntary treatment claim that extremely low-weight patients with anorexia nervosa are incapable of making treatment decisions for themselves, due to both the cognitive effects of semistarvation and their distorted thinking surrounding food and body image. Detractors of involuntary treatment cite a host of concerns. Some believe that conceptualizing anorexia nervosa as an illness meriting compulsory treatment overemphasizes its medical aspects and ignores the many pertinent emotional and social factors that may contribute to the illness. Others argue that prospective patients are generally neither psychotic nor grossly impaired in cognitive function and therefore do not lack capacity to make treatment decisions. An additional concern is that patients who are forced into treatment will not be willing to continue treatment once their dire medical situation is resolved and that clinicians who take action to commit their patients against their wishes will destroy the therapeutic relationship (Russell 2001).

Three studies, only one of which took place in the United States, compared the outcomes of patients who had been hospitalized involuntarily with those of voluntary patients (Griffiths et al. 1997; Ramsay et al. 1999; Watson et al. 2000). In the short term, voluntary and involuntary patients made equally strong progress in terms of weight gain, although in some cases involuntary patients required a longer hospital stay to achieve their target weights. No systematic follow-up was done on the patients in these three samples, so the question of long-term effects of involuntary treatment remains open. However, based on the examination of a national mortality register roughly 5 years after hospitalization, one group reported higher mortality rates in involuntary patients. Further study of both the ethical basis and the practical utility of involuntary treatment is needed.

## Conclusion

Disordered eating is an important component of the clinical presentation of a variety of patients with weights ranging from emaciated to severely obese. In some cases, disordered eating is of sufficient severity to warrant an eating disorder diagnosis in its own right, whereas in other cases, eating disorder symptoms may complicate the clinical picture of patients with other medical or psychiatric illness. Although the most common eating disorder

diagnosis is eating disorder NOS, it is also the most inadequately studied. However, a knowledge of the assessment, differential diagnosis, medical complications, and treatment of the classic eating disorders will aid the psychiatric practitioner in developing a treatment approach for patients with a wide range of eating disorder symptoms and in contributing to the multidisciplinary treatment of severely ill patients who are medically compromised by their eating disorder.

# 16 Sleep Disorders

---

Lois E. Krahn, M.D.

Jarrett W. Richardson, M.D.

**OBTAINING SUFFICIENT QUANTITY** and quality of sleep is important for good health. Chronic partial sleep deprivation, also known as insufficient sleep, is common in our society. The consequences include depressed mood, interpersonal irritability, decreased daytime vigilance, and cognitive impairment (Pilcher and Huffcutt 1996). However, determining the appropriate amount of required sleep is difficult for several reasons. Sleep duration gradually decreases from a starting length of 16 hours per 24-hour day as human beings make the transition from infancy to adulthood. Interindividual differences in the optimal amount of sleep range from 6 to 12 hours with a mean of 7.5 hours for adults. When a primary sleep disorder, such as obstructive sleep apnea, is present, the continuity and depth of sleep may be compromised independently of sleep duration. These complexities preclude a simplistic identification of a precise target of sleep duration for any individual. Nonetheless, there is consensus that chronically inadequate sleep is detrimental.

## Physiological Mechanisms of Normal Sleep

---

Sleep can be subdivided into two major components: rapid eye movement sleep (REM), which is characterized by high levels of cortical activation in the presence of muscle atonia to prevent corresponding movements, and non-rapid eye movement sleep (NREM), which consists of four stages. Table 16-1 summarizes the characteristics and percentage of time spent in each sleep stage by healthy, middle-aged adults.

Normal sleep progresses from wakefulness to stage I NREM sleep. From this stage of twilight sleep, a patient

can be easily awakened by environmental stimuli. Stage II NREM sleep is deeper, and moderate environmental stimuli, such as a crack of thunder, no longer cause arousal but rather result in a distinctive electrophysiological event, the K complex. Sleep spindles and K complexes are used to identify stage II sleep. When the electroencephalographic (EEG) tracing slows until at least 20% of the activity consists of higher-voltage slow waves, the sleep is rated stage III or IV. These two deeper sleep stages are also known collectively as *delta wave sleep*, *deep sleep*, and *slow wave sleep*. A person awakes from this sleep only when environmental stimuli are marked, such as the prolonged loud noise of an alarm.

As the normal sleep cycle progresses, the EEG activity gradually returns to the most common stage, stage II sleep. Stage II sleep evolves into the first REM sleep episode of the night. REM sleep consists of high-frequency EEG activity, episodic bursts of vertical eye movements, muscle atonia, and penile tumescence. The first REM episode is often brief and typically occurs 70–100 minutes after the person falls asleep. There is marked interindividual variability in arousal threshold in REM sleep (Carskadon and Dement 1994). The sleep cycle repeats four or five times during the night, subsequent REM episodes being of longer duration. In general, slow wave sleep is more common early in the night, and REM periods become longer toward morning. Because the last REM episode occurs at the very end of the major sleep period, people recall their dreams, and men experience morning erections.

The data in Table 16-1 are useful as normative data because sleep study reports typically describe the percentage of the night spent in each complete stage, and thus subjects with normal sleep patterns can be compared with subjects who are patients. In healthy elderly subjects, the

**TABLE 16–1. Sleep stages in healthy adults**

Stage	Percentage	Polysomnographic characteristics	Physiological changes
Stage I	2–5	Slow eye movements	Easy to arouse
Stage II	45–55	Spindles, K complexes	More difficult to arouse
Stage III/IV	13–23	Slow EEG frequency	Difficult to arouse
REM	20–25	Rapid eye movements Muscle atonia Increased EEG frequency	Variable arousal threshold Penile engorgement

*Note.* EEG=electroencephalographic; REM=rapid eye movement.

relative percentage of time spent in slow wave sleep decreases, and sleep is generally more fragmented. Patients with disrupted sleep often spend most of the night in stages I and II and have little slow wave or REM sleep. The exact roles of slow wave sleep and REM sleep in a refreshing night's sleep are not well understood, but significant reductions in either state can lead to undesirable results, including daytime sleepiness, depressed mood, and cognitive impairment. In animal studies, prolonged absolute sleep deprivation has resulted in death attributed to sepsis because of suspected underlying compromise of immune function (Bergmann et al. 1996).

## Evaluating Sleep

### Office Evaluation

A detailed diagnostic interview and physical examination remain the foundation of the sleep evaluation. Table 16–2 lists the many issues that must be evaluated in an assessment for a possible sleep disorder. The decision to refer for a specialty evaluation and diagnostic testing is based on the findings at the history and physical examination conducted by the primary care provider or referring physician. Sleep studies are not absolutely necessary for some

disorders (e.g., restless legs syndrome) and can be avoided if the classic symptoms of the disease are identified in the absence of any other factors. Clinicians need to obtain both thorough medical and thorough psychiatric histories because many illnesses and disorders can alter sleep. As people age, sleep complaints become more common, not because of primary sleep disorders but because of comorbid conditions (Vitiello et al. 2002). Tables 16–3 and 16–4 list disorders that may lead to sleep problems. Treatment should therefore be concentrated on stabilizing the underlying disease.

Because many patients minimize excessive daytime sleepiness or slowly adapt to it, they may lose insight into the degree of their excessive daytime sleepiness. History from other sources, such as family members, may be necessary. Daytime symptoms related to excessive sleepiness can be evaluated with the brief and convenient Epworth Sleepiness Scale (Table 16–5) (Johns 1991). Unfortunately, no similar scale or questionnaire has been used widely in clinical practice to screen for nocturnal sleep symptoms and disorders.

A detailed interview with a bed partner is of great value, if feasible, especially in regard to snoring and respiratory pauses. The more observant the bed partner, the more likely it is the clinician will be able to obtain a useful history of what actually happens while the patient sleeps.

**TABLE 16–2. Selected causes of excessive daytime sleepiness**

<b>Primarily neurologic</b>	
Restless legs syndrome	Periodic limb movement disorder
Idiopathic narcolepsy or hypersomnia	Narcolepsy caused by lesion near the third ventricle
Delirium	Central sleep apnea
Kleine-Levin syndrome	Prader-Willi syndrome
<b>Primarily medical</b>	
Obstructive sleep apnea	Gastroesophageal reflux
<b>Primarily psychiatric</b>	
Medication-induced disorder (alcohol, hypnotic, sedative, etc.)	Stimulant withdrawal
Mood disorder	Altered sleep-wake schedule

**TABLE 16-3. Selected causes of insomnia**

<b>Primarily medical</b>	
Obstructive sleep apnea	Angina
Chronic obstructive pulmonary disease	Hypoglycemia
Asthma	Congestive heart failure (orthopnea, paroxysmal nocturnal dyspnea)
Gastroesophageal reflux	Hyperthyroidism
Acute pain	Chronic pain
<b>Primarily neurologic</b>	
Central sleep apnea	Restless legs syndrome
Dementia	Fatal familial insomnia
<b>Primarily psychiatric</b>	
Medication-induced (xanthines, psychostimulants, etc.)	Withdrawal-related (alcohol, benzodiazepines, etc.)
Psychophysiological insomnia	Sleep state misperception
Anxiety disorders	Mood disorders (depression, mania)
Altered sleep-wake schedule	
<b>Primarily environmental</b>	
Community noise (traffic, alarms, neighbors, gunshots, etc.)	Altered temperature (too hot, too cold)

**TABLE 16-4. Essential issues in a sleep diagnostic interview of patients and bed partners**

Presenting complaint?	Previous sleep evaluations?
Sleep schedule—Parenting issues?	Work schedule—Rotating shifts?
Nap schedule—Frequent or prolonged?	Exercise schedule—Late in the evening?
Sleep environment—Bed partner? Bright light? Noisy? Too hot/cold? Pets?	Insomnia—Early? Middle? Late?
Nocturnal movements?	Sleep walking? Somnambulism? Enuresis?
Excessive daytime somnolence?	Motor vehicle accident?
Cataplexy? Sleep paralysis? Hallucinogenic experiences?	Alcohol, street drug, or caffeine use, abuse, or dependence?
Observed apnea?	Sleep position?
Gastrointestinal reflux—Diagnosed? Partially treated?	Pain—Chronic? Acute? Medications wear off?
Erectile problems?	Snoring?
Depression, mania, or panic attacks?	Vivid dreams, nightmares?
Prescription drug use, abuse, or dependence?	Herbal preparations?
Family sleep history	Childhood sleep history

Sometimes, even if the patient sleeps alone, a family member can provide useful information if the partner moved out of a shared bedroom because of intolerable snoring or unusual behaviors. Although this interview results in limited specific information about current symptoms, it can clearly raise suspicion that a pathological condition is present.

During the physical examination, the examiner should note the patient's level of alertness (in the waiting room and during the appointment), body mass index, neck circumference, nasopharyngeal abnormalities, thyroid size, pulmonary findings, findings at cardiac auscultation, and cognition. Valuable laboratory tests include measurement of thyroid-stimulating hormone, ferritin, cobalamin, and folate and a complete blood cell count. The findings of

these studies are helpful in identifying medical disorders that can enter into the differential diagnosis of several sleep disorders.

Because of the cost and inconvenience of sleep studies, a clear need exists for cost-effective screening tools for determining which patients are good candidates for more definitive diagnostic testing. In children, careful visualization of tonsillar size has been found highly sensitive and specific as a screening test for obstructive sleep apnea (A. Li et al. 2002). In adults, other factors, the most significant of which is body mass index, confound clinical prediction models that rely solely on the findings of the nasopharyngeal examination. In one large-scale study with a community-based sample, investigators found that in adults, male sex, older age, higher body mass index, greater neck circumference, snoring, and repeated respiratory pauses were all independent correlates of moderate to severe breathing-related sleep disorder (Young et al. 2002b).

## Diagnostic Procedures

Techniques for measuring sleep and body functions during sleep have evolved since the initial description of REM sleep in 1953. Currently, most sleep studies are conducted in facilities using sophisticated computerized equipment that is steadily replacing the older paper-and-ink polygraph units. These recording devices typically monitor and store the multiple physiological measurements considered essential for a polysomnographic study (Table 16–6). Trained technologists attend the patient during the study, making adjustments and assisting as needed. Sleep disorders centers designed for the evaluation and treatment of the full spectrum of sleep disorders are free-standing or located in a hospital. Although there is considerable interest in portable systems with which sleep studies can be performed in the patient's home, these systems are not widely available owing to quality and reimbursement issues.

In some tertiary care hospitals, portable polysomnographic equipment can be deployed to the medical-surgical floor or intensive care unit. In selected cases of a primary sleep disorder coexisting with another process, such as severe chronic obstructive pulmonary disease, identifying and treating the sleep disorder may be necessary before a patient can be stabilized and discharged (Olson 2001). Less research has been conducted on how to screen or test for primary sleep disorders in the patient's home or other settings, such as nursing homes. Sleep diaries can be used but often are inaccurate owing to the patient's poor recall of sleep parameters, lack of adherence to daily documentation, or distorted recall (Mercer et al. 2002).

Use of devices such as wrist actigraphs has been studied in the hospital setting, but these devices are used mostly

**TABLE 16–6. Components of polysomnography**

### Essentials

Electroencephalography (typically three channels)  
 Electromyography (surface)—chin and lower extremity  
 Electro-oculography (two channels)  
 Electrocardiography  
 Respiratory effort measurement  
 Airflow monitoring (nasal pressure or temperature)  
 Pulse oximetry

### Options

Videotaping (conventional or digital) with infrared lighting  
 Transcutaneous carbon dioxide monitoring  
 Esophageal pressure monitoring  
 Esophageal pH monitoring  
 Additional electromyography (upper extremities, intercostal muscles)  
 Additional electroencephalography (seizure detection)

in ambulatory practices (Krahn et al. 1997). Precise determination of sleep-wake status is impossible with actigraphs because the equipment counts limb movements and does not record EEG activity. In addition, specific sleep stages cannot be identified. One distinct advantage of actigraphy, however, is that the compact device can be worn 24 hours per day for 1–4 weeks. This longitudinal monitoring also allows identification of irregular sleep-wake patterns while the patient is living in the community.

Other portable monitoring devices, which do not enable the full complement of measures obtained with polysomnography, have been marketed, but all have limitations. Several models monitor only respiratory function without EEG data. Similarly, overnight pulse oximetry measures only oxygen saturation and heart rate. With this equipment, the clinician does not know heart rhythm, body position, or whether the patient is asleep or awake or in NREM versus REM sleep (Netzer et al. 2001). False-negative results can be obtained from patients with obstructive sleep apnea so severe that they cannot fall asleep. Oxygen saturation looks deceptively normal while patients are lying awake in bed at night. Only after patients fall asleep do they begin to experience significant oxygen desaturation. The setting of the oximeter unit can greatly influence the appearance of the compressed overnight printout and contribute to false-positive and false-negative impressions regarding sleep-related breathing conditions (Davila et al. 2002). The results should specify the time settings. Setting up the equipment to acquire data with briefer time periods—for example, 3 seconds rather than 12 seconds—is preferable in screening for breathing-related sleep disorder.

Portable equipment that does monitor EEG activity is prone to malfunction owing to displacement during sleep if sleep technologists are not available to rectify a faulty signal or respond to the patient's needs. Given the importance of an accurate diagnosis for determining long-term prognosis and sometimes expensive treatments, the cost of a high-quality, reliable, and monitored sleep study, such as polysomnography, in a sleep laboratory is worthwhile for appropriately chosen patients (Reuven et al. 2001). Polysomnography yields the highest diagnostic accuracy and reduces uncertainty in the evaluation of patients with sleep disorders. Continuous videotaping is helpful for assessing possible parasomnias or unusual nocturnal movements. Sleep technologists can record body position and describe snoring intensity.

The multiple sleep latency test is used to identify disorders of excessive daytime sleepiness, including narcolepsy (Krahn et al. 2001). Patients must first undergo an overnight sleep study for exclusion of other sleep disorders caused by disrupted nocturnal sleep. If the patient has had, at minimum, 6 hours of sleep to preclude sleep deprivation, then a valid multiple sleep latency test can be conducted the next day. Patients are asked to take four or five scheduled naps wearing a simplified set of leads including only EEG, electromyographic, and electrooculographic leads. The test is used to measure initial sleep latency and initial REM latency, if present, for each nap. Patients are asked to stay awake between naps, to refrain from stimulants such as caffeine and prescribed medications, and to undergo drug screening for occult sedative use. The maintenance of wakefulness test is a similar procedure with slight modifications. Instead of being asked to fall asleep, patients are asked to stay awake during four specified daytime sessions (Mitler et al. 1982). The data can be used to document that a patient with a treated sleep disorder such as obstructive sleep apnea or narcolepsy can sustain wakefulness sufficiently to drive or operate equipment requiring sustained vigilance. The result of this test is sometimes used as a marker of successful treatment outcome.

## Sleep Disorders

---

Several disorders that are closely tied to sleep or the 24-hour sleep-wake schedule are generally classified as sleep disorders. Many other disease states, such as tumor growth and chemotherapy tolerability, vary according to a 24-hour schedule, but circadian rhythmicity is not the most prominent feature (Mormont and Levi 2003).

## Narcolepsy and Other Disorders of Excessive Daytime Sleepiness

Narcolepsy is a prime example of a disorder with dysfunction of a specific sleep state, in this case REM sleep. Isolated fragments of REM sleep intrude into wakefulness, and the result is the characteristic symptoms that invariably cause excessive daytime sleepiness. Narcolepsy in humans was first described in 1880 by the French neurologist Gelineau (Gelineau 1880). Since that time, this sleep disorder has been observed in several dog breeds as well as in horses and sheep. These naturally occurring animal models have greatly facilitated investigations into the pathophysiological mechanisms of narcolepsy.

### *Prevalence*

Narcolepsy is a more common disorder than many recognize. As a result, the need to identify and treat it offers a valuable opportunity to prevent medical, occupational, and social complications. When patients present with sleepiness, many other conditions, including insufficient sleep and breathing-related sleep disorder, are suspected before narcolepsy is considered. The average delay between onset of symptoms and diagnosis is 10 years.

In a U.S. community sample, narcolepsy was observed to have prevalence of 0.06% (Silber et al. 2001). All cases of narcolepsy met the diagnostic criteria on the basis of excessive daytime sleepiness and laboratory findings. In 64% of these cases the patient had cataplexy. Incidence data from the same study confirmed the long-standing impression that narcolepsy is slightly more common in men (1.72 per 100,000) than women (1.05 per 100,000). The disease most commonly starts in the second decade of life and is a chronic condition.

Narcolepsy is no longer believed to be a familial disease, although a small number of affected families have been identified (Overeem et al. 2001). When narcolepsy is familial, the mode of inheritance is not a simple recessive or dominant one. The debate centers on whether narcolepsy is the result of an autoimmune or neurodegenerative process. The association between 85% of cases of narcolepsy with cataplexy and a specific HLA allele (DQB1\*0602) is the basis of postulation about an autoimmune mechanism; despite several investigations, no confirmatory evidence had been found as of early 2004 (Black et al. 2001). The possibility of the presence of an extremely selective degenerative process stems from the autopsy finding of gliosis in the hypothalamus of narcolepsy patients (Thannickal et al. 2000).

### ***Clinical Features***

Narcolepsy is characterized by chronic excessive daytime sleepiness with episodic sleep attacks. Approximately 65%–75% of patients with narcolepsy have cataplexy, which is a condition in which an emotional trigger, most commonly laughter, provokes abrupt muscle atonia without loss of consciousness. Other associated symptoms of narcolepsy include sleep paralysis (isolated loss of muscle tone associated with REM in normal sleep) and hypnagogic and hypnopompic hallucinations (vivid dreaming occurring at the time of sleep onset and awakening that can be difficult to distinguish from reality). When related to the dissociated components of REM sleep, such as muscle atonia (cataplexy and sleep paralysis) and vivid dreams (hypnagogic and hypnopompic hallucinations), these phenomena can intrude into wakefulness. Disturbed nocturnal sleep has been added as a fifth part of this constellation of symptoms.

### ***Pathophysiological Mechanism***

In 2000, patients with narcolepsy were reported to have undetectable levels of a newly identified neuropeptide, hypocretin (also known as orexin), in cerebrospinal fluid. Hypocretin is synthesized by a small number of neurons in the anterior hypothalamus that project widely throughout the central nervous system (CNS). After studies of other sleep and neurological disorders, the absence of this neuropeptide appears to be highly specific (99%) for narcolepsy (Mignot et al. 2002). Hypocretin influences sleep, appetite, and temperature. As of early 2004, the relevance of hypocretin as a neuromodulator in diseases other than narcolepsy was unknown. The genes for the ligands and receptors for hypocretin have been knocked out in mice with the development of excessive sleepiness, cataplexy, and obesity (Smart and Jerman 2002).

### ***Investigation***

The most important part of an evaluation for narcolepsy is a careful interview conducted as a screen for long-standing excessive daytime sleepiness and spells triggered by emotions. The definitive bedside test for cataplexy is demonstrating the transient absence of deep tendon reflexes during the episode (Krahn et al. 2000). This procedure also aids in differentiating cataplexy from pseudo-cataplexy (Krahn et al. 2001b). However, cataplexy is difficult to provoke, and the episode is often too short-lived to allow a physical examination.

In most cases diagnostic testing in a sleep disorders center is necessary to supplement the clinical interview. The diagnosis must be as certain as possible before a life-

long course of treatment is begun. An overnight sleep study is important for ruling out other causes of excessive daytime sleepiness. This study is ideally preceded by wrist actigraphy to confirm adequate sleep in the weeks before testing and to eliminate sleep deprivation as the cause. If polysomnography reveals that the patient has obstructive sleep apnea or another primary sleep disorder, these conditions must be stabilized before reliable daytime testing can be conducted. The multiple sleep latency test quantifies the time to fall asleep during daytime naps and confirms the presence of inappropriate daytime REM sleep. Testing for hypocretin in the cerebrospinal fluid is not yet part of clinical practice.

### ***Complications***

Narcolepsy is associated with a reduction in quality of life beyond that of epilepsy (Broughton and Broughton 1994). Without treatment, patients are at risk of motor vehicle accidents and occupational injuries related to sleepiness. Patients with narcolepsy have a higher-than-expected rate of obstructive sleep apnea, REM sleep behavior disorder, and periodic limb movements (Krahn et al. 2001a). New data indicate that patients with narcolepsy have higher rates of obesity, which may be linked to the hypocretin deficiency. Current pharmacological treatments for sleepiness do not appear to have a significant mitigating effect on weight gain (Schuld et al. 2002).

### ***Treatment***

Treatment options for narcolepsy include methylphenidate or amphetamines, which target excessive daytime sleepiness (Mitler and Hayduk 2002). More-extended-release preparations of methylphenidate and amphetamines have the advantage of continuous drug delivery, which reduces the daytime variability in alertness that may occur with the immediate-release forms, which are taken twice or three times a day. Modafinil is a unique wake-promoting medication that was approved by the U.S. Food and Drug Administration (FDA) in 1999. Modafinil is not considered a psychostimulant and lacks sympathomimetic activity, and the mechanism of action is not well understood (U.S. Modafinil in Narcolepsy Multicenter Study Group, 1998). The newest treatment option is sodium oxybate (also known as gamma-hydroxybutyrate), which was approved by the FDA in 2002. This novel hypnotic is approved specifically for the treatment of cataplexy. An endogenous substance, sodium oxybate increases the amount of slow wave sleep and improves the continuity of sleep (Lammers et al. 1993). Improving the quality of nocturnal sleep appears to reduce the severity of all of the classic narcolepsy symptoms. Because of the ex-

pense and inconvenience of consuming a liquid medication at sleep onset and 4 hours later, this medication is reserved for patients whose condition is more refractory to treatment. Taken as prescribed, sodium oxybate is well tolerated in general. Risks arise from combining it with other sedative agents and taking it in excessive amounts. Tricyclic antidepressants and, to a lesser degree, selective serotonin reuptake inhibitors (SSRIs) historically have been used to treat cataplexy. These agents increase the level of norepinephrine in the brain and thus suppress REM sleep-related symptoms. Patient education should emphasize the importance of a consistent sleep-wake schedule, the need for adequate sleep, the value of brief daytime naps, and refraining from driving a car when sleepy.

### Idiopathic Hypersomnia

Idiopathic hypersomnia is a disorder of unknown etiology characterized by excessive daytime sleepiness without other specific symptoms. Patients typically have a prolonged duration of nocturnal sleep as well as unrefreshing daytime naps. The prevalence of idiopathic hypersomnia is unknown, but the condition appears to develop at equal rates in both male and female patients. As in narcolepsy, symptoms first appear in adolescence or young adulthood. This condition increases the risk of motor vehicle accidents and occupational or educational problems due to sleepiness. Depression may be another consequence (Bassetti and Aldrich 1997).

The clinical interview should concentrate on the duration of excessive daytime sleepiness, the sleep-wake schedule, and the presence of mood disorders. The presence of a mood disorder complicates the evaluation because both depression and antidepressant medications can alter sleep architecture. The evaluation for idiopathic hypersomnia consists of wrist actigraphy, polysomnography, multiple sleep latency testing, and drug screening. Special attention is paid to respiratory arousals, which can indicate the presence of upper airway resistance syndrome or subclinical sleep-related breathing disorder as the cause of persisting excessive daytime sleepiness. The diagnosis of idiopathic hypersomnia is established on the basis of the finding of quantifiable excessive daytime sleepiness on the multiple sleep latency test. Unlike patients with narcolepsy, those with idiopathic hypersomnia have no sleep-onset REM episodes and have normal levels of hypocretin in the cerebrospinal fluid.

The treatment approach to idiopathic hypersomnia, which includes patient education and medications, is similar to that used for narcolepsy. Daytime naps are not encouraged because they are not refreshing, as they are for patients with narcolepsy. Once sleep tests are completed,

use of an antidepressant is appropriate and does not cause problems if the results at evaluation suggest the presence of a coexisting mood disorder.

Kleine-Levin syndrome, also known as recurrent hypersomnia, is an important part of the differential diagnosis of idiopathic hypersomnia. Patients with recurrent hypersomnia are generally male adolescents who engage in binge eating and have periodic hypersomnia that lasts several weeks (Minvielle 2000).

### Parasomnias

Parasomnias are disorders in which patients have inappropriate intermittent motor behaviors during sleep. REM sleep behavior disorder is arguably of most interest because of the relationship with other neurological conditions. Patients with REM sleep behavior disorder appear to “act out their dreams” by yelling or gesturing during REM sleep. They lack the muscle atonia normally found in REM sleep and move in response to dream imagery. REM sleep behavior disorder appears more common than originally suspected, although the prevalence has not been established. Risk factors for this sleep disorder are male sex (90% of patients described in the literature) and advanced age (most patients have been 50 years or older) (Olson et al. 2000). SSRIs and venlafaxine have been suggested as possible triggers. Patients and their bed partners can be seriously injured by hitting, kicking, rolling, and other more complex behaviors. REM sleep behavior disorder is associated with several neurological disorders, including Parkinson's disease (15%–33% of patients), multiple system atrophy (69%–90%), and dementia with Lewy bodies (prevalence of REM sleep behavior disorder unknown) (Comella et al. 1998; Plazzi et al. 1997). These neurodegenerative disorders share the pathological finding of cerebral intracellular inclusion bodies containing alpha-synuclein.

Polysomnography with extra electromyographic leads and synchronized videotaping can be useful for documenting increased electromyographic tone during REM sleep. Some patients have an inappropriate degree of muscle tone without reports of disruptive or inappropriate behaviors. These patients are not yet considered to have REM sleep behavior disorder, but the disease may evolve. Polysomnography also helps identify complicating disorders, such as obstructive sleep apnea, which is of particular importance if benzodiazepines are used later. Nocturnal seizures should be excluded from the diagnosis. Treatment includes modifying the bedroom to reduce injury to the patient and bed partner. Bed partners often choose to sleep apart. Clonazepam has become the medication of choice because it reduces the muscle movement that occurs during REM sleep, reducing the risk of injury (Schenck and Mahowald 1990).

NREM parasomnias, unlike REM sleep behavior disorder, are markedly more common in children and adolescents than in adults. Patients act unusually, walk, or eat when not fully alert. Polysomnography is not always needed because the behaviors are often intermittent and therefore difficult to observe with a single night of monitoring. Sleep deprivation, shifting bedtimes, and consumption of alcohol can precipitate episodes in susceptible individuals. In one study sleep deprivation was used as a trigger of sleepwalking. The intriguing results indicated that this test may be a means of confirming the diagnosis or increasing the likelihood that an episode will occur during polysomnography (Joncas et al. 2002).

Treatment of NREM parasomnias includes modifying the sleeping environment to promote safety, a consistent sleep schedule, and, if warranted, medications such as hypnotics to prevent arousal (Mahowald and Schenck 1996). The relationship between parasomnias and post-traumatic stress disorder is unclear and merits further study.

Nocturnal panic disorder is increasingly regarded as a rare disorder. However, panic disorder with attacks occurring both during the day and at night is not rare. Treatment of this condition ideally includes a combination of medications and behavioral measures. When panic or anxiety exists exclusively at night, most typically in NREM sleep, a broad differential diagnosis should be used to screen for breathing-related sleep disorder, nightmares, and medical disorders (e.g., arrhythmia, angina, and gastroesophageal reflux) triggering the anxiety. Confirmed treatment of nocturnal panic disorder relies on medications because behavioral measures are less feasible when an attack develops while the patient sleeps. Hypnosis at bedtime has been tried (Hauri et al. 1989).

Whenever a patient presents with unusual behavior at night, the differential diagnosis must include epilepsy. In particular, seizures arising from a locus in the frontal lobe can result in stereotypical but bizarre events during slow wave sleep (Dyken et al. 2001).

## Sleep-Related Breathing Disorder and Snoring

Sleep-related breathing disorder comprises obstructive sleep apnea, central sleep apnea, and obesity hypoventilation syndrome. Obstructive sleep apnea is the most notable of these conditions because of its high prevalence and association with numerous medical conditions if untreated (Walker 2001). Obstructive apnea is defined as cessation of airflow that lasts at least 10 seconds owing to impedance of respiratory effort as the result of airway obstruction. Hypopnea is defined as reduction in airflow resulting in at

least a 4% decrease in oxygen saturation. Table 16–7 outlines the diagnostic criteria for obstructive sleep apnea. Apnea and hypopnea both are considered clinically significant markers of disease and as a result are reported together as the apnea–hypopnea index. Since these criteria were published, sleep specialists have recognized that hypopnea with an oxygen desaturation greater than or equal to 4% must be quantified in addition to pure apnea.

### Prevalence

Patients with obstructive sleep apnea are the largest subgroup of patients referred to sleep disorders centers. This disorder, which affects at least 2% of women and 4% of men ages 30–60 years (Young et al. 1993), is strongly associated with obesity. Obstructive sleep apnea is more common without marked obesity in several racial groups, including Asians, in whom craniofacial anatomic features can produce a narrower nasopharyngeal airway (K. Li et al. 2000). Advanced age, male sex, and postmenopausal state are all associated with a higher prevalence of this condition (Young et al. 2002a). In subpopulations of patients with hypertension, heart disease, and adult-onset diabetes mellitus, as many as 30%–40% of patients can have obstructive sleep apnea (Partinen 1995).

---

**TABLE 16–7. American Academy of Sleep Medicine diagnostic criteria for obstructive sleep apnea**

---

#### Essential signs and symptoms

1. Excessive daytime sleepiness
2. Obstructed breathing during sleep

#### Essential polysomnographic findings

1. More than five episodes of apnea (>10 seconds) per hour of sleep with evidence of respiratory muscle effort and one of the following:
    - a. Apnea causing frequent arousals
    - b. Apnea causing oxygen desaturation  $\geq 4\%$
    - c. Bradycardia
- 

Source. Adapted from American Academy of Sleep Medicine 1997.

### Clinical Features

Most patients with obstructive sleep apnea snore. Family members may observe disruptive snoring intermixed with quiet periods and reduced respiration. Although essentially all patients with obstructive sleep apnea snore, the reverse is not the case. Snoring is an extremely common phenomenon in the community, affecting 25% of men and 15% of women. For this reason, screening for obstructive sleep apnea must rely on more than simply a history of snoring. Patients may have restless sleep at times,

to the point they are believed to have a parasomnia such as REM sleep behavior disorder. Excessive sweating and morning headaches can be present. Patients may report choking or being awakened by their snoring. An increased rate of nocturia has been described, possibly because the patient is more aware of bladder fullness when awakened by the breathing disorder (Pressman et al. 1996). Obstructive apnea can lead to respiratory arousals and oxygen desaturation, which can cause transient elevations in blood pressure initially at night (Dart et al. 2003). Hypertension is common, especially in patients with severe obstructive sleep apnea. Initially, blood pressure increases follow each obstructive event, but if apneic or hypopneic episodes are frequent, blood pressure can remain elevated throughout the night and day. Pulmonary hypertension also has been an associated finding, particularly with severe obstructive sleep apnea.

The hemodynamic alterations of obstructive sleep apnea include systemic hypertension, increased right and left ventricular afterload, and increased cardiac output. Earlier reports attributed the association between obstructive sleep apnea and cardiovascular disease to the common risk factors such as age, sex, and obesity. However, newer epidemiological data confirm an independent association between obstructive sleep apnea and these cardiovascular diseases. Possible mechanisms include a combination of intermittent hypoxia and hypercapnia, repeated arousals, sustained increase in sympathetic tone, increased platelet aggregation, reduced baroreflex sensitivity, and elevated plasma fibrinogen and homocysteine levels (Bananian et al. 2002).

### ***Pathophysiological Mechanism***

Patients with obstructive sleep apnea experience intermittent compromise of the upper airway. The most common site of obstruction is the pharynx, a hollow tube that collapses during swallowing and speech. The pharyngeal musculature serves to keep the upper airway open and opposes the subatmospheric pressure in the pharynx itself. The genioglossus muscles also pull forward to keep the upper airway clear of obstruction. This balance is further influenced by anatomic structures (adipose tissue, tongue size, mandibular length, soft palate, and tonsils) and neuromuscular mechanisms (activity of the pharyngeal muscles affected by sleep state, muscle relaxant, and hypnotic medications) (Rama et al. 2002). The obstructed upper airway leads to cessation or reduction of airflow that results in the finding of an arousal on the EEG tracing. Some patients have marked respiratory arousals without actual apnea or partial apnea (hypopnea). Snoring or increased effort to ventilate due to narrowing but not full

collapse of the airway is called *upper airway resistance syndrome*, a potentially distressing but subclinical form of obstructive sleep apnea that occurs more often in women than in men (Guilleminault et al. 2001).

### ***Diagnostic Testing***

Results of polysomnography conducted in a sleep disorders center are the standard of reference for the diagnosis of breathing-related sleep disorder (Bresnitz et al. 1994). Other screening techniques, such as overnight pulse oximetry and use of portable devices, have not been demonstrated to be cost-effective, reliable, or sufficiently sensitive. Many centers use “split-night” sleep studies, often in response to reimbursement issues. Under these circumstances, patients are observed for at least 2 hours while they are sleeping, ideally experiencing both NREM and REM sleep in both the supine and nonsupine positions. Once a diagnosis of breathing-related sleep disorder is established, the technologist introduces treatments such as nasal continuous positive airway pressure (CPAP). Nasal CPAP is applied through a nasal mask connected to a blower that can be adjusted so that pressurized air is delivered to the upper airway. Having positive pressure keep open the airway is particularly important during expiration, when the airway most commonly collapses in patients with obstructive sleep apnea. The nasal CPAP pressure setting can be carefully titrated in response to airway narrowing during the rest of the sleep study. In the morning, the patient can be asked about comfort and acceptance of this therapy. A split-night study is an opportunity for clinician and patient to compare the untreated versus the newly treated state. The procedure is controversial because of the limited time available for both the diagnostic study and the treatment trial. In most cases, a split-night study eliminates the need for a second night in the laboratory (Strollo et al. 1996).

### ***Complications***

The complications of obstructive sleep apnea lead to significant morbidity and mortality. Risk factors for obstructive sleep apnea (see section “Evaluating Sleep” earlier in this chapter) are male sex, older age, high body mass index, greater neck circumference, snoring, and observed pauses in breathing at night (Young et al. 2002b). Untreated obstructive sleep apnea has been associated with systemic hypertension, right-sided heart failure, and cerebrovascular accidents (Dyken et al. 1996). The excessive daytime sleepiness that can result from untreated obstructive sleep apnea can put patients at risk of motor vehicle accidents, cognitive problems, and interpersonal difficulties. An association once was found between ob-

structive sleep apnea and gastroesophageal reflux; however, more recent work indicated that one condition does not appear to cause the other. Nevertheless, treatment with antireflux medication reduces arousals but not apneic episodes, and intervention for obstructive sleep apnea with nasal CPAP does reduce reflux (Ing et al. 2000).

### **Treatment**

Since the early 1980s, the treatment of obstructive sleep apnea has been revolutionized by the use of nasal CPAP. This treatment involves delivering pressurized air (typically 3–18 cm of water pressure) to sites of upper airway collapse (generally the oropharynx and less commonly the nasopharynx) and forcing the airway open. Apnea and snoring are eliminated, allowing the patient to sleep continuously without being aroused to breathe. Nasal CPAP is generally introduced when the patient is sleeping in the sleep laboratory, where staff can adjust the pressure appropriately and assist with mask fit. Newer technology entails the use of self-titrating devices that modify the pressure setting breath by breath without requiring technologist involvement (Berry et al. 2002). The extent to which these more sophisticated machines may replace nasal CPAP titrations conducted in a sleep laboratory is not clear.

Patients with severe obstructive sleep apnea often report marked improvement, within days, in their mood and energy. This improvement is positive reinforcement that leads to good compliance with nasal CPAP treatment (Sullivan and Grunstein 1994). Patients with mild to moderate obstructive sleep apnea have more adherence problems, the compliance rate being estimated at 10%–50%. Even patients who use this device nightly typically use it for only several hours (Clark et al. 1996).

Patients with obstructive sleep apnea who consume alcohol close to bedtime pose a challenge, because alcohol has been observed to decrease the neuromuscular tone of the upper airway. These patients often need higher nasal CPAP settings to prevent apnea. In addition, if the sleep study is done when the patient has not been consuming alcohol often, the selected pressure settings are insufficient on nights when the patient has ingested alcohol (Berry et al. 1991). Certain medications, especially long-acting benzodiazepines, can exert a similar effect and can depress the reticular activating system to reduce the arousal threshold and prevent arousals that effectively interrupt prolonged episodes of apnea (Dolly and Block 1982).

Another treatment of obstructive sleep apnea is bilevel positive airway pressure. This therapy represents a modification of CPAP whereby the positive pressure fluctuates depending on whether the airflow is inspiratory or expiratory. Bilevel pressure therapy is considerably more ex-

pensive than conventional CPAP and is reserved for patients who cannot tolerate CPAP because of discomfort or emergence of central apnea at necessary pressure settings. Supplemental oxygen alone is inadequate for obstructive sleep apnea because the oxygen cannot pass the obstruction to reach the lungs. Patients with both breathing-related sleep disorder and intrinsic lung disease who have persistent hypoxia despite CPAP can benefit from supplemental oxygen delivered through the nasal CPAP mask.

For patients who have apnea only in the supine position, effective treatment may include having them use a device such as a T-shirt with an attached cloth tube of tennis balls (George et al. 1988). This soft lump keeps patients from lying on their backs. Inflatable devices resembling backpacks can serve the same purpose. Few data are available regarding long-term adherence with these practical interventions. Some patients who refuse CPAP and have severe apnea during REM sleep have been offered a REM-suppressant medication such as a monoamine oxidase inhibitor. No published data are available regarding this practice. Abrupt discontinuation of the pharmacological agent should be avoided because of REM rebound, which can increase the risk of apnea.

Weight loss through diet and exercise is an important component of the treatment plan for any overweight patient with breathing-related sleep disorder (Flemons 2002). Motivated patients can succeed. Weight loss should be primary treatment only of patients with mild to moderate disease, particularly if they are not interested in other modalities. Gastric bypass surgery can be especially important for management of medically complicated obesity (see Chapter 30, "Surgery"). In general, a 10-pound weight loss can reduce the required CPAP pressure; however, many patients eventually seem to gain rather than lose weight with the result that CPAP pressure needs to be increased.

Patients with abnormalities of the soft tissue or skeletal structures surrounding the upper airway may consider surgery. Surgical procedures include laser-assisted uvulopalatopharyngoplasty, tonsillectomy, mandibular advancement, and tracheostomy (Littner et al. 2001; Lojander et al. 1996). Patients must be carefully selected. They must have upper airway obstructions that are resectable, for example, large tonsils, and have no other comorbid conditions, such as an elevated body mass index that compromises upper airway patency at multiple points.

There have been promising results with oral appliances that pull the tongue or mandible forward (Clark et al. 1996). Hypnotic agents may be used to treat patients with obstructive sleep apnea, particularly if adherence to nasal CPAP is suboptimal because of discomfort causing

insomnia. Medications such as zolpidem and zaleplon have been well tolerated. Benzodiazepines should be used cautiously in the care of patients with obstructive sleep apnea. These agents may prevent a patient from arousing during an episode of apnea and taking a compensatory breath. Some clinicians fear that if patients using benzodiazepines remove the nasal CPAP mask, they may experience longer apnea because they are not aroused when hypoxia develops. Furthermore, nightly use of benzodiazepines may decrease the amount of slow wave sleep and lead to physical dependence.

### Central Sleep Apnea and Obesity Hypoventilation

Central sleep apnea and obesity hypoventilation are two additional breathing-related sleep disorders of interest. Central sleep apnea is more likely to be asymptomatic than is obstructive sleep apnea, given that it is less likely to be associated with sleep disruption. Because the patient's airway is not narrowed and vibrating, snoring is not a warning sign. Patients often present with insomnia rather than excessive daytime sleepiness. Patients with central sleep apnea are often older and have associated cardiac or cerebrovascular disease. Central sleep apnea can be differentiated from obstructive sleep apnea by the absence of snoring, this differentiation being confirmed by the presence of polysomnographic features of the apnea (Quaranta et al. 1997). Treatment can include a hypnotic agent to decrease arousals or supplemental oxygen to reduce hypoxia (Guilleminault and Robinson 1998). When central apnea and obstructive sleep apnea coexist, treatment may include CPAP or bilevel positive airway pressure therapy.

In some patients with marked obesity, obstructive sleep apnea with repetitive desaturation is occasionally absent, but patients still have a sleep-related breathing condition. Particularly during REM sleep, when muscle atonia affects all muscles but the diaphragm, patients may be unable to properly ventilate because of the difficulty in expanding their lungs owing to their body mass. In obesity hypoventilation, polysomnography shows persisting oxygen desaturation without the fluctuating cessation of airflow and oxygen desaturation that occur in obstructive sleep apnea. Arterial blood gas panels typically reveal hypercapnia (Kessler et al. 2002). Obese patients commonly have both obesity hypoventilation and obstructive sleep apnea, in which case CPAP is indicated. Other treatment options include weight loss, avoiding any factor that may aggravate hypoventilation (e.g., discontinuing sedatives), CPAP with supplemental oxygen, and bilevel positive airway pressure therapy.

### Restless Legs Syndrome and Periodic Limb Movements

Patients with restless legs syndrome describe subjective discomfort of the lower extremities that worsens at night. Patients can have an irresistible need to move their legs in bed or during prolonged periods of sedentary activity, such as airplane flights. This condition was first described by Ekbom in 1945. As a result of these distressing symptoms, patients can experience insomnia or have unrefreshing sleep.

#### *Prevalence*

Restless legs syndrome is often unrecognized but is far from rare. For years, all data about this condition were collected in clinical settings and the prevalence in community samples was essentially unknown. A community-based survey showed a prevalence of restless legs syndrome of 3% in respondents ages 18–29 years, 10% in those ages 30–79 years, and 19% in those age 80 years and older. The overall prevalence was 10% with equal rates for male and female respondents. In the study, risk factors for restless legs syndrome were identified as greater age and high body mass index as well as nicotine dependence, diabetes mellitus, and lack of exercise (Phillips et al. 2000). Another survey of community-dwelling adults in five European countries had slightly different findings. The prevalence of restless legs syndrome according to the criteria of the International Classification of Sleep Disorders (Table 16–8) was 5.5% and associated with older age, female sex, musculoskeletal disease, hypertension, use of an SSRI, and engaging in physical activities close to bedtime (Ohayon and Roth 2002).

Restless legs syndrome sometimes occurs in association with anemia and iron deficiency. The condition can develop during the third trimester of pregnancy, likely because of the presence of functional anemia (Allen and Earley 2001a). Case reports have shown that patients with restless legs syndrome who donate blood may have an exacerbation of the condition, which warrants more medication. Patients with restless legs syndrome should care-

---

**TABLE 16–8. Clinical characteristics of restless legs syndrome**

---

Desire to move the limbs because of subjective discomfort
Motor restlessness
Symptoms worse or exclusively associated with sedentary activities
Symptoms at least partially relieved by activity
Symptoms worse in the evening or night

---

fully consider the condition a risk of donating blood (Silber and Richardson 2003).

Restless legs syndrome is known to be secondary to diabetes, peripheral neuropathy, and uremia; 20%–30% of patients with renal failure experience restless legs syndrome (Winkelmann et al. 1996). Familial occurrence of restless legs syndrome has been described. In several large families, an autosomal dominant mode of inheritance has been observed. In a large French Canadian kindred, restless legs syndrome was mapped to chromosome 12q (Desautels et al. 2001). In familial restless legs syndrome, the disorder can have a childhood onset.

### *Clinical Features*

Periodic limb movement disorder is a condition that frequently overlaps with restless legs syndrome. Approximately 80% of patients with restless legs syndrome have intermittent muscle twitches called periodic limb movements (Montplaisir et al. 1997). These movements are involuntary leg jerks that occur at night. They can cause insomnia and, as a result, excessive daytime sleepiness. Almost all patients with restless legs syndrome have periodic limb movements, but many patients with periodic limb movements have no symptoms (Chaudhuri et al. 2001). The periodic limb movements can affect a variety of muscles in the legs or arms. Periodic limb movements in the absence of subjective symptoms of restlessness are of uncertain clinical significance (Nicolas et al. 1999).

Periodic limb movements must be differentiated from nocturnal leg cramps, which are extremely painful sustained muscle contractions, particularly involving the gastrocnemius and soleus muscles. Predisposing factors include pregnancy, diabetes mellitus, electrolyte disturbances, and prior vigorous exercise. Nocturnal leg cramps are not periodic and usually occur, at most, several times a night. The differential diagnosis of restless legs syndrome and periodic limb movement disorder includes neuropathic pain, arthritis, restless insomnia, and drug-induced akathisia.

### *Complications*

Patients with restless legs syndrome experience irritability, depressed mood, or cognitive disturbance due to disturbed sleep; headache, especially on awakening; depressed mood; social isolation; and reduced libido (Ulfberg et al. 2001).

### *Pathophysiological Mechanism*

Restless legs syndrome is believed to be a condition associated with decreased dopamine levels. Treatment with dopamine antagonists aggravates the symptoms, and this

syndrome occurs with increased frequency in Parkinson's disease. Positron emission tomographic studies of restless legs syndrome have shown decreased dopaminergic functioning in the caudate and putamen regions of the brain (Ruottinen et al. 2000). Treatment with dopaminergic agonists, even low doses, leads to marked improvement. Restless legs syndrome has been strongly associated with anemia. Deficient iron stores appear to play a role in the pathophysiological mechanism because iron is hypothesized to be a cofactor for tyrosine hydroxylase, the enzyme for the rate-limiting step in the synthesis of dopamine (Earley et al. 2000).

### *Diagnostic Testing*

A rating scale for restless legs syndrome has facilitated diagnosis (Allen and Earley, 2001b). Attempts to develop a self-administered screening survey for restless legs syndrome in dialysis populations have been less successful because of low specificity and a high false-positive rate (Cirignotta et al. 2002).

An overnight sleep study is not essential, because the diagnosis of restless legs syndrome can be based on the patient's history. Polysomnography is valuable when a patient may have a coexisting sleep disorder, such as obstructive sleep apnea, or if the patient does not respond to treatment of restless legs syndrome diagnosed on the basis of history alone. Useful laboratory tests include complete blood count to assess for anemia and ferritin, especially when levels are less than 50 µg/L.

### *Treatment*

Treatment of restless legs syndrome is primarily with dopaminergic medications. Direct dopamine receptor agonists, such as pramipexole, have become first-line agents (Comella 2002). These drugs have replaced low-dose, controlled-release carbidopa and levodopa because of a lower incidence of side effects and improved efficacy. There have been encouraging reports about the benefits of gabapentin (Garcia-Borreguero et al. 2002). Long-acting benzodiazepines, such as clonazepam, and opioids, including codeine and methadone, also have been used. Medications that can lead to physical dependence require careful monitoring for tolerance. As a result, these drugs are not preferred treatment choices. Most clinicians use drug treatment of restless legs syndrome. Nonpharmacological options include physical therapy.

### *Insomnia*

As outlined in Table 16–4, insomnia can be caused by a variety of medical, neurological, psychiatric, and environ-

mental conditions. If possible, any factors that cause or exacerbate insomnia, such as gastric regurgitation, should be corrected (Konermann et al. 2002; Ohayon and Roth 2003). However, many patients have no specific triggers of insomnia, and insomnia is not a symptom of an underlying disorder.

Patients with the classic type of, or psychophysiological (conditioned), insomnia learn to associate sleeplessness with certain circumstances, such as their own bedrooms. These patients become progressively more tense as bedtime approaches. The prevalence of this condition is unknown. Polysomnography is not generally useful in establishing the diagnosis. Sometimes a patient's best sleep in years occurs in the unfamiliar setting of the sleep disorders center (Chesson et al. 2000).

### **Treatment**

Treatment of insomnia includes improvement in sleep hygiene with the techniques listed in Table 16–9; behavioral techniques, such as relaxation strategies including tapes, self-hypnosis, and music; and occasional doses of hypnotic medication (Toney and Ereshefsky 2000).

More medications are now available that were specifically developed as hypnotics. The newer nonbenzodiazepine hypnotics zolpidem and zaleplon have a short half-life that reduces the morning hangover effect. Patients have been shown to have alertness adequate for driving and other activities that require sustained vigilance (Richardson et al. 2001). Physical dependence has not been reported with the short-term use approved by the FDA. Benzodiazepines, although less expensive than nonbenzodiazepine hypnotics, can cause dependence and alter cognition the morning after use. Several antidepressants with prominent sedative side effects, such as mirtazapine and trazodone, are valuable therapeutic options, especially if the patient has a coexisting mood or anxiety disorder. Mirtazapine has prominent antihistaminergic side effects at doses of 15 mg or less; however, undesirable weight gain can occur (Artigas et al. 2002). Because of cardiac and anticholinergic side effects, tricyclic antidepressants should seldom be used expressly for insomnia. Antihistamines such as diphenhydramine are generally a poor choice because they quickly lose effectiveness and can exacerbate confusion in the medically ill. Hypnotic medications have an important role in the management of short-term or intermittent insomnia, but most sleep specialists prefer a meaningful trial of nonpharmacological interventions in the care of patients with the chronic form of primary insomnia. The intent is to alter the thoughts and behaviors that lead to the development of poor-quality nocturnal sleep.

---

**TABLE 16–9. Sleep hygiene**

---

#### **Circadian issues**

Avoid daytime naps  
 Limit time in bed to 8 hours  
 Get daily exercise, preferably finishing at least 4 hours before bedtime  
 Keep regular sleep–wake cycle 7 days per week  
 Avoid bright light in the evening or at night  
 Seek bright light in the morning

#### **Reducing sleep disruption**

Avoid large quantities of fluids in the evening  
 Minimize caffeine; a hot drink without caffeine may be beneficial  
 Avoid alcoholic drinks  
 Keep the bedroom quiet, dark, and at a comfortable temperature  
 Develop a relaxing bedtime ritual  
 Avoid worrying in bed by using tools such as list writing during the day  
 Manage stress optimally during the day  
 Do not use the bed and bedroom except for sleep and for sexual activity  
 Get assistance with pets and children  
 Avoid large meals soon before bedtime  
 Pursue medical intervention for problems such as gastroesophageal reflux, pain, and nausea

---

More specific behavioral studies have produced basic information about sleep habits that can be helpful to patients who have disturbed sleep. These sleep hygiene factors have been found to have particular efficacy in the care of patients with chronic insomnia. Establishing a regular waking time 7 days a week optimizes biological rhythms. This regimen is particularly helpful for patients who need to keep morning commitments but tend to naturally be “night owls” or have problems falling asleep at the needed bedtime. However, the clock tends to drift rapidly back to the old schedule as soon as there is variability in arising time (Brown et al. 2002). Discipline and consistency are important.

When regular exercise is an option, exercising in the late afternoon several hours before bedtime may improve sleep. One postulated mechanism is that a decrease in body temperature is associated with sleep, and body temperature decreases approximately 4 hours after exercise (Montgomery and Dennis 2002). Avoiding “clock watching” can help reduce the arousal effects of becoming annoyed when tracking the slow passage of time throughout the night. Most people recall only periods of wakefulness at night, so clock watching can reinforce the perception that no sleep has occurred. Patients should avoid alcohol, nonprescribed sedatives, and stimulants, including nicotine and caffeine at any time during the day. Patients, par-

ticularly patients prone to gastroesophageal reflux, should not sleep on a full stomach. Introducing relaxing routines around bedtime can be helpful to many patients with sleep complaints. Treating gastroesophageal reflux with antacids and histamine<sub>2</sub>-blocking medication before sleep can be beneficial.

More specific behavioral evaluation may lead to suggestions that a patient learn relaxation techniques or develop stress management strategies (Morin et al. 1999). Psychotherapy can be helpful for sleep-related anxiety. One of the techniques recommended to those who find that they spend inordinate amounts of time worrying when awake at night is called “worry time” or “thinking time.” This technique entails the recommendation that patients take 15–30 minutes in the late afternoon or early evening (not near sleep onset) during which there is time to devote attention to worries. Patients are expected to use this time to list their concerns and then identify which they may be able to have some control over and which they do not. When patients awaken at night and begin to worry about a “new” problem, this worry is added to the list, to be included in the next day’s session. Eventually the energy and time spent worrying at night diminish, and wakefulness is not perpetuated by anxious thought content (Hauri and Esther 1990).

Stimulus control techniques have been used to help patients with psychophysiological, or conditioned, insomnia (Bootzin and Perlis 1992). These patients find they are sleepy near bedtime, but as soon as they enter the sleeping environment, they become aroused and unable to sleep. This conditioned association between sleeplessness and the bedroom may need to be interrupted by instructing patients to avoid “trying to sleep.” Patients who find they are hyperaroused while lying in bed should not try to sleep. They are advised instead to get up and go to a different setting and engage in a different activity (e.g., reading a book, watch relaxing television, or listening to music) until they become sleepy again and return to bed. They should repeat this process as often and as long as needed to extinguish the arousal state conditioned to the bedroom. Some patients find that rather than getting out of bed or leaving the bedroom, they can achieve the same results by watching a monotonous videotape in the bedroom with the VCR set to turn off automatically (Pallesen et al. 2003).

For patients with severe persistent insomnia, a sleep restriction management method may be helpful. In this modality, patients are instructed to allow no more hours in bed than they estimated they slept the previous night. Initially this period may be considerably less than 7.5 hours. When they are able to sleep for essentially all the time in bed for several nights, patients are advised to increase their time in bed by half-hour increments until

they achieve optimal sleep time and sleep efficiency. Although pharmacological and behavioral treatments are effective for insomnia management over the initial weeks of treatment, results of a randomized, controlled trial of these treatments in the care of elderly patients suggested that behavioral treatment was associated with more sustained improvement than was pharmacological therapy (Morin et al. 1999). Other findings suggested that, if possible, behavioral techniques ought to be tried without concomitant hypnotic medications because patients taking hypnotics appeared not to have as good an outcome as those who did not take the drugs (Hauri 1997). The availability of medication may reduce patients’ motivation and confidence in behavioral techniques.

### Sleep State Misperception

Sleep state misperception is a rare type of primary insomnia. Patients with this disorder report subjective sleep disturbance that is not consistent with objective data. For the criteria for this diagnosis to be met, polysomnography must demonstrate normal duration and quality of sleep (American Academy of Sleep Medicine 1997). As the understanding of sleep increases, specific sleep disorders may eventually be diagnosed in some of these patients. Treatment involves discussing with the patient the discrepancy between subjective and objective data. Behavioral techniques and hypnotic medications have been used successfully in this group of patients.

### Medications and Sleep

---

Any substance that crosses the blood-brain barrier will very likely have an effect on CNS receptors that affect sleep and wakefulness. Essentially all drugs that have been studied have been found to have such effects, and many that have not been studied are known by clinicians to influence sleep and wakefulness. Growing understanding of the physiological mechanisms of normal and abnormal sleep indicates that in addition to the classically understood brainstem sleep influences, the hypothalamus is a key center for sleep regulation. Sleep mechanisms were thought to be predominantly due to the interactions of acetylcholine, dopamine, serotonin, and norepinephrine primarily within the brainstem. More recent research findings indicated that the hypothalamic neurotransmitters adenosine, dopamine, gamma-aminobutyric acid (GABA), histamine, and hypocretin also play an important role in the physiological mechanisms of sleep. The latest observations suggest that connections between the thalamus (cortical activation, sleep spindle formation, and

EEG synchronization), hypothalamus (sleep–wake switch), suprachiasmatic nucleus (circadian clock), and the brain stem (ascending cortical activation and REM sleep–wake switch) organize circadian, ultradian, and intrinsic sleep function (Mignot et al. 2002).

Some CNS substances primarily affect the circadian pacemaker system, which is controlled by the suprachiasmatic nucleus (arginine-vasopressin, GABA, melatonin, gastrin-releasing peptide, neuropeptide Y, peptide histidine isoleucine, vasoactive intestinal peptide, glutamate, pancreatic polypeptide, and corticosteroids). Other substances affect intrinsic sleep parameters, such as sleep latency, awakenings, percentage of various stages of sleep, nocturnal wakefulness, and evidence of sleep interruptions manifested primarily at a sleep EEG study. Many drugs have known effects on primary sleep disorders such as restless legs syndrome, obstructive sleep apnea, and insomnia from many causes. The known effects of drugs on sleep are summarized in Table 16–10 (Armitage 2000; Dietrich 1997; Gursky and Krahn 2000; Nicholson 1994; Nicholson et al. 1994; Novak and Shapiro 1997; Obermeyer and Benca 1996; Parrino and Terzano 1996; Pascoe 1994; Placidi et al. 2000; Winokur et al. 2001).

Few drugs have unadulterated beneficial effects on sleep, and effects on healthy study subjects and on patients may not coincide. Rather than assume that these various factors are too complex to be useful in the psychiatric care of a medically ill patient, the consultation psychiatrist can learn the few basic groups of drugs with empirically demonstrated significant effects on sleep (see Table 16–11 for summary of hypnotic effects). Combining this information with knowledge of the physiological mechanisms of sleep will allow the clinician to logically infer the effects of most other drugs on sleep.

The following are general rules about drugs that can help in application of sleep knowledge to patient care.

1. Most CNS drugs decrease slow wave and REM sleep, at least acutely. It is reasonable to learn the relatively short list of drugs known to increase REM sleep and assume that others will suppress or disrupt normal REM sleep function. The medications that increase REM sleep are reserpine, yohimbine (and other alpha-antagonists), and physostigmine (and other cholinomimetic drugs, perhaps including cholinesterase inhibitors such as donepezil) (Slatkin et al. 2001).
2. Many drugs cause daytime sedation. It is reasonable to learn the short list of drugs that cause increased daytime alertness and perhaps anxiety as well (psychostimulants, modafinil, and caffeine) and to presume that most others will either be neutral or negative toward daytime alertness.
3. Stopping drugs suddenly commonly produces adverse effects. The entity suppressed will likely rebound. Thus stopping drugs that suppress REM sleep (most CNS agents) will often lead to REM sleep rebound, which can be associated with insomnia, nightmares, and even hallucinations.
4. Stopping drugs that stimulate the CNS (and have depleted or displaced stimulating neurotransmitters) can lead to temporary depression. This effect is surprisingly uncommon even in patients who have taken high doses of stimulants for a long time. Depression and decreased alertness are common but usually are transient.
5. Many drugs continue their activity on sleep and wakefulness far beyond the intended therapeutic time. Many medications used to promote sleep are associated with some “hangover” experience the next day. The few exceptions are drugs with an ultrashort half-life, such as zaleplon (definitely demonstrated) and perhaps triazolam and zolpidem (less clearly demonstrated) (see Table 16–11).
6. Alternative therapies and herbal preparations may be helpful. Although effort similar to FDA efficacy and safety guidelines is increasingly being put into examining alternative therapies and herbal preparations, little definitive information is available. Many of these agents are pharmacologically active in the CNS, and many have interactions with prescribed medications.

## Herbal Agents

Aside from the likelihood that herbal preparations may be contaminated with unknown substances (e.g., anti-inflammatory agents, steroids, diuretics, antihistamines, tranquilizers, hormones, and heavy metals), more information is becoming available about potential adverse effects of herbal preparations taken as sleep aids, as daytime stimulants, and for other purposes. A review of complementary therapies from an Eastern perspective describes in detail an extensive list of Chinese herbal treatments and their potential toxicities (Cheng 2000). A number of authors have reviewed the safety of complementary therapies as they apply to the practice of emergency medicine (Nelson and Perrone 2000) and oncology (Markman 2002). Melatonin, 5-hydroxytryptamine, catnip, chamomile, gotu kola, hops, L-tryptophan, lavender, passionflower, skullcap, and valerian are agents that have been used to manage sleep disorders (Cauffield and Forbes 1999). The toxicities of herbal substances most commonly used for sedative or stimulant purposes among consultation-liaison populations are shown in Table 16–12 (Crone and Wise 1998).

Yohimbine bark ( <i>Pausinystalia yohimbine</i> or <i>Corynanthe yohimbe</i> )	Hallucinations and anxiety, hypertension and tachycardia, and nausea and vomiting

## Melatonin

Because melatonin is readily available and patients commonly self-administer it, a brief review of this agent is pertinent. Melatonin is sold over the counter in airports, health food stores, and other venues and is widely used to manage jet lag and insomnia in general. This agent is also being used as an antioxidant. The safety and efficacy of health-food-store melatonin have been studied formally in only a limited way. In one analysis of three commercially prepared over-the-counter melatonin preparations, investigators found several contaminants in each preparation. The substances found included structural analogues of contaminants found in preparations of L-tryptophan that had been associated with eosinophilia-myalgia syndrome (Williamson et al. 1997). Other evidence suggests that even with pharmacologically pure preparations, the varying bioavailability of oral doses of melatonin results in as much as a 20-fold difference in plasma levels of the agent (Di et al. 1997).

A careful review of the literature on jet lag indicates that melatonin is remarkably effective in preventing jet lag, and occasional short-term use appears to be safe. However, the pharmacological and toxicological mechanisms of melatonin need systematic study, and routine pharmacological quality control of melatonin products must be established. There is evidence that a low dose (0.5 mg) of melatonin improves initial sleep quality in selected elderly persons with insomnia. However, large, randomized, controlled trials are yet to be conducted (Olde Rikkert and Rigaud 2001). The literature contains reports of many adverse effects that have yet to be systematically defined so that an appropriate risk–benefit discussion can take place. The reports include autoimmune hepatitis, optic neuropathy, fragmented sleep, psychosis, nystagmus, seizures, headache, skin eruption, and confusion from overdose (Morera et al. 2001).

The mechanisms of action of melatonin are not clearly defined, although there is evidence of an active feedback process between the pineal gland and the suprachiasmatic nucleus. The known interaction in the dopaminergic system has led to investigation of melatonin as an agent in the treatment of parkinsonism, neurodegenerative disorders, tardive dyskinesia (Zisapel 2001), and postoperative delirium (Hanania and Kitain 2002).

In summary, the long-term use of over-the-counter melatonin has not been demonstrated to be safe or effective, and studies of pure preparations of this hormone in carefully controlled research settings have not yet established appropriate indications or risk–benefit assessments. Preferential use of other medications and methods of improving sleep for medically ill patients is recommended.

## Conclusion

Sleep takes up one-third of a typical day. Obtaining adequate quantity and quality of sleep is optimal for good health and the prevention of complications. We have addressed the major sleep disorders by discussing their clinical features, diagnostic testing, and treatment. Sleep medicine is a vibrant medical specialty with many developments promoting understanding of the mechanisms of sleep disorders and their treatment. Intervention can prevent undesirable medical, psychiatric, and social consequences. The chief goal at present is to help educate the medical community and the general public about these conditions so that patients can benefit from these discoveries by having dysfunctional sleep recognized and carefully assessed. Once the diagnosis of a specific sleep disorder is made, numerous treatment options are available.

# 17 Sexual Disorders

---

George R. Brown, M.D.

Richard C. Haaser, M.D.

**SEXUALITY IS AN** important component of quality of life, but it is often overlooked or relegated to a minor role by those caring for the medically ill. When physicians do focus on sexuality, they usually do so from the perspective of sexual dysfunction rather than sexual health. All phases of the human sexual response are subject to influence by a variety of medical and psychiatric conditions. Whether sexual dysfunction occurs as a direct consequence of medical or surgical illness (e.g., erectile dysfunction from spinal cord injury or diabetic neuropathy), a reflection of psychological struggle arising from illness (e.g., negative body image in psoriasis), a comorbid psychiatric illness (Rosen et al. 1999), or a combination of two or more factors, the psychiatrist has the unique opportunity to address these complex interactions (Nankervis 1989). However, it is not a simple matter to determine the relative contributions of somatic disorders and psychological processes in diagnosing sexual problems in the medically ill.

Fagan et al. (1990) suggested the following seven factors that may indicate a psychological source of sexual dysfunction in patients with discrete medical illnesses:

1. History of sexual trauma or abnormal sexual development
2. Restrictive religious or moral sexual attitudes
3. Preexisting sexual dysfunction
4. Situational or partner-specific dysfunction
5. Evidence of morning or masturbatory full tumescence
6. Evidence of masturbatory arousal and orgasm in women
7. Sexual dysfunction following the onset of another psychiatric disorder

Patients' wishes for privacy or their feelings of embarrassment may collude with their physicians' avoidance of sexual issues and a businesslike tendency to focus on the purely medical aspects of the illness. Consequently, sexual dysfunction can easily escape evaluation and treatment. Patients' physicians might avoid discussing sexual health because of time limitations, discomfort with the topic, or fear of having little to offer even if a problem is identified. Therefore it is important for psychiatrists to routinely address the issue as part of assessment.

We discuss specific medical, surgical, and pharmacological deterrents to healthy sexual functioning. DSM-IV (American Psychiatric Association 1994), and its text revision, DSM-IV-TR (American Psychiatric Association 2000), list specific categories for sexual dysfunction due to a general medical condition. These diagnoses are to be used when patients exhibit clinically significant sexual dysfunctions judged to be etiologically related to a general medical or surgical condition. If psychological factors play a role in initiating, maintaining, or aggravating the sexual dysfunction, the specific sexual dysfunction is diagnosed, and the subtype "due to combined factors" is added to the formal diagnosis. Substance-induced sexual dysfunction is another specific category often seen in hospitalized patients. All too often physicians approach sexual dysfunction in their patients with the question, "Is it physical or psychogenic?" Although this question is a natural one, the reality is that in many, if not the majority, of medically ill patients with sexual problems, biological, psychological, and social factors all contribute. This diagnosis covers not only sexual dysfunction due to the use of intoxic-

---

icants, alcohol, and illicit drugs but also the commonly undetected iatrogenic effects of prescribed medications. In addition to the sexual consequences of common medical and surgical disease entities, we discuss primary sexual and gender identity disorders that may be encountered in medical settings and the treatments that are available for patients with these disorders. Many references are cited and provided with the caveat that sexual functioning often involves a personal, highly subjective set of parameters. The many biological, psychological, social, and spiritual complicating factors with which it is fraught make sexual functioning difficult to assess in studies of groups of patients with possibly little more in common than a specific disease, illness, or surgical procedure.

## Sexual Expression in Hospitalized Patients

---

Although sexual expression in hospitalized patients has received little attention in the medical literature, the focus has been on the “problem” of “inappropriate” sexual behaviors by patients in hospitals and nursing homes (Ehrenfeld et al. 1999). These behaviors might not be dysfunctional but merely uncomfortable for staff members. Patients who are hospitalized for extended periods might well have intact sexual function and sexual expression, whether it is through masturbation or with an intimate partner. This activity poses problems for the staff, because hospital settings rarely offer the necessary privacy. The need for privacy might not be appropriate for very ill patients who need close monitoring, but when the hospitalization becomes protracted and the acuity level lower, treatment plans could readily incorporate protected private time. What may appear to be a request to deal with “inappropriate sexuality” may in fact represent an impasse between a patient in need of privacy and a staff member unwilling to accept the reality that sexual needs may transcend the circumstances of hospitalization. The psychiatrist may then act as a mediator in recognizing the “real” issue and brokering a deal between the patient and the treatment team that is mutually beneficial.

Inappropriate expressions of sexual behaviors are indeed common. These activities include attempted involvement by patients with staff (e.g., spinal cord injury patients who are adapting poorly and patients with boundary issues or personality disorders admitted for treatment of medical conditions) and sexual expression by delirious or demented patients, frontal lobe injury patients, and patients who are intoxicated or disinhibited from other causes.

## Sexual Functioning in Medical Illness

---

### Heart Disease

Most studies of patients with heart disease that have addressed sexual functioning have focused on men; however, evidence suggests that the general findings might not be substantially different in women (Skinner 1979). Although study designs and specific findings vary, general conclusions have been supported consistently. Sexual activity decreases and the perception of sexual dysfunction increases after myocardial infarction (Nankervis 1989; Skinner 1979). In a study of 276 Israeli men having a first acute myocardial infarction, 12% of subjects had not resumed sexual activity within 3–6 months. Of the men who did resume sexual activity, 35% reported reduced frequency and 35% reported reduced satisfaction (Drory et al. 1998). Resuming post-myocardial infarction sexual activity with one’s prior partner and in the usual setting does not increase morbidity (Silber 1987). Results of previous studies have suggested that most impediments to a satisfying sexual life after myocardial infarction are psychological rather than physiological (Drory et al. 1998; Skinner 1979). Drory et al. (1998) found that the frequency and satisfaction of sexual activity after myocardial infarction were explained by the frequency and satisfaction with sexual activity before myocardial infarction. Depression, age, and education contributed in a smaller but significant way (Drory et al. 1998). Physical limitations can be important, too. Patients with low ejection fraction in advanced heart disease experience marked reductions in libido and in ability to perform sexually (Jaarsma 1996).

The percentage of heart disease patients wanting to discuss resumption of sexual functioning far exceeds the percentage of patients who believe that they have been informed adequately (Bedell et al. 2002a). Male patients are more likely to have their sexual concerns addressed (Bedell et al. 2002a). In one study only 24% of patients ever specifically discussed sildenafil with their cardiologists before the drug was prescribed (Bedell et al. 2002b). Guidelines for stratifying cardiac risk in resuming sexual activity should facilitate the discussion of sexual function between cardiologists and other physicians and their heart disease patients (DeBusk et al. 2000). These guidelines should reassure most patients who fall into the low-risk category (controlled hypertension; mild, stable angina; successful coronary revascularization; history of uncomplicated myocardial infarction; mild valvular disease; no symptoms; and fewer than three cardiovascular risk factors) that they can safely resume sexual activity or receive treatment of sexual dysfunction (DeBusk et al. 2000).

Erectile dysfunction (ED) is highly prevalent among patients with coronary artery disease and has most of the

same risk factors (Feldman et al. 2000; Jensen et al. 1999; Johannes et al. 2000; Martin-Morales et al. 2001; McVary et al. 2001). The link between hypertension, smoking, diabetes, obesity, dyslipidemia, and ED is sufficiently strong to prompt some investigators to consider ED a marker of covert coronary artery disease (Jensen et al. 1999; Kirby et al. 2001; O'Kane and Jackson 2001). In a prospective study of middle-aged men, increasing exercise reduced the risk of ED, but weight reduction, cessation of smoking, and reduction of alcohol use did not (Derby et al. 2000). The study did not address the outcome that would have occurred had lifestyles been modified in the young adult years.

The advent of effective treatments of ED (Padmanathan and Giuliano 2001) shifted the discussion beyond the question of when cardiac patients can safely resume sexual activity to the question of how and when to treat sexual dysfunction in such patients. Sildenafil has been shown to be safe and effective in patients with stable angina or congestive heart failure providing that they do not take oral, topical, or sublingual nitrates (Arruda-Olson et al. 2002; Bocchi et al. 2002; Jackson 2000). In a prospective, placebo-controlled trial with patients in New York Heart Association classes II and III congestive heart failure, sildenafil not only was safe and effective but also provided relief of depressive symptoms and improvement in perceived quality of life (Webster et al. 2004). Sildenafil does not change the onset, extent, or severity of ischemia, as measured by exercise electrocardiography and echocardiography, in men with coronary artery disease and ED (Arruda-Olson et al. 2002). DeBusk (2002) found, however, that most serious sex-related coronary events are not caused by ischemia produced by arterial obstruction but rather are caused by the rupture of vulnerable coronary arteries. The risk of a coronary event is the consequence of the increased cardiac workload inherent in sexual activity, resumption of which is facilitated by sildenafil but is not caused by sildenafil directly (Marwick 2002). Careful assessment of the patient's functional capacity for work therefore is needed before sildenafil is prescribed.

Sexual dysfunction in cardiac patients has prompted some physicians and patients to avoid otherwise-indicated drugs, such as the beta-blockers. Newer research findings suggest this concern is exaggerated (Ko et al. 2002; Lama 2002). In a prospective, randomized, placebo-controlled study, metoprolol did not worsen ED as was expected (Franzen et al. 2001).

An increasing number of patients are living after receiving heart transplants. As survival after heart transplantation continues to improve, attention to subsequent quality of life has increased. Mulligan et al. (1991) reported that libido that was generally strong before surgery re-

mained strong afterward, and a majority of the 71 male respondents perceived that their partner's libido increased postoperatively. Sixty percent of the respondents reported posttransplantation anorgasmia. Pretransplantation erectile disability and anorgasmia appeared to increase 3 and 12 months after transplantation. Twenty-seven percent of patients in a sample in Italy reported unsatisfactory sexuality after transplantation (Balestroni et al. 2002). Patients commonly experience sexual concerns after transplantation but rarely pursue their questions (Tabler and Frierson 1990), which are usually similar to those of patients who have undergone cardiac surgery. A unique concern among heart transplant recipients is the absence of acceleration in heart rate during sexual excitement or orgasm owing to denervation of the new heart.

## Malignancy

The high prevalence of sexual dysfunction among cancer patients calls for the routine assessment and treatment of sexual problems in oncology centers (Bokhour et al. 2001; Gallo-Silver 2000; McKee and Schover 2001; Monturo et al. 2001; Rice 2000). Particularly in men, a concept of sexual function that goes beyond the traditional focus on ED and intercourse frequency is being recognized (Bokhour et al. 2001; Fox et al. 1999). Educational materials and discussions regarding sexual function and sexual adverse effects allow for improved informed consent before cancer treatments (Gallo-Silver 2000; McKee and Schover 2001). Advanced-practice nurses making home visits can improve communication between men with prostate cancer, their partners, and the treatment team about sexual dysfunction and its treatment after cancer treatments (Monturo et al. 2001).

Breast, cervical, ovarian, endometrial, and vulvar cancers threaten female sexual function through a variety of mechanisms, including altered body image, radiation sequelae, loss of libido, and loss of lubrication (Schover et al. 1987). More effort is being expended to address these factors, but it cannot alter premorbid sexual adjustment and function, which also contribute greatly to sexual function and satisfaction after oncology treatments (Schover 1991).

The sexual effects of breast cancer surgery have been explored in detail. In a study of 18 women undergoing lumpectomy or mastectomy, loss was the predominating theme (Wilmoth 2001). Loss of body part, loss of the perception of youth, loss of sexual sensations, and loss of womanhood were specifically noted. Wilmoth (2001) found that women who actively sought information about the sexual side effects of cancer surgery and who had strong

intimate relationships achieved the most successful adjustment. Breast-conserving treatment (lumpectomy) correlates with better sexual satisfaction and body image (Amichetti and Caffo 2001; Greendale et al. 2001). A strong correlation between the quality of cosmesis and sexual functioning has been found for breast-conserving treatment of breast cancer (Al-Ghazal et al. 1999).

It has been expected that breast reconstruction after mastectomy would lead to improved body image and, consequently, improved sexual function, but this connection is not clear. Body image and perceived sexual attractiveness did not improve in women who underwent mastectomy and breast reconstruction compared with women who underwent mastectomy alone (Rowland et al. 2000; Yurek et al. 2000). On the other hand, Al-Ghazal et al. (2000) documented improved body image, self-esteem, sexual feeling of attractiveness, and sexual satisfaction when breast reconstruction was performed immediately after mastectomy rather than being delayed. Regardless of body image and perceived attractiveness, women had equivalent sexual functioning after breast-conserving treatment, modified radical mastectomy, and modified radical mastectomy with breast reconstruction (Rowland et al. 2000; Yurek et al. 2000). The studies cited were not randomized, so the respective groups may not be entirely comparable. As is likely true in all studies of sexuality, whatever the findings for a given study group, breast-conserving treatment will have more or less sexual importance for particular individuals that is difficult, if not impossible, to capture in group studies.

Chemotherapy for breast cancer affects sexual functioning. Premature menopause is often induced by chemotherapy, and hormone replacement therapy is contraindicated (Greendale et al. 2001). The result is vaginal dryness, decreased libido, dyspareunia, and difficulty in achieving orgasm (Young-McCaughan 1996). The negative sexual impact of chemotherapy for breast cancer can be ameliorated through assessment of menopausal symptoms, education and counseling, and specific pharmacological and behavioral interventions (Ganz et al. 2000; Rogers and Kristjanson 2001).

Marked deterioration in sexual functioning after gynecological surgery has not been typical. Prospective multicenter studies have not shown significant changes in frequency of sexual contact or satisfaction after treatment of early gynecological cancers (Kylstra et al. 1999; Leenhouts et al. 2002). Another study, in which findings for 20 women undergoing radical hysterectomy for stage 1B cervical cancer, 18 women undergoing hysterectomy for a benign gynecological condition, and 20 gynecologically healthy women were compared, showed no significant difference in sexuality (Grumann et al. 2001). Even so,

psychosexual counseling after gynecological cancer surgery may provide benefits (Maughan and Clarke 2001).

Sexual functioning after treatment of prostate cancer remains the best-studied issue for men. Many men believe their choice is between death if they are untreated and sexual dysfunction if they are treated (Bertero 2001). The impact of prostate cancer treatments on ED has been well described. Most men (85%) have ED after prostatectomy or radiotherapy (Schover et al. 2002), but the effects go much farther. Twelve to 24 months after treatment, Bokhour et al. (2001) recorded decreases in quality of sexual intimacy, in quality of everyday interactions with women, in extent of sexual imagining and fantasy, and in perception of masculinity. Results of a large survey study revealed that distress from the loss of desire and anorgasmia equaled the distress from ED (Schover et al. 2002). Better sexual outcomes were correlated with younger age, no history of neoadjuvant chemotherapy, no current antiandrogen treatments, nerve-sparing surgical and brachytherapy treatments, better pretreatment in regard to mental and physical health, and a history of normal erections before treatment.

Antiandrogen treatments of prostate cancer severely hinder sexual function. Sexual activity was lost in 92% of men prescribed flutamide and 88% of men prescribed cyproterone over 2 years (Schroder et al. 2000). Cryosurgery appears to be somewhat more sparing of sexual functioning. Observed over 36 months, 5 of 38 men regained erectile function and 13 of 38 men were sexually active with the help of aids after cryosurgery (Robinson et al. 2002). Treatments that better preserve sexual functioning are being explored. Bilateral nerve-sparing prostatectomy (Ofman and Auchincloss 1992; Schover et al. 2002) and three-dimensional conformal radiotherapy (Wilder et al. 2000) reduce the prevalence of ED. Two-thirds of men treated with this form of radiotherapy maintained erectile function after 3 years of observation (Wilder et al. 2000). Sildenafil improved erections in 74% of men left with ED following <sup>125</sup>I seed implantation radiotherapy (Raina et al. 2003).

Testicular cancer is another commonly encountered cancer in men. In a demographically distinct group of young men with testicular cancer, 30% of the men indicated that sexual performance difficulties were bothersome 1 year after diagnosis (Rieker et al. 1989). However, their concerns about performance were less prominent than their concerns about retrograde ejaculation and infertility. Electroejaculation has been successful in the treatment of infertility in this context (Ohl et al. 1991). Intramuscular injection of androgens appears to enable good sexual and psychosocial adjustment in men who have undergone bilateral orchiectomy for testicular cancer (Fossa et al. 1999). In a study of men who underwent

orchiectomy followed by radiotherapy for seminoma, 20% of the subjects indicated reductions of interest in sex, sexual activity, and pleasure in sex but not to a degree significantly different from that of age-matched healthy controls (Incrocci et al. 2002). In both prostate and testicular cancer, psychiatrists may be called on to assist the patient in choosing between treatments that are effective but are harmful to sexual function and treatments that spare sexual functioning at the expense of cancer-fighting efficacy (Singer et al. 1991).

Tumors of nongenital sites, such as bladder, colon, and rectum, and lymphoma also can be associated with sexual dysfunction, either as a direct consequence of treatments (e.g., retroperitoneal lymph node dissection) or as a result of the negative effects on a patient's self-esteem and body image. For example, ostomy patients might have a particularly difficult struggle with regaining comfortable sexual expression (Ofman and Auchincloss 1992) (see Chapter 30, "Surgery"). ED, ejaculatory difficulties, and dyspareunia all are reported to occur in ostomy patients (Sprunk and Alteneider 2000). New surgical techniques are being explored for preserving sexual functioning in bladder cancer patients (Colombo et al. 2004; Horenblas et al. 2001).

The chemotherapies used to treat cancers distant from the genitourinary system, such as lung cancer, can negatively affect sexual function (Schwartz and Plawecki 2002). All cancer patients should be asked specifically about sexual issues and sexual history, and questions should be addressed to the patient's partner when possible. Health care professionals should not make any assumptions about sexual orientation and should convey a sense of openness to the range of human sexual expression. Negative attitudes in society, among professionals, and within the health care culture, can contribute to the sexual dysfunction of cancer patients by promoting neglect of this aspect of a quality life (Rice 2000). A positive stance should be taken, and an informed capacity for basic counseling and further referral when indicated is necessary (Auchincloss 1989).

## Diabetes Mellitus

Many physicians are aware of the nearly threefold increase in ED among diabetic patients (Dey and Shepherd 2002). However, sexual dysfunction in diabetic patients is considerably more pleomorphic than commonly recognized. Fairburn et al. (1982a, 1982b) noted a variety of sexual problems in addition to ED, including a range of ejaculatory disturbances, loss of sexual interest, persistent morning erections in one-half of subjects, and spontaneous erections in one-third. ED in men with type 1 diabetes

correlates with increasing age, duration of diabetes, chronic diabetic complications, and reduced levels of androgens (Alexopoulou et al. 2001). ED in diabetic men also correlates with smoking, obesity, and high levels of glycosylated hemoglobin (Dey and Shepherd 2002).

Psychological factors (e.g., premorbid sexual difficulties and marital discord) may contribute significantly to the presence of ED. Forsberg et al. (1989) conducted a study in which the subjects were 37 diabetic men with ED. The investigators concluded that psychosocial factors were the sole cause of ED in only two patients. Nevertheless, despite identification of neuropathic, hormonal, and vascular contributions in the other 35 men, nearly two-thirds of them had psychosocial factors of importance. One-half of these factors were judged to be of great importance in the diagnosis and treatment of sexual dysfunction.

Lustman and Clouse (1990) further examined the unfortunate but common assumption that diabetic ED is wholly "organic." They used a standardized interview to study 37 diabetic men who had established peripheral neuropathy, peripheral vascular disease, or both. All eight men with neuropathy who met criteria for either current major depression or generalized anxiety disorder had ED. Among the 20 men with neuropathy but neither of the psychiatric diagnoses, only six had ED. Although the study was retrospective and causality was not established, the results suggested that the association between neuropathy and ED often may be dependent on the psychiatric status of the patient.

A meta-analysis of the literature showed that depression was significantly associated with a variety of diabetic complications, including sexual dysfunction (De Groot et al. 2001). Thase et al. (1988) showed that depression alone can produce abnormal findings in nocturnal penile tumescence studies. These observations strengthened the call for caution in assigning undue emphasis to diabetic "organicity" solely on the basis of time-honored evaluations such as nocturnal penile tumescence studies. In a placebo-controlled study in which the subjects were 268 men with diabetes and ED, Rendell et al. (1999) found that 56% of the men reported improved erections using sildenafil and that 10% reported improved erections using placebo. This response rate was 20%–40% lower than that found in a study of sildenafil response in a urology clinical practice (Marks 1999). Taken together with the correlation between psychiatric diagnosis and ED, the need for a comprehensive psychosocial evaluation during assessment and treatment of sexual dysfunction in diabetic patients is emphasized (Sarica et al. 1994).

Sildenafil has been proved beneficial in treating ED in diabetic men (Hatzichristou 2002). Intracavernosal al-

prostadil injection also is effective treatment. In an open-label, flexible dose-escalating study in which the subjects were diabetic men with ED, 99% of the men reported satisfactory erectile response with intracavernosal alprostadil injection (Heaton et al. 2001). The treatment was well tolerated, albeit with a 24% rate of penile pain. In a survey of 400 diabetes treatment centers in Italy, intracavernosal alprostadil injection was the primary treatment of 85% of diabetic men with ED (Fedele et al. 2001).

The sexual functioning of diabetic women has come under increasing study. In one study, Forsberg et al. (1989) concluded that diabetic women do not have a greater incidence of sexual dysfunction than women in the general population. Webster (1994), however, found that problems with libido, arousal, and orgasm were common to both men and women with diabetes. Erol et al. (2002) found lack of libido in 77% of young women with type 2 diabetes. These investigators also found the patients reported diminished clitoral sensation (62.5%), vaginal discomfort (41.6%), and vaginal dryness (37.5%). In another study, 27% of women with type 1 diabetes reported diminished sexual function; only 15% of control subjects reported this problem (Enzlin et al. 2002). Sexual dysfunction was correlated with the degree of diabetic complications and reduced vaginal lubrication. Quality of marriage and number of endorsed depression symptoms correlated with the presence of sexual dysfunction in both diabetic subjects and healthy control subjects.

## Renal Failure

Sexual dysfunction is common in both women and men with renal failure. ED, menstrual abnormalities, and reduced libido and fertility in men and women are highly prevalent (Palmer 1999). The widespread impact of renal failure on multiple organ systems produces a variety of physiological disturbances implicated in sexual dysfunction.

Endocrinological changes in uremic men include decreased testosterone level, increased estradiol level, and excess parathyroid hormone, and all these disorders are linked to sexual dysfunction (Campese and Liu 1990). In men, the impact of renal failure appears to be expressed primarily at the testicular end of the hypothalamic-pituitary-gonadal axis. In women, the impact appears to be more marked in the central nervous system (Palmer 1999). Autonomic dysfunction (Vita et al. 1999), elevated cholesterol level (Cerqueira et al. 2002), and vascular insufficiency (Campese and Liu 1990) all contribute to ED arising from renal failure. More than one-half of uremic women report decreased sexual interest and anorgasmia (Finkelstein and Steele 1978). Medications commonly

used in chronic renal failure (e.g., antihypertensives) may further aggravate sexual dysfunction. The anemia of renal failure can drain patients of the desire and energy for sexual activity. Erythropoietin treatment of anemia in men with end-stage renal disease has been shown to improve both gonadotropic hormone levels and sexual function (Wu S et al. 2001).

Entry into long-term dialysis does not appear to alleviate sexual dysfunction. The prevalence of sexual dysfunction is high among renal failure patients undergoing hemodialysis (Naya et al. 2002) and peritoneal dialysis (Juergense et al. 2001). Rates of 62.9% and 75% among men and women, respectively, have been reported for hemodialysis and rates of 69.8% and 66.7% among men and women, respectively, for peritoneal dialysis (Diemont et al. 2000). The prevalence of ED appears to gradually worsen with dialysis treatment (Dillard et al. 1989; Malavaud et al. 2000). Some research findings suggest the possibility of ethnic differences. Older white hemodialysis patients reported greater sexual dysfunction than did matched black counterparts (Kutner et al. 2000).

The prevalence of sexual dysfunction declines after renal transplantation. Rates of 48.3% in men and 44.4% in women have been reported (Diemont et al. 2000). As is the case before transplantation, penile arterial and venous insufficiency plays a substantial role in the pathogenesis of ED in male transplantation patients (Abdel-Hamid et al. 2002). The effect of renal transplantation on sexual functioning remains mixed. In one study (Schover et al. 1990) in which the subjects were 54 men and 36 women who had undergone successful transplantation during the previous 5 years, sexual desire increased significantly for both men and women. Many men also reported substantial improvement in the ability to achieve an erection and experience orgasm. Women enjoyed less definitive improvement in their capacity for orgasm. Although the frequency of sexual activity in women after transplantation doubled to once per week, this rate did not achieve statistical significance. Overall sexual satisfaction levels remained constant before and after transplantation. Approximately 25% of the sample retained sexual dysfunction after transplantation. Tsujimura et al. (2002a) found that 35.5% of posttransplantation patients reported improvement in overall sexual functioning, but 28.1% described overall worsening. Notably, 15 of 20 patients with no intercourse history before transplantation initiated intercourse after transplantation. All 15 patients were younger than 40 years, suggesting a need for earlier transplantation intervention.

Development of end-stage renal disease before adulthood is reached creates obstacles to the achievement of intimate relationships. Schover et al. (1990) found that

37% of people in whom end-stage renal disease developed before adulthood did not marry, compared with only 7% of people in whom end-stage renal disease developed after the person reached adulthood. Although 75% of young patients with renal disease expressed a broad interest in information on sexuality, only one-third of them had received it. This finding points to a particular—and often unmet—need for sexual education and counseling of younger patients with end-stage renal disease to facilitate their development of committed relationships.

As in other illnesses, sildenafil has been used in the treatment of ED in patients with renal disease. The drug has been reported to be safe, reliable, and effective in patients undergoing hemodialysis or peritoneal dialysis (Turk et al. 2001). However, one study showed a benefit among only 13% of peritoneal dialysis patients treated with sildenafil (Juergense et al. 2001), but only one-half of the subjects offered participation chose to take sildenafil. Sildenafil treatment proved to be safe and effective in a group of renal transplantation patients (Prieto Castro et al. 2001). Sildenafil has not been shown to alter immunosuppressant drug levels despite clearance through the same metabolic pathways (Christ et al. 2001; Prieto Castro et al. 2001). Christ et al. (2001) did recommend the lowest possible starting dose of sildenafil and a downward adjustment of preexisting antihypertensive medications because of instances of low blood pressure during concomitant use of sildenafil and tacrolimus.

## HIV/AIDS

Patients with early stages of HIV infection, defined as  $>400$  CD4 cells/mm<sup>3</sup> of blood and usually no physical symptoms, may express sexual concerns that have become both quality-of-life and relationship issues for themselves and their partners. New onset of hypoactive sexual desire disorder—operationally defined for this population as at least a one-third decrease in baseline levels of sexual fantasies or desire for sexual activity of any type persistently present for at least 1 month and beginning at least 1 month after notification of HIV seroconversion (among other specific criteria) (Brown et al. 1992)—is one of the most common psychiatric diagnoses in both men and women with early-stage HIV disease. For example, 21.7% of 442 men (Brown et al. 1992) and 31%–41% of 25 women (Brown and Rundell 1990, 1993) were found to have disorders of sexual desire in a U.S. Air Force population. Impaired sexual desire also has been reported in men with HIV disease in Australia (32% of men) (Dunbar et al. 1991) and the Netherlands (23% of men) (Van Buuren et al. 1991). Additionally, the prevalence of depression, with its impact on sexual desire, is higher in men who have sex

with men, independent of HIV status (Mills et al. 2004). Rosser et al. (1997) reviewed the sexual issues of gay men living with HIV.

Among women with early HIV disease who are not chemically dependent, marital problems and hypoactive sexual desire disorder may be the only psychiatric problems with substantially increased clinical frequency (Brown and Rundell 1993). Later stages of the illness are associated with increased rates of depression and anxiety disorders, both of which complicate sexual functioning (Morrison et al. 2002). When hypoactive sexual desire disorder is present in HIV-infected women, the women usually describe it in a typical manner 4–18 months after learning of their HIV seropositivity: gradual onset over a 2- to 6-month period, usually in the presence of a willing partner and in the absence of comorbid medical or psychiatric conditions (Brown et al. 1995). The sexual desire problems usually are not a component of mood or anxiety disorders, although such disorders should be ruled out. Most patients in whom hypoactive sexual desire disorder develops a year or more after notification of seropositivity are puzzled by the symptoms and frequently convey that these symptoms threaten previously established levels of intimacy in important relationships. This phenomenon, possibly due to direct infection of the brain by HIV, has been found in women from middle-class backgrounds free of poverty and drug abuse as well as in the inner city populations of intravenous drug users, who often face the challenges of poverty and instability in all areas of life (Goggin et al. 1998).

Patients with late-stage HIV disease (AIDS) may be physically debilitated by the opportunistic infections, wasting, and fatigue that often bring them into the hospital (Tindall et al. 1994). Depression is a frequent concomitant of later HIV disease and contributes not only to sexual dysfunction but also to heightened susceptibility to infectious diseases and diminished longevity in both men (Leserman et al. 1999) and women (Morrison et al. 2002). Testosterone supplementation in HIV-infected men with both mood symptoms and decreased libido has proved effective in controlled studies (Rabkin et al. 1999, 2000).

Sexual health is often overlooked in both the psychiatric and medical care of HIV-infected patients. Patients with positive results of serological tests for HIV may be reluctant to discuss their sexual dysfunction, especially when the topic is not broached by their physicians. Communication is further hampered when the primary physician suggests that complete abstinence from interpersonal sexuality is the only acceptable “safe” alternative. Such absolutism serves only to jeopardize informed, collaborative decision making about sexual and reproductive

behavior (Minkoff and Moreno 1990). With the success of prenatal and postnatal antiretroviral treatments that has been replicated in numerous trials, perinatal transmission in the United States has been reduced to less than 7%, making the decision by HIV-positive women to have children substantially safer than in the early years of the epidemic. Negative or moralistic attitudes on the part of the consultant can also lead to dangerous sexual “acting out.” HIV/AIDS in developed countries has become a chronic illness managed over possibly decades of infection, covering many years of the reproductive life span. For those who have access to these life-prolonging treatments, there is evidence that this availability may increase the likelihood that uninfected patients engage in risky sexual behaviors (Strathdee et al. 2000; Vanable et al. 2000). Psychiatrists can make a useful contribution by opening a dialogue on sexual issues and communicating the view that sexual health may incorporate responsible, “safer sex” approaches that can limit HIV transmission. Patients should be informed that an undetectable viral load, for example, does not eliminate transmission risk, as is often perceived to be the case (Martin et al. 2001). Additional didactic information may include the potential benefits of masturbation and mutual masturbation with a partner. Major depression and dementia (Atkinson et al. 1988) may also complicate all stages of HIV infection, especially later stages. Sexual desire disorders and, less commonly, secondary ED may accompany these independently treatable conditions.

Psychiatrists caring for HIV/AIDS patients must be aware of the clear connection between increased high-transmission risk behaviors (e.g., unprotected intercourse with seronegative partners) and substance use (Vittinghoff et al. 2001). Use of volatile nitrites (“poppers”) at the point of orgasm to intensify the experience has been linked to higher-risk behaviors (Ostrow et al. 1991), as have alcohol and illicit drug use (Crosby et al. 1991; Ostrow and McKirnan 1997). Methamphetamine use by gay and bisexual male patients is strongly linked to higher probabilities of medical illness and unsafe sexual activity (Shoptaw et al. 2002). In the 1990s there appeared to be a decrease in the use of high-risk sexual behaviors, possibly linked to declines in illicit drug use. However, more recent surveys of men having sex with men revealed a continuing strong association between drug and alcohol intoxication and unprotected anal intercourse in a new generation of men who have not known a world without HIV (Stueve et al. 2002). There is evidence to support the concept that at least some men who have sex with men, especially those who are not gay-identified, use substances to deal with internalized homophobia or with anxiety over the risk of contracting HIV infection (Dolezal et al. 2000).

## Sexual Functioning in Neurological Disorders

---

Disorders involving the nervous system can have profound effects on sexuality, involving all phases of the sexual response cycle. Sipski (2001) reviewed sexual functioning in women with neurological disorders, including spinal cord injuries, multiple sclerosis (MS), and dementia, and cerebrovascular accidents (CVAs).

### Spinal Cord Injury

The central, peripheral, and autonomic nervous systems are all essential to sexual functioning. Injury to one or more components can disrupt an individual's patterns of function. When spinal cord injury occurs at the cervical or thoracic level, ascending sensory and descending upper motor neuron tracts are compromised. The capability of psychogenic erection or clitoral engorgement is compromised. However, the genital spinal cord reflex allows genital arousal and orgasm to occur in response to mechanical stimulation (Higgins 1978). The patient, however, cannot feel genital sensations, and the reflexive erections usually are unpredictable and often insufficient to sustain intercourse. If the injury occurs at the lumbar or sacral level, the genital spinal cord reflex is lost, and reflexogenic erections do not occur. However, if the injury has spared the autonomic nervous system, the capability of psychogenic genital arousal is preserved. The loss of sensation varies according to the lesion (Kaufman 1990; Stewart 1991).

The erectile disabilities and anorgasmia of spinal cord injury patients are compounded by the potential for bowel and bladder incontinence, the frequent necessity for urinary catheters, and the loss of accustomed mobility and normal sensation. Stewart (1991) properly emphasized the value of discussing sexual possibilities with spinal cord injury patients to affirm the reality of some retained sexual behavior and feelings after the injury, a reality the patient often doubts. This overture also presents the opportunity for patients to share sadness over what has been lost in both the sexual and nonsexual spheres of life (Stewart 1991). A physical therapist with experience in the sexual problems of spinal cord injury can provide invaluable practical assistance.

Spinal cord injuries occur most often in active people younger than 40 years who are usually otherwise healthy. Premorbid sexual and reproductive functioning in most cases is normal. Although women with spinal cord injuries commonly report sexual dysfunction in all phases of the sexual response cycle (including desire-phase disorders, diminished lubrication and swelling, and anorgasmia),

most of the literature focuses on ED in paraplegic and quadriplegic men.

Sildenafil may improve the quality of erections after spinal cord injury without the need for a complicated autoinjection regimen. Derry et al. (1998) studied a group of 27 patients who maintained at least a partial reflexogenic erectile response to penile vibratory stimulation after sustaining T6–L5 lesions. After 28 days, 75% of the patients taking sildenafil and 7% taking placebo reported that treatment had improved their erections. In a study of 170 outpatient men with spinal cord injuries, sildenafil improved erections as evidenced by the reports of 88% of the men and 85% of their partners, regardless of the baseline characteristics of the spinal cord injury (Ramos et al. 2001). Similarly, a double-blind, placebo-controlled, crossover study of sildenafil in men with ED secondary to spinal cord injury showed 78% of the men reported improved erections (Giuliano et al. 1999). Derry et al. (2002) performed a comprehensive review of the use of sildenafil in men with spinal cord injury. Women with spinal cord injury also appear to gain benefit with sildenafil. In a double-blind, placebo-controlled, crossover study of 19 women with spinal cord injury, Sipski et al. (2000) found significant increases in the women's subjective report of arousal, particularly when the active drug was paired with a program of visual and manual sexual stimulation. Spinal cord injury patients should generally use a trial of oral therapy with sildenafil or other nitric oxide synthetase inhibitors before resorting to pharmacological erection programs or autoinjections.

Because the etiology of ED in men with spinal cord injuries usually is neurogenic, these men may be candidates for intracavernosal pharmacotherapy. These treatments are best accomplished in the form of home autoinjections for paraplegic men with adequate motivation and dexterity or as a partner-assisted erection program for quadriplegic men (Gerstenberg et al. 1992).

If oral treatment is not effective or appropriate for a patient with spinal cord injury, pharmacological erection programs (Padma-Nathan and Kanellos 1992; Padma-Nathan et al. 1987) may prove a viable option for safely restoring adequate erectile function for intercourse. Originally, fixed combinations of phentolamine mesylate and papaverine hydrochloride were administered by injection with a 0.5-inch (1.27 cm), 28-gauge needle into the lateral base of the penis at the level of the corpus cavernosum. A firm erection for an hour after treatment was the targeted outcome. Corporal scarring (3%) and extended priapism (variable rates) were the major side effects. Advances in this therapy entail a more physiological combination of prostaglandin E<sub>1</sub> and phentolamine mesylate or a triple mixture of papaverine, phentolamine, and

alprostadil (prostaglandin E<sub>1</sub>) (Chao and Clowers 1994). Test doses are increased until the optimal dose is achieved (erection of sufficient rigidity for intercourse for about 1 hour). The pharmacologically induced erection is often enhanced in both duration and rigidity by sexual stimulation, which then allows a decrease in medication dose. Although priapism remains a risk, the incidence of corporal scarring has been greatly reduced with the substitution of prostaglandin E<sub>1</sub>. The average frequency of autoinjection or partner-assisted injection has been reported to be seven times per month, and the partner and patient satisfaction rating is more than 90% (Padma-Nathan and Kanellos 1992).

Other treatments available to patients with spinal cord injuries and ED include a variety of penile prostheses, topical applications of nitroglycerin (Meyhoff et al. 1992), and use of a negative-pressure, or vacuum erection, device (Witherington 1988). Vacuum devices produce negative pressure by using suction and causing mechanical entrapment of blood in the penis. Care must be exercised in the application of such devices owing to the lack of protective sensitivity in the genitals.

Inappropriate sexual behavior on the part of young, male spinal cord injury patients is not uncommon. Impulsive, excitement-seeking individuals are overrepresented in this clinical population (e.g., they have been injured in motorcycle accidents, falling from heights while intoxicated, and in high-speed car crashes). Some of these men do not readily adapt to the literal and figurative impotence associated with spinal cord injury and act out sexually toward the staff they depend on for their care. This behavior jeopardizes the quality of care these patients receive, because the staff may begin avoiding them (consciously or unconsciously) to avoid these uncomfortable interactions. The psychiatrist can gently but firmly discuss this issue with the patient, pointing out that such behavior drives away caregivers and thus deprives the patient of the good care he deserves. The psychiatrist can deliver this message while making it clear that the behavior is unacceptable but without scolding or shaming the patient.

## Multiple Sclerosis

MS generally affects individuals between the ages of 20 and 40 years, a time when base rates of sexual dysfunction are otherwise relatively low. Because MS has a variable course and is associated with primary and secondary psychiatric disorders, psychiatrists are often involved in the care of MS patients. Sexual dysfunction is rarely the initial symptom of MS but regularly appears during the course of illness. Deleterious effects on sexuality have been found in 60%–91% of men and 52%–77% of women (Hulter

and Lundberg, 1995; Zorzon et al. 2001). Even in cases of “mild” MS with minimal chronic neurological manifestations of the disease, the frequency of sexual dysfunction in both men and women may be high (43% of men, 52% of women) compared with the frequency among the general population (Minderhoud et al. 1984). In a case-control study of 108 MS patients, Zorzon et al. (1999) found anorgasmia or hyporgasmia (37% women), reduced vaginal lubrication (35.7%), diminished libido (39.5% men, 31.4% women), ED (63.2%), and ejaculatory and orgasmic dysfunction (50% men). ED is the most common sexual problem among men with MS; at least 90% of cases are diagnosed as neurogenic and less than 10% as “mainly psychogenic” (Kirkeby et al. 1988). In contrast, disorders in the orgasm phase (48%) and desire phase (58%) are most common in women. A minority of both men and women report that pelvic sensory defects (21% men, 29% women) and fatigue (26% men, 29% women) contribute to sexual dysfunction.

Longitudinal studies of both male and female patients with MS indicated that the number of patients with at least one type of sexual dysfunction increases with time in both sexes (Stenager et al. 1996). On the other hand, in light of the high baseline rates of sexual dysfunction early in the disease process, Zorzon et al. (2001), in a 2-year prospective study of the longitudinal course of MS, found no progression of the greater than 70% baseline prevalence of sexual dysfunction, even as the extent and severity of neurological symptoms advanced. After removal of psychological factors by multivariate analysis, bladder dysfunction was the physical symptom with an independent relationship to sexual dysfunction. Among psychological factors, depression is most closely linked to sexual dysfunction in MS (Janardhan and Bakshi 2002).

The impact of sexual dysfunction cannot be overestimated: sexual problems were predictive of self-reported low quality of life even among MS patients whose neurological disabilities were otherwise mild (Nortvedt et al. 2001). In patients with MS, changes in sexual functioning are not highly correlated with overall ability to ambulate but are correlated with neurological symptoms that can be traced to the sacral segments and to the presence of vertigo and ataxia (Hulter and Lundberg 1995).

Few patients with MS report that the importance of sexual activity decreases after diagnosis, and only 5% endorse the view that chronic illness constitutes a “good reason” for reduced sexual interest and activity (Minderhoud et al. 1984). It has been reported that rare patients with MS paradoxically develop transient hypersexuality (Gondim and Thomas 2001) and, in one case, paraphilia (Frohman et al. 2002). As in most of the other conditions discussed in this chapter, sexual dysfunction in one sexual

partner can jeopardize intimacy in spousal or other supportive relationships. Dupont (1996) has thoroughly reviewed sexual functioning in patients with MS.

## Dementia

The emergence of disruptive sexual behavior in patients with dementing diseases causes significant distress for family members and hospital staff. Psychiatrists are asked to evaluate patients with compulsive public masturbation, frequent genital exposures, fondling of other patients and staff, and dangerous sexual behaviors (e.g., vaginal or rectal insertions of sharp objects or chair legs). In a study of 133 consecutive admissions to a dementia unit, caretakers in 15% of cases reported inappropriate sexual behaviors without correlation to age, age at dementia onset, gender, educational level, Mini-Mental State Examination score, or type of dementia (Tsai et al. 1999). Patients with Klüver-Bucy syndrome, resulting from bilateral lesions of the temporal lobes, frequently act in inappropriate, hypersexual ways. Normal inhibitory controls appear to be impaired, and primitive sexual displays result. Problems related to hypersexuality may be the cause of hospital admission in patients with Huntington’s chorea. A longitudinal study of patients with Huntington’s chorea revealed abnormal sexual behavior in 63% of patients, including exhibitionism, sexual aggression, voyeurism, and hypersexuality (Dewhurst and Oliver 1970). Sexual “acting out” by patients with Alzheimer’s disease or multi-infarct dementia may frequently reflect disordered frontotemporal inhibitory mechanisms and cause a release phenomenon (Cooper 1987). Behavior is rarely predatory or dangerous but may involve inadvertent self-harm (e.g., during episodes of compulsive or aggressive masturbation). For example, we evaluated a patient with Alzheimer’s disease who was hospitalized after public masturbation in a shopping mall. During the admission, the patient was found publicly masturbating while inserting the leg of his desk chair rectally.

Antiandrogen treatment may be effective in some men with dementia and sexual disorders. This treatment may decrease dangerous sexual behaviors. In one study, 300 mg of medroxyprogesterone acetate (MPA) administered intramuscularly each week suppressed dangerous and troublesome sexual behaviors within 14 days in four elderly demented patients, ages 75–84 years (Cooper 1987). After 1 year, MPA was discontinued and three of four patients’ behavior remained under control for a 1-year, drug-free follow-up period even though serum testosterone levels had returned to baseline normal levels within 4 weeks of discontinuation. Gonadotropin-releasing hormone analogues, such as triptorelin, goserelin, and others, may be considered in treatment when these behaviors

are severe. If this type of treatment is used, caregivers need to be aware that an initial increase in testosterone level after the initial injections is followed by a rapid decline. In this early treatment phase, it is possible for the offending behaviors to temporarily worsen. Because of the ethical and legal issues associated with using pharmacological agents for behavioral “control” of patients with dementia, physicians are advised to seek informed consent from guardians, next of kin, or the courts.

## Other Neurological Conditions

There is a growing literature on sexual problems in other neurological conditions. For example, more than 50% of patients who have sustained traumatic brain injury have a decrease in sexual arousal after injury (Crowe and Ponsford 1999). After correction for the level of postinjury depression, reduced cognitive capacity for forming sexual imagery was found to correlate with reduced sexual arousal. The sleep fragmentation in obstructive sleep apnea has been demonstrated to cause diminished levels of luteinizing hormone and testosterone, thereby reducing libido in men with this disorder (Luboshitzky et al. 2002). Awareness of the central role of temporal lobe structures in sexual functioning is growing. In a study of 60 epileptic patients, temporal lobe seizure was related to the development of sexual dysfunction (Souza et al. 2000). Mendez et al. (2000) reported two cases of increasing sexual behavior and late-life-onset homosexual pedophilia developing in the context of brain disease. Positron emission tomographic scanning highlighted right temporal lobe hypometabolism in both men. Krueger and Kaplan (2000) reviewed disorders of sexual impulse control in various neuropsychiatric conditions.

Parkinson's disease commonly causes sexual dysfunction. In their study of 115 patients with Parkinson's disease, Sakakibara and colleagues (2001) found decreased libido in 84% and 83% and decreased sexual intercourse in 55% and 88% of women and men, respectively. These investigators also reported reductions in orgasm (87%), erections (79%), and ejaculation (79%) in the men. Sildenafil had good efficacy in a randomized, placebo-controlled, crossover trial involving 12 men with Parkinson's disease and 12 men with multiple-system atrophy (Husain et al. 2001). The authors cautioned that exacerbation of hypotension was a problem in using sildenafil to treat men with multiple system atrophy. Sildenafil also was found efficacious in an open-label trial in which the subjects were men with Parkinson's disease and depression (Rafaele et al. 2002). There was both improvement in erections (85% of patients) and alleviation of depressive symptoms (75%).

## Cerebrovascular Accident (Stroke)

Unlike those with MS or spinal cord injuries, most patients who experience a CVA are older than 50 years. Because American society tends to “asexualize” elderly and medically ill people, it is not surprising that studies of sexuality in elderly CVA patients have been few, despite the fact that CVA is one of the most common causes of long-term disability. Approximately one-third of patients die of the acute consequences of CVA; one-third are seriously disabled; and one-third largely recover. Sexual functioning after a CVA is generally characterized by reduced desire and decreased frequency of activity in both men and women. There is no general agreement, however, on the causes of decline in sexual functioning, and the relative contributions of the lesion and psychosocial factors are unclear.

In two large studies, all phases of sexual response were impaired after CVA (Table 17–1). In an early study of CVA patients whose average age was approximately 68 years, Monga et al. (1986) found poststroke decreases in desire (54%), erection (56%), lubrication (34%), and orgasm (51% men, 32% women) compared with baseline measurements. Korpelainen et al. (1999) replicated these findings in a sample in Finland, finding that both CVA patients and their spouses were highly likely to experience major disruptions in sexual interest (57%–65%), regularity of intercourse (55%, including cessation altogether in 33%), erectile capacity (75%), vaginal lubrication (46%), and overall sexual satisfaction compared with prestroke baseline values. In a study of Italian patients 1 year after stroke, Giaquinto et al. (2003) found that both patients and their partners were quite forthcoming with information about the significant decline in sexual activity and the reasons for it when directly queried. These investigators also found that the average decline in “frequency of performance” compared with baseline was 83% irrespective of age. More than one-half of men reported severe ED, although 3% reported an increase in sexual activity after stroke. All of these men had a right-sided temporal lesion. This increase was true hypersexuality, not to be confused with the occasional increase in libido noted in some patients when the location of the lesion appears to be irrelevant. For example, Korpelainen et al. (1999) found that 19 of 192 patients experienced an increase in libido in the months after CVA compared with their baseline values. These investigators found that none of the patients were pathologically hypersexual. The investigators speculated that the enhancement in sexual interest was within the normal range and was most likely linked to the improved relationship experienced by these patients and their spouses during rehabilitation.

**TABLE 17-1. Changes in sexual functioning after stroke**

Phase	Before CVA (%)	After CVA (%)
Normal desire, male	75	21
Normal desire, female	60	34
Normal erection	94	38
Normal lubrication	63	29
Normal orgasm, male	73	22
Normal orgasm, female	43	11
Anorgasmia, female	34	77
Premature ejaculation	13	43

Note. CVA=cerebrovascular accident.

Source. Adapted from Monga T, Lawson J, Inglis J: "Sexual Dysfunction in Stroke Patients." *Archives of Physical Medicine and Rehabilitation* 67:19-22, 1986. Copyright 1986, WB Saunders. Used with permission.

In women, right-hemisphere lesions appear to cause less sexual dysfunction than left-hemisphere CVA. The reverse may be true for men. In one study, 75% of men with unilateral right-hemisphere CVA had sexual dysfunction compared with 29% of those with left-hemisphere CVA (Coslett and Heilman 1986). It has been hypothesized that limbic activation of the dominant hemisphere for sexual function is required for intact sexual functioning in men. Other investigators have not found that changes in sexual functioning in general are based on the location of the lesion (Korpelainen et al. 1999).

In addition to experiencing loss of independence or control over some body movements, CVA patients often experience the loss of their sexual life (Hawton 1984). Monga et al. (1986) found that 95% of men and 76% of women in their late 60s were satisfied with their sexual lives before CVA, whereas only 26% of men and 37% of women remained satisfied after CVA. The most common self-reported cause of both decreased satisfaction and increased dysfunction is fear of having another CVA initiated by blood pressure elevations associated with sexual activity. Other reported causes include diminished self-esteem, anxiety about sexual performance, fear of partner rejection, and pharmacotherapy toxic to sexual functioning (e.g., anti-anxiety, hypotensive, antidepressant, and hypnotic medications). In a review of poststroke urogenital and sexual problems, Marinkovic and Badlani (2001) found that an additional concern is urinary incontinence, which is considered the best single indicator of future disability, having 60% sensitivity and 78% specificity (Taub et al. 1994). Unlike patients with MS and spinal cord injury, much of whose sexual dysfunction has a clear neurogenic etiology, those surviving one or more CVAs appear more likely to have substantial psychological concerns

that may account for or contribute to their post-CVA sexual problems. Giaquinto et al. (2003) identified that the main issues regarding sexual dysfunction 1 year post-stroke were based far more on psychosocial and marital issues than on the location or size of the lesion. These issues included fear of recurrence on the part of the patient or partner, belief that sex is limited to those who are healthy, and the partner's being "turned off" by the idea of having intercourse with a "sick person."

Emotional incontinence is a frequent sequela of CVA and MS and has been linked to both subacute and chronic sexual dysfunction. The presence of emotional incontinence 3 months after stroke was predictive of decreased sexual interest, frequency of intercourse, and erectile capacity at 2 years (Choi-Kwon and Kim 2002).

Although no guarantees can be offered, patients can be informed that the changes in heart rate, blood pressure, and oxygen uptake during most forms of conventional sexual activity with an established partner are similar to those experienced during light to moderate short-term exercise (Bohlen et al. 1984). Orgasm lasting only seconds is associated with the greatest increases in these physiological parameters, which then quickly return to baseline values during the resolution phase of the sexual response cycle. To further decrease stroke risk for men, it has been suggested that couples engage in longer foreplay and minimize or eliminate use of the man-on-top coital position. Self-stimulation and partner stimulation to orgasm using noncoital techniques may further limit the risk of adverse circulatory events.

Psychiatrists should be aware that sexual morbidity after CVA may be largely unrelated to the CVA itself. Diabetes, coronary artery disease, peripheral vascular disease, and hypertension are all very common in CVA patients. Premorbid relationship problems, including loss of interest in sex or in the partner, may be important contributors, the CVA presenting a convenient and socially acceptable reason to exempt oneself from a previously unsatisfactory sexual relationship. In these situations, it is often the spouse who seeks assistance for the identified patient's sexual dysfunction. In addition, loss of sexual desire is a common symptom of major depressive syndromes, for which patients have a heightened risk after stroke.

## Medications and Sexual Functioning

Many medications are associated with sexual dysfunction in all phases of the human sexual response cycle. DSM-IV included a new diagnostic category that can be used to differentiate these disorders of substance-induced sexual dysfunctions from nonprescribed substance use. Hospi-

talized patients are frequently taking several of the medications listed in Table 17-2 that may contribute to sexual dysfunction, but patients may be hesitant to discuss these problems.

Fluoxetine and paroxetine, typical of the selective serotonin reuptake inhibitor (SSRI) drugs, can delay or prevent normal orgasm. This fact has led to use of these drugs in treating premature ejaculation (Waldinger et al. 1997). Sildenafil citrate (Viagra) has revolutionized the treatment of ED in men with physiological compromise, whether vascular or neurologically induced (Eid 2000). The extraordinary prevalence of ED—39% of 40-year-olds, 67% of 70-year-olds (Feldman et al. 1994)—has resulted in the resounding success of this medication in the licit and illicit marketplaces. Sildenafil has become the medication most frequently marketed by illegal Internet “pharmacies.”

Sildenafil has a proven record of efficacy compared with placebo in a variety of contexts producing ED. ED arising from diabetes, cardiovascular disease, spinal cord injury, and MS is amenable to sildenafil treatment, and sildenafil shows promise for ED resulting from prostate cancer and its treatments, end-stage renal disease, Parkinson's disease, spina bifida, and multiple organ transplantation (Sadovsky et al. 2001). Sildenafil is effective for aging men, 65.7% having a good response (Tsujimura et al. 2002b). Pooled safety data from 18 studies involving more than 3,700 men showed a remarkable safety profile (Gregoire 1998). Patients with renal and hepatic disease can be treated with this generally safe agent. Typical side effects are minor and include headaches, flushing, nasal congestion, transient changes in color vision, and dyspepsia. However, in one study only 2% of men discontinued treatment because of side effects (Gregoire 1998).

The success of sildenafil has substantially changed practice patterns. Some authors have argued that the medical evaluation of ED no longer requires such historically standard procedures as duplex ultrasonography, nocturnal penile tumescence studies, and penile pharmacotesting (Aversa and Fabbri 2001). Oral therapy with sildenafil or apomorphine (administered in Europe) is the recommended first-line treatment of ED because it is effective and lacks invasiveness (Aversa and Fabbri 2001). Notably, 75% of men with successfully established regimens of intracavernosal alprostadil injection for ED respond well to sildenafil, and when they are given the choice of sildenafil or intracavernosal alprostadil injection, 64% prefer sildenafil (Hatzichristou et al. 2000). Topical alprostadil cream is efficacious and provides an alternative for men who cannot take phosphodiesterase inhibitors and who will not tolerate the invasiveness of intracavernosal injection (Becher 2004).

Drug treatment without consideration of psychological and relationship factors will have much less chance of sustained success than a more comprehensive approach that takes into account both physical and psychological contributions to the problem. For example, 50%–60% of men discontinue successful pharmacological treatment of ED (Althof 2002). Wise (1999) reported the destabilization of a relationship, previously characterized by long-term sexual abstinence, after the introduction of sildenafil. It should be noted that sildenafil is ineffective in the absence of physical sexual stimuli, a fact not always shared with patients.

Because of its success in men, sildenafil has been used to treat women with sexual arousal disorder, and results of the initial open-label research were promising (J.R. Berman et al. 2001; Kaplan et al. 1999). In general, randomized, controlled trials of sildenafil in the treatment of women with sexual arousal disorder have not shown benefit (Basson et al. 2002; Caruso et al. 2001; Laan et al. 2002). A clinical trial of sildenafil in women with spinal cord injuries did demonstrate benefit (Sipski et al. 2000) (see earlier section, “Spinal Cord Injury”).

The negative efficacy of sildenafil in arousal disorders in women highlights the need for a global, biopsychosocial approach. For example, women with a childhood history of sexual abuse, a developmental insult highly correlated with later adult sexual dysfunction, did not benefit from sildenafil (L.A. Berman et al. 2001). Because of the recent heavy emphasis on oral medication, Bancroft (2002) admonished physicians not to “medicalize” female sexual dysfunction. He noted that female sexual functioning is, in general, more broadly affected by social and psychological factors than is the sexual functioning of men and that many behaviors labeled as sexual dysfunction in women are actually healthy adaptations to difficult circumstances, such as stress, depression, fatigue, or the “continuing presence of negative or threatening patterns of behavior in the partner” (Bancroft 2002, p. 454).

The future of sexual pharmacology appears bright. A variety of oral erectogenic agents are in late-phase development, including the centrally active dopamine agonist sublingual apomorphine and the peripheral nonselective alpha-blocker oral phentolamine (Rosen 2000). The recently available phosphodiesterase inhibitor vardenafil has proven its efficacy and tolerability in randomized, placebo-controlled studies and offers the advantage of rapid onset of action (Kendirici et al. 2004). In an open-label, short-term, multicenter trial of 147 men taking sildenafil for ED, 90.5% opted to remain with tadalafil after a 9-week crossover phase (Stroberg et al. 2003). In a multicenter, randomized, double-blind crossover study of 215 men, 66% preferred initiation with tadalafil to sildenafil (Govier et al. 2003).

**TABLE 17-2. Medications and substances associated with sexual dysfunction**

<b>Medication</b>	<b>Reported adverse effect</b>
Alcohol	Chronic abuse: decreased libido, ED, abnormal ejaculation, dyspareunia
$\alpha_1$ -Adrenergic antagonists	ED, decreased libido, abnormal ejaculation
Amiloride	ED, decreased libido
Aminocaproic acid	Dry ejaculation
Amiodarone	Decreased libido
Amphetamines	Chronic abuse: ED, abnormal ejaculation, anorgasmia (women)
Amyl nitrite	Decreased libido, ED
Anabolic steroids	ED, decreased libido, testicular atrophy
Angiotensin-converting enzyme inhibitors (captopril, trandolapril)	ED, decreased libido, abnormal ejaculation
Anticholinergic agents	ED
Anticholinergic ganglion blockers	ED, decreased libido
Antidepressants	
Mirtazapine	Decreased libido, ED
Nefazodone	Spontaneous ejaculation
Selective serotonin reuptake inhibitors	Anorgasmia, ED, decreased libido, abnormal ejaculation
Trazodone	Priapism, clitoral priapism, decreased libido, abnormal ejaculation, anorgasmia
Tricyclic	Decreased libido, ED, abnormal ejaculation, abnormal orgasm
Venlafaxine	Decreased libido, ED, abnormal ejaculation, delayed orgasm
Antihyperlipidemic (fibrate) agents	Decreased libido, ED
Antipsychotics	
Conventional	Abnormal ejaculation, ED, priapism, decreased libido
Second generation	Abnormal ejaculation, ED, decreased libido, priapism
Atorvastatin calcium	Decreased libido, ED, abnormal ejaculation
Baclofen	ED, no ejaculation
Barbiturates	Decreased libido, ED
Benzodiazepines	Decreased libido, anorgasmia, abnormal ejaculation
Beta-blockers	ED, decreased libido, abnormal ejaculation
Bromocriptine	Painful clitoral tumescence, ED
Bupirone	Priapism
Busulfan	ED
Calcium-channel blockers	ED
Cannabis	Increased libido
Carbamazepine	ED
Carbidopa-levodopa	Priapism, increased libido
Cetirizine hydrochloride	Decreased libido
Chlorambucil	ED
Clonidine	ED, abnormal ejaculation, decreased libido
Cocaine	Priapism
Cyclophosphamide	ED
Cyproterone acetate	Decreased libido
Cytosine arabinoside	ED, decreased libido, dyspareunia
Danazol	Increased or decreased libido
Delavirdine mesylate	Decreased libido, ED
Diethylpropion	ED, delayed ejaculation, anorgasmia (women)
Digoxin	Decreased libido, ED
Disopyramide	ED
Disulfiram	ED
Donepezil	Increased libido

**TABLE 17–2. Medications and substances associated with sexual dysfunction (continued)**

<b>Medication</b>	<b>Reported adverse effect</b>
Estrogens	Increased or decreased libido
Ethosuximide	Increased libido
Ethoxzolamide	Decreased libido
Etretinate (and acitretin)	ED, decreased libido
Fat emulsion	Priapism
Finasteride	Decreased libido, ED, ejaculatory failure
Glutethimide	Decreased libido
Gonadotropin releasing factor analogues	ED, decreased libido, loss of sexual fantasy
Guanabenz	ED
Guanadrel	Decreased libido, abnormal ejaculation, delayed orgasm (women)
Guanfacine	ED
Histamine <sub>2</sub> blockers	ED
HIV protease inhibitors	ED, decreased libido, priapism
Hydralazine	ED, priapism
Indapamide	Decreased libido, ED
Interferon- $\alpha$	Decreased libido, ED
Ketoconazole	ED, decreased libido
Levodopa	Increased libido
Lithium	Decreased libido, ED
LSD	Increased or decreased libido, ED, abnormal ejaculation
Mazindol	ED, spontaneous ejaculation, painful testes
MDA	Increased or decreased libido, ED, abnormal ejaculation
Melphalan	ED
Methaqualone	ED, abnormal ejaculation, decreased libido (women)
Methotrexate	ED
Methyldopa	Decreased libido, ED, abnormal ejaculation, delayed or no orgasm (women)
Metoclopramide	ED, decreased libido
Metyrosine	ED, no ejaculation
Mexiletine	ED, decreased libido
Midodrine	ED
Monoamine oxidase inhibitors	ED, abnormal ejaculation
Naltrexone	Delayed ejaculation, ED
Naratriptan hydrochloride	Decreased libido, inflammation of breast, vagina and fallopian tubes
Nilutamide	Decreased libido, testicular atrophy
Nonsteroidal anti-inflammatory drugs	ED, decreased libido, abnormal ejaculation
Omeprazole	Painful nocturnal erections
Opioids	Decreased libido, ED, abnormal ejaculation
Papaverine	Priapism, especially with neurological disorders
Pergolide	Hypersexuality, priapism, spontaneous ejaculation
Phencyclidine	Increased or decreased libido, ED, abnormal ejaculation
Phenmetrazine	ED, delayed ejaculation
Phenoxybenzamine	Dry ejaculation
Phentolamine	ED
Phenytoin	Decreased libido, ED, priapism
Pramipexole dihydrochloride	Decreased libido, ED
Primidone	Decreased libido, ED
Probucol	ED
Procarbazine	Decreased libido, ED, dyspareunia

**TABLE 17-2. Medications and substances associated with sexual dysfunction (continued)**

Medication	Reported adverse effect
Progestins	ED
Propofol	Sexual disinhibition
Riluzole	Increased or decreased libido, ED
Selegiline	Transient anorgasmia, decreased penile sensation
Sildenafil citrate	Abnormal ejaculation, genital edema, anorgasmia
Spirolactone	Decreased libido, ED
Steroids	Increased or decreased libido
Sulfasalazine	ED
Sulfonamide carbonic anhydrase inhibitors	ED, decreased libido
Tamoxifen	Priapism
Testosterone	Priapism
Thiabendazole	ED
Thiazide diuretics (and chlorthalidone)	ED
Tiagabine	Increased or decreased libido, ED
Tolcapone	Increased or decreased libido, ED
Trimethaphan	ED
Trovafloxacin mesylate	Decreased libido, ED
Valsartan	ED
Vinblastine	Decreased libido, ED, dyspareunia
Zolpidem tartrate	Decreased libido, ED, anorgasmia

Note. ED=erectile dysfunction; MDA=methylenedioxyamphetamine.

## Psychotropic Medication–Induced Sexual Dysfunction

SSRIs are often associated with one or more types of sexual dysfunction, including decreased libido, diminished genital sensation, ED, decreased lubrication, and delayed or inhibited orgasms (Rosen et al. 1999). A review of five randomized, controlled trials showed SSRIs to be associated with a high incidence of sexual dysfunction, between 30% and 60% (Gregorian et al. 2002). Bupropion (immediate and sustained release), mirtazapine, and nefazodone are associated with significantly less risk of inducing sexual dysfunction and might therefore prove superior first choices for depressed medically ill patients who express a desire to remain or attain “normal” sexual functioning (Coleman et al. 1999; Croft et al. 1999).

A variety of strategies are available for dealing with medication-induced sexual dysfunction in patients who are doing well with their antidepressants and are reluctant to relinquish them (Clayton 2002; Rosen et al. 1999). Observation to determine whether the sexual problem is a primary depressive symptom or a medication side effect is the first step. Watchful waiting in the latter case generally demonstrates the tenacity of this side effect, which is un-

like the other, typically acute, side effects of SSRI treatment (Rothschild 2000). As a second step, the psychiatrist should consider lowering the dose, if possible, or changing the timing of the dose to be as distant as possible from anticipated sexual activity. The etiology of sexual dysfunction appears to be based on levels of drug in the periphery and is therefore related to dose and half-life. For patients in stable remission from depression and who are taking short-half-life SSRIs such as paroxetine, fluvoxamine, and sertraline, a drug holiday might be considered (Rothschild 1995). Central nervous system levels of short-half-life SSRIs remain high well after the peripheral levels have dropped to the point at which sexual function can occur normally. Several “antidote” approaches to dealing with SSRI-induced sexual dysfunction have been reported. The drugs include amantadine (Balon 1996; Shrivastava et al. 1995), cyproheptadine, yohimbine, and bupropion. Although results of an open-label study indicated reduced SSRI-induced sexual dysfunction with the addition of bupropion (Kennedy et al. 2002), results from two placebo-controlled trials were contradictory (Clayton et al. 2004; Masand et al. 2001). Findings from open-label studies and case reports suggested that sildenafil might have a beneficial role to play in reversing antidepressant-induced sexual dysfunction in men and women (Nurn-

berg et al. 1999; Salerian et al. 2000; Shen et al. 1999). Results of a randomized, controlled trial demonstrated in men the efficacy of sildenafil in reversing sexual dysfunction from serotonin reuptake-inhibiting antidepressants (Nurnberg et al. 2003).

Priapism, long associated with trazodone use in men but also reported to occur with use of other antidepressants and antipsychotics, must be considered carefully in hospitalized patients who may have other reasons for sluggish blood flow through cavernosal erectile tissues. These factors include leukemia, sickle cell disease, and other hypercoagulable states in both men and women (clitoral priapism). Concurrent treatments with alpha-blockers such as prazosin may make this potentially dangerous side effect even more likely.

The sexual side effects of antipsychotic medications have been underestimated and understudied (Compton and Miller 2001) but most often are related to hyperprolactinemia or autonomic dysfunction (Smith et al. 2002). Side effects have been reported with the new second-generation antipsychotic medications (Wirshing et al. 2003).

## Primary Sexual and Gender Disorders That May Be Present in Medical-Surgical Patients

### Gender Identity Disorders

Genital self-mutilation was first reported in the medical literature more than 100 years ago (Stroch 1901) and is a rare but highly disturbing reason that surgeons request consultation. Dramatic examples of autocastration and autopenectomy (Fisch 1987; McGuire et al. 1998; Mellon et al. 1989), autoamputation of the labia majora (Wise et al. 1989), and self-inflicted vulvar and vaginal lacerations (Standage et al. 1974) have appeared since the mid 1960s. The patients often have gender dysphoric symptoms with or without psychosis. Clinical considerations in the differential diagnosis of gender dysphoria include the conditions listed in Table 17-3 (Brown 2001). Schizophrenia, with or without gender identity disorder, is a major consideration in patients who have self-inflicted genital wounds (Agoub 2000), although most patients who desperately engage in this behavior are not acutely psychotic at the time. We are aware of several cases of incarcerated persons with gender identity disorder who removed their testicles, penises, or both as a result of not receiving hormonal and surgical treatment of the primary condition. These prisoners were not psychotic at the time and had indicated in advance that they would “self-treat” in this

**TABLE 17-3. Differential diagnosis of gender dysphoria**

Primary and secondary transsexualism (DSM-IV-TR gender identity disorder)
Transvestic fetishism with depression or regression
Homophobic homosexuality (sexual disorder not otherwise specified)
Schizophrenia with gender identity disorder
Borderline personality disorder
Body dysmorphic disorder
Gender identity disorder not otherwise specified
Ambiguous or androgynous gender role adaptation
Pseudohermaphroditism
Malingering or factitious disorder
Career female impersonator in crisis
Transgenderist (nonoperative transsexual) in crisis (DSM-IV-TR gender identity disorder NOS)

manner by eliminating the “offending” organs. Catalano et al. (2002) reviewed published case reports of repetitive genital self-mutilation and found differences between those who engaged in this activity repeatedly and those who did so once or twice as a form of self-treatment. Among the differences was that the patients who engaged in repeated activity had a propensity to depressive disorders and “unusual” masturbatory practices.

In hospitals where surgical procedures are performed as part of a comprehensive gender confirmation program, consultation may be requested in the preoperative and perioperative periods. Standards of care for all mental health professionals involved in the evaluation and treatment of patients with gender identity disorder have been established and should be reviewed before consultation (Brown 2001; Meyer et al. 2001). These standards are not full practice guidelines but are minimum requirements of care for both the evaluation and treatment of patients with gender identity disorder. Table 17-4 lists the common somatic treatments of patients with gender identity disorders. When a consultation is requested, patients may be at various stages of physical transition and are likely to be receiving one or more treatments, including cross-sex hormonal treatments that may interact with other medications ordered while the patient is in the hospital (Brown 2001; Lothstein and Brown 1992). Futterweit (1998) discussed the complications of cross-sex hormonal treatments, which are often medically necessary and critical to the mental and physical well-being of these patients. Psychosis in the period immediately after castration, penectomy, and neovaginal construction is rare but is a concern. Rejection by family members or loved ones contributes to depressive symptoms in some patients with gender iden-

**TABLE 17-4. Medical and surgical treatments of gender identity disorders<sup>a</sup>**

<b>Adult natal men with gender identity disorder</b>
Estrogen treatment (lifelong; reduced dose after orchiectomy)
Electrolysis (25–300 hours of manual treatment or four to six sessions of laser treatment)
Laryngeal cartilage shaving
Vocal cord shortening or other voice alteration operations
Liposuction
Rhinoplasty
Jaw reconfiguration
Other facial cosmetic procedures
Penectomy
Neovaginal construction
Augmentation mammoplasty
<b>Adult natal women with gender identity disorder</b>
Testosterone treatment (lifelong; reduced dose after oophorectomy)

Hysterectomy
Oophorectomy
Bilateral mastectomy
Chest wall contouring
Neophallus construction (multiple stages)
Testicular implants
Genitoplasty (maximization of hypertrophied clitoral prominence)

<sup>a</sup>Not all patients need all treatments.

tity disorders both before and after irreversible genital surgery. At times, antidepressant treatment has limited effectiveness, whereas cross-gender hormonal treatment, alone or in combination with antidepressants, can result in dramatic positive responses, including resolution of chronic suicidality.

Patients admitted to surgical or urological services for major genital surgery ideally should already be receiving care from a mental health professional familiar with the case. Because patients often undergo these procedures at a considerable distance from their homes, local psychiatric consultation may be requested. Psychiatrists who are not familiar with these patients should examine their potential negative countertransference reactions in advance (Lothstein 1977). For example, Lothstein (1978) reported that countertransference anxiety in a male anesthesiologist nearly resulted in the death of a male transsexual patient during penectomy and orchiectomy. Brown (1988) and Lothstein (1982) discussed ethical dilemmas surrounding the appropriateness of providing or withholding irreversible genital surgical procedures for gender-dysphoric patients. Although most psychiatrists are not well-versed in the evaluation and treatment of patients

with gender identity disorder, they can still assist the treatment team by providing referral sources and support group contacts for patients with this chronic and severe condition, such as the Harry Benjamin International Gender Dysphoria Association (Meyer et al. 2001).

## Other Sexual Disorders

The paraphilias do not often come to clinical attention in medical settings. “Accidental” injuries in the course of practicing paraphilic activities are cause for admission to medical and surgical units. Comorbidity with other sexual disorders, mood disorders, substance use disorders, and attention-deficit disorders are common (Kafka 2001; Kafka and Prentky 1998). We discuss some of these disorders.

Potentially harmful genital manipulation may be present as an active form of autoerotic behavior (a type of fetishistic interest) or as masochistic instrumentation (i.e., a form of factitious disorder). Catalano et al. (2002) reported the case of a man who repeatedly injected air into his scrotum as part of a paraphilic masturbatory ritual. Wise (1982) reported seven cases of urethral manipulation, including those of a woman with borderline personality disorder who repeatedly inserted razor blades into her urethra and a 14-year-old boy who lodged a pencil in his bladder after urethral masturbation. Complete urinary tract obstruction due to the self-infusion of an expandable foam sealant through the urethra is another example of an unusual situation meriting psychiatric consultation (Kim et al. 2002).

In contrast to active forms of urethral manipulation, Wise (1982) described individuals who frequently presented with recurrent inability to void or persistent pain with urination, readily accepted repeated cystoscopy and catheterization, and may have visited several emergency departments for these interventions. Patients who exhibit this type of behavior often have a less obvious psychopathological condition (e.g., obsessional behavior, sadomasochistic fantasies, or monosymptomatic hypochondriasis) than do “active instrumenters” (those with borderline personality disorder, schizophrenia, or multiple paraphilias). Psychiatric consultation usually is requested after medical and urological evaluations uncover no apparent physical causes of the complaints or when foreign objects are discovered in the bladder. Active inserters may initially deny self-instrumentation, but tactful and nonjudgmental questioning may yield a more complete clinical picture. Psychotherapy may be the treatment of choice and involves a dynamic understanding of “libidinal, structural, and ego psychological constructs” (Wise 1982, p. 225). Although these behaviors appear to

have fetishistic and sadomasochistic elements, analogies to factitious disorder (Munchausen syndrome) are clear, and engaging such patients in treatment may be very difficult (Ford and Feldman 2002).

The paraphilia classified hypoxyphilia in DSM-IV, coded sexual masochism in DSM-IV-TR, and labeled in the literature as *asphyxiophilia*, *autoerotic asphyxia*, and *erotized repetitive hangings* involves the deliberate induction of cerebral anoxia during masturbation to heighten orgasmic intensity (Hucker and Stermac 1992). Practitioners of this potentially lethal sexual behavior rarely seek treatment, but near-fatal self-strangulation may be mistaken for a suicide attempt when encountered in the hospital setting (Johnstone and Huws 1997). However, evidence of suicidal intent was present in only 2 of 157 fatal cases of hypoxyphilia (Hazelwood et al. 1983). Although this behavior is practiced more by men than women, identical “accidental autoerotic death” scenes involving women have been reported (Behrendt et al. 2002).

The literature provides few examples of specific treatment interventions for hypoxyphilia and no results of long-term outcome studies (Hucker 1990). Treatment strategies for other paraphilias used to manage hypoxyphilia include behavior therapy with covert sensitization (Haydn-Smith et al. 1987) and antiandrogenic hormonal treatment (Hucker and Stermac 1992). Lithium carbonate also has been reported to be useful (Cesnick and Coleman 1989). Uva reviewed the literature on this disorder (Uva 1995).

New onset of paraphilic behavior after the age of 30 (assuming the history is accurate and reliable) is extremely uncommon and when present often is associated with structural lesions of the brain. For example, Frohman and colleagues (2002) described a man with known MS who suddenly experienced a paraphilia involving an insatiable urge to touch women’s breasts. New lesions in the right sides of the hypothalamus, mesencephalon, red nucleus, substantia nigra, and internal capsule were found. Developmental disorders such as Asperger’s syndrome also may be associated with the onset of paraphilias (Milton et al. 2002).

Finally, patients with other paraphilias may seek emergency medical treatment for a variety of inadvertent injuries, including trauma from zoophilic contacts with animals (Kirov et al. 2002) and burns due to sadomasochistic activities involving fire, branding, or application of hot waxes (Tanabe et al. 2002). Transvestic fetishists (i.e., cross-dressers) (Brown 2001) who engage in high-risk public behaviors may be assaulted or even killed by homophobic men who engage in violence directed toward transgender, gay, or bisexual persons.

## Pharmacological Treatments of Paraphilic Disorders

Patients who have severe paraphilias necessitating medical or surgical treatment are likely to need pharmacological intervention in addition to psychotherapeutic treatment (Kafka 2001). Antiandrogenic medications are used as an adjunctive treatment of some malignant diseases to limit tumor growth (e.g., prostate cancer) and as primary treatment of moderate to severe sexual disorders and paraphilias (Bradford and Greenberg 1996). “Pure” antiandrogens, including flutamide and nilutamide, block the action of androgen only at the target organs, and the result is greatly elevated gonadotropin and circulating testosterone levels. These drugs are not adequate for monotherapy for paraphilias. Other antiandrogens, including cyproterone acetate (CPA; not available in the United States) and MPA, have progestogenic and antigonadotropic properties, which result in both inhibition of androgen biosynthesis and inhibition of androgen action in the periphery (Bradford 2001; Reilly 2000). In addition, CPA and MPA appear to block central androgen receptor sites that may be important in the generation of deviant sexual fantasies (Cooper 1986, 1987). Results of placebo-controlled trials support the use of antiandrogens for the treatment of moderate to severe paraphilias (Cooper 1981; Kafka 2001), and clinical use of antiandrogens in properly selected and informed patients with paraphilias can yield dramatic results (Neumann and Kalmas 1991; Thibaut et al. 1996). Long-term treatment with MPA is associated with weight gain, increases in systolic blood pressure, gallstone formation, and infertility and possibly with changes in glucose tolerance.

Leuprolide is a synthetic gonadotropin-releasing hormone analogue (luteinizing hormone-releasing hormone agonist) approved by the U.S. Food and Drug Administration in 1985 for the treatment of prostatic cancer. Leuprolide initially stimulates release of luteinizing hormone, follicle-stimulating hormone, and, therefore, testosterone, but further release of luteinizing hormone and follicle-stimulating hormone is blocked after 3–5 days (Allolio et al. 1985). Serum levels of testosterone then decrease to the castrate level. The most common side effect is hot flashes and an initial worsening of sexual symptoms because of the transient increase in testosterone. A depot preparation allows for once-monthly subcutaneous injections in most patients (Krueger and Kaplan 2001). Triptorelin and goserelin are long-acting gonadotropin-releasing hormone analogues that have shown substantial promise in centrally blocking the production of testosterone. Goserelin has been widely used in prostate cancer

treatment (Brogden et al. 1995). Both agents are being used increasingly in the treatment of patients with severe sexual disorders that respond to marked lowering of circulating testosterone levels (see Dickey 1992; Rosler and Witztum 1998). The initial month of treatment is associated with increased levels of testosterone before a rapid depletion of testicular stores occurs. Long-term use of these potent agents is associated with bone demineralization due to the effects of loss of testosterone (Krueger and Kaplan 2001), although it appears that this side effect can be mitigated with bone-saving treatments (Dickey 2002).

In addition to antiandrogens and gonadotropin-releasing hormone agents, orally administered estrogens (e.g., ethinyl estradiol, 0.10 mg/day) have been used as monotherapy for some sexual disorders. Success rates have not been as good as with CPA and MPA, but more important is that the side-effect profile of estrogen is distinctly unfavorable compared with the profiles of CPA and MPA. Specifically, estrogen treatment results in feminization (breast growth, decreased upper-body muscle mass, increased hip fat, and changes in body hair), nausea, vomiting, and the risk of breast cancer in men. These side effects may be desired by some patients with either gender identity disorder or transvestic fetishism, because many of these patients seek feminization as a primary treatment end point (Brown 2001; Meyer et al. 2001). Use of hormonal agents is not without some controversy despite their efficacy in many cases. Cordier et al. (1996) reviewed some of these issues.

Because they have nonspecific effects and significant risks, neuroleptic medications are no longer recommended. Results of small, uncontrolled trials of fluoxetine for a variety of paraphilic and nonparaphilic "sexual addictions" have suggested that this medication may have promise in decreasing the compulsivity associated with these disorders (Kafka 2001). However, many patients who have responded have also met criteria for a mood disorder (Kafka and Prentky 1992). Additional studies are necessary before any definitive statements can be made about the efficacy of SSRIs in the management of sexual disorders, alone or in combination with hormonal treatments (Fedoroff 1995; Levitsky and Owens 1999). The consensus, however, appears to be that these treatments are far more benign than hormonal manipulations and should be considered an initial attempt at treatment in doses similar to those used for obsessive-compulsive disorder. Psychiatrists considering this modality should review published treatment algorithms before initiating treatment (Bradford 2001; Krueger and Kaplan 2000; Reilly et al. 2000).

## Conclusion

---

All phases of the human sexual response are subject to influence by a variety of medical diseases and medications. The question, "Is the sexual dysfunction physical or psychogenic?" is commonly raised, but in every case, consideration should be given to the possible contributions of biological, psychological, and social factors. As this chapter illustrates, it is not a simple matter to determine the relative contributions of somatic disorders and psychological processes in diagnosing sexual problems in the medically ill.

This chapter has reviewed sexual issues in heart disease, cancer, diabetes, renal failure, HIV, and a variety of neurological disorders, but sexuality is affected by most chronic medical illnesses. Nevertheless, because of both patient and physician avoidance, sexual dysfunction can easily escape evaluation and treatment. A disconnect remains between physician application of new knowledge and the patients who need it, because of embarrassment and stigma. Yet, effective psychological and pharmacological treatments are available. Recent advances, such as the use of oral medications for erectile dysfunction, SSRIs for premature ejaculation, bupropion for arousal problems or to treat sexual side effects of other medications, and other drugs that hold promise for the near future, should help close the gap between knowledge and practice.

# 18 Substance-Related Disorders

---

John E. Franklin Jr., M.D., M.Sc.

James L. Levenson, M.D.

Elinore F. McCance-Katz, M.D., Ph.D.

**THE ABILITY TO** recognize and treat substance use disorders (SUDs) is a core competence in psychosomatic medicine. SUDs are common in both inpatient and outpatient medical settings. Alcohol and tobacco use alone contribute to a host of medical illnesses. Illegal drug use taxes the health care system. Drug and alcohol dependence disorders are best characterized as chronic medical illnesses (McLellan et al. 2000). Hepatitis C is an example of a potential long-term complication of even brief drug use, injection drug users being at increased risk. Emergency departments have seen a steady increase in overdoses of drugs, including “club drugs” not prevalent until recently. The long-term effects of perinatal drug abuse are becoming known (Baer et al. 2003; Buka et al. 2003; Thapar et al. 2003). Devastating complications result from the internal concealment of illicit drugs (e.g., body packing) (Traub et al. 2003). Core competence in addiction medicine includes the ability to make accurate diagnoses, initiate treatment, and plan and coordinate services. Some hospitals have specialized addiction consultation services (Fleming et al. 1995; Fuller and Jordan 1994; McDuff et al. 1997), but there is a shortage of board-certified addiction psychiatry specialists. All psychiatrists working in general medical settings are on the front lines of substance abuse and must be sufficiently knowledgeable.

The span of issues for psychiatrists in medical settings includes drug overdose, withdrawal regimens, diagnosis, engaging patients in the therapeutic process, interface with pain management, assessing transplantation candidates, care of trauma and burn patients (who have a high frequency of drug dependency), substance abuse among

pregnant women, drug abuse in geriatric or adolescent patients, and referral to substance abuse specialists. American Psychiatric Association practice guidelines (1995a, 1995b) are valuable resources for the treatment of alcohol, cocaine, and opioid use disorders, and the U.S. Veterans Health Administration has published more recent guidelines (Management of Substance Use Disorders Working Group 2001). Ideally, the psychiatrist is part of an integrated, multidisciplinary approach to thorough medical evaluation and education, nutritional assessment, housing and family assessment, and complex legal issues.

In this chapter, we provide an update on addiction medicine and highlight issues that arise on general medical units, including intoxication and withdrawal and their complications; psychological and psychiatric factors; treatment resistance; recovery environment; and relapse potential.

## DSM-IV-TR Substance-Related Disorders

---

In DSM-IV-TR (American Psychiatric Association 2000), the broad diagnostic category “substance-related disorders” includes disorders caused by substances taken by individuals to alter mood or behavior, disorders caused by unintentional use of a substance, and medication side effects. Substance-related disorders are divided into *substance use disorders*, which include abuse and dependence, and *substance-induced disorders*, which include intoxication,

withdrawal, delirium, dementia, sexual dysfunction, and amnesic, psychotic, mood, anxiety, and sleep disorders.

Substance abuse is a diagnosis of exclusion, to be used only when a patient does not meet, and has never met, criteria for substance dependence. This distinction can be confusing, because the term *substance abuse* is often used in a nondiagnostic sense to refer to a broad spectrum of substance use patterns.

## Definitions

*Abuse* is the harmful use of a substance. *Misuse* is the use of a prescription drug for other than accepted medical practice. *Addiction* is characterized by impaired control over drug use, compulsive use, continued use despite harm, and craving. *Physical dependence* is a state of adaptation that manifests as a specific withdrawal syndrome. *Psychological dependence* is the feeling of need for a specific substance, either for its positive effects or to avoid negative effects associated with abstinence from it.

*Withdrawal* is a substance-specific constellation of symptoms that may occur after cessation or a decrease in use of alcohol or drugs by individuals who are physiologically dependent. Withdrawal syndromes are characterized by symptoms opposite to those characteristic of use of the substance. Withdrawal syndromes vary in severity and are not necessarily proportional to the amount of substance use. Some withdrawal syndromes are associated with significant morbidity and, possibly, mortality if not recognized and treated aggressively (e.g., alcohol and benzodiazepines), whereas others are associated with considerable discomfort but are not life-threatening (e.g., opioids). Withdrawal can sometimes precipitate delirium, psychosis, mood disturbances, anxiety, and disordered sleep. It has been postulated that after acute withdrawal from alcohol, opiates, and stimulants, many milder physiological and psychological disruptions can persist for weeks to months (e.g., disordered sleep and mood disturbance). The concept of a protracted substance-specific withdrawal syndrome has been proposed, but its existence and management remain controversial (Begleiter and Porjesz 1979; Geller 1994; Satel et al. 1993).

*Tolerance* is the need for increasing amounts of a substance to obtain the desired effect (e.g., intoxication) or lesser effect of a substance with continued use of the same amount over time. For example, a series of alcoholic patients in an emergency department had an average blood alcohol concentration of 467 mg/dL—a level known to cause coma or death in an alcohol-naïve individual, yet 88% of these patients were oriented to time, person, and place (Minion et al. 1989).

## General Principles

General principles of management for patients with SUDs in medical settings are summarized in Table 18–1. In general hospitals, there are a number of barriers to detection and treatment of SUDs. The psychiatrist may enter a clinical situation in which considerable misunderstanding and animosity have developed between the patient and the medical care team. Nurses and physicians may overestimate or underestimate the impact of a patient's substance use or may be overly frustrated by rebuffs of attempts to engage an unmotivated patient. Health care professionals may become nihilistic or angry at patients who are repetitively hospitalized with complications of substance use (e.g., alcoholic pancreatitis). Intense negative emotional responses toward patients with SUDs can interfere with proper care (e.g., giving lower rather than higher than usual doses of narcotics for postoperative pain to a heroin addict). Patients may acknowledge their substance use but either not realize or deny its relation to their medical and psychosocial problems. The social network of those with SUDs may be either chaotic or unsupportive or composed mainly of other substance abusers. Patients with SUDs typically do not request psychiatric assistance and often are not told that a psychiatric consultation has been requested. In general, earlier consultations are more desirable, especially if treatment linkage is necessary. While acutely medically ill, patients are often more open to treatment recommendations. Because some patients are reluctant to fully disclose substance abuse or dependence owing to possible legal problems (e.g., issues relating to motor vehicle collisions) or fear of job loss, information gathering can be difficult.

In medical settings, a high index of suspicion for drug and alcohol use disorders is warranted because of their

**TABLE 18–1. General principles of management for patients with substance use disorders in medical settings**

Have a high index of suspicion for drug abuse  
Use early urine toxicological screens.

### Carefully assess for detoxification

Determine the need for inpatient versus outpatient care.

Tailor detoxification for medically ill patients (this approach often needed in this patient population).

Carry out alcohol and sedative detoxification first in case of polysubstance dependence.

Order challenge tests or use conservative estimates if the initial detoxification dose is not clear.

prevalence in the medically ill and their adverse physiological and behavioral effects on disease outcome. Urine toxicological screening should be performed early in the diagnostic evaluation. Tailored detoxification is often needed by medically ill patients; for example, although alcohol detoxification does not routinely necessitate hospitalization, it may for a patient with unstable angina. In polysubstance dependence, alcohol and sedative detoxification is the priority because of the higher risk of morbidity and mortality than with other substances. As a rule, challenge tests or conservative estimates should be used if there is doubt about the initial detoxification dose.

## Acute Assessment

The elements of a basic substance use history are listed in Table 18–2. Important additional aspects of assessment include identifying significant negative countertransference, triage, and establishing patient eligibility for follow-up care (this function is an administrative one, but a consultant must not make unrealistic recommendations). It is often difficult and sometimes impossible during the initial consultation to differentiate the effects of substance intoxication, withdrawal, or chronic use from other psychiatric disorders. A carefully obtained history provides clues that can aid diagnostic differentiation between substance-induced disorders and major mental disorders with comorbid substance abuse or dependence, including the historical sequence of substance use and symptoms of a mental disorder. Elements in the history also indicate whether the psychiatric symptoms have occurred during periods of prolonged sobriety. The family history is important given increasing evidence of the heritability of SUDs. Evaluation of the patient's family is essential as a source of collateral information, for learning the extent of the substance use and its consequences, and because a family system that accommodates the patient's substance use also may reinforce it. Including the family in treatment increases the chances that the patient will remain abstinent.

## Treatment

Proper implementation of treatment always involves patients and their other medical providers. The steps include 1) educating the patient, 2) motivating the patient to accept the recommended treatment plan, 3) encouraging others to work collaboratively with the patient, 4) suggesting pharmacological treatments, when needed, 5) integrating substance abuse treatment into the overall medical and psychiatric treatment plans, and 6) facilitating transfers to appropriate treatment facilities when appropriate.

**TABLE 18–2. Elements of the substance use history**

Chief complaint
History of present illness
Current medical signs and symptoms
Substance abuse review of symptoms for all psychoactive substances
Dates of first use, regular use, heaviest use, longest period of sobriety, pattern, amount, frequency, time of last use, route of administration, circumstances of use, reactions to use
Medical history, medications, HIV status, hepatitis B and C status
History of past substance abuse treatment, response to treatment
Family history, including substance abuse history
Psychiatric history
Legal history
Object-relations history
Personal history

*Source.* Adapted from Frances RJ, Franklin JE Jr: *Concise Guide to Treatment of Alcoholism and Addictions*. Washington, DC, American Psychiatric Press, 1989, p. 62. Used with permission.

Detoxification alone does not constitute treatment of addiction. Some patients with mild substance abuse may resolve drug- or alcohol-related problems without additional treatment (Sobell et al. 1996) or with brief intervention by the consultant or another physician (Barnes and Samet 1997). Brief interventions by primary care physicians have shown promise for heavy drinkers in early addiction patterns (Aalto et al. 2000; Beich et al. 2003; Fleming et al. 2002). Substance dependence, however, is best viewed as a chronic medical illness (McLellan et al. 2000), and many substance-dependent patients benefit from referral to specialized treatments that may be required long-term. Failure to refer can reinforce denial of substance-related problems and enable continued addiction. Treatment of SUDs integrated with regular medical care may reduce inpatient hospitalization rates (Laine et al. 2001).

It is difficult to arrange proper aftercare during a short hospitalization or when financial resources are limited. Insurance coverage varies considerably. In the United States, Medicare and many state Medicaid programs do not cover treatment of SUDs. Many private insurance plans require preauthorization and use a very limited panel of providers. Patients with little or no coverage usually must wait until public treatment slots are available. While waiting, patients often continue use or have relapses. This problem is especially prevalent among patients who have a poor support system and problems with housing, employment, and income (Humphreys et al. 1996).

Recovery is a process in which patients must develop responsibility for their own addiction. Therefore, the role of the psychiatrist and other health care providers is to empathically confront the patient about substance-related problems and to provide support, information, and access to resources, but not to assume total responsibility for patient follow-up. Education and a motivational approach, rather than continuous confrontation, usually work best. The psychiatric consultant is typically not directly involved in a patient's aftercare, so a brief intervention model is needed. An early treatment goal is to have patients accept that their substance use is causing them problems and that some form of treatment is needed.

The most common referrals are to a specialized substance abuse treatment program or to a 12-step group such as Alcoholics Anonymous (AA). Most drug and alcohol treatment programs in the United States emphasize a combination of psychoeducation, participation in a 12-step program, and individual, group, and family counseling. Although resource availability is often a determining factor in follow-up treatment recommendations, guidelines such as those developed by the American Society of Addiction Medicine (Mee-Lee et al. 1994) can be used in referring patients to different levels of care. Because most treatment programs require that patients themselves call for services, the role of the consultant is to inform patients and encourage them to contact programs directly.

AA is a worldwide self-help group of recovering alcoholic individuals that was started in 1936 by Bill Wilson and Robert Smith (Dr. Bob). The only requirement for membership is a desire to stop drinking. Meetings provide members with acceptance, understanding, forgiveness, confrontation, and a means for positive identification. AA uses a 12-step program—12 tenets of recovery that members work through on their way to overcoming addiction. The steps include admitting powerlessness over alcohol, conducting a personal assessment, making amends, and eventually helping others. Members may contact one another outside meetings for sobriety support, and newer members team up with more experienced AA members, sponsors who guide them through the process. Although AA is not affiliated with any religion (25% of AA members identify themselves as atheists), the organization encourages spiritual reevaluation. Members frequently remain active in AA for many years, and AA involvement is generally associated with favorable outcome (Connors et al. 2001; Humphreys et al. 1996; McKellar et al. 2003; Owen et al. 2003; Vaillant 1995) comparable with that of other standard treatment approaches (Ouimette et al. 1997). A prospective study of employed alcoholic patients found that treatment plus AA participation was more effective than AA involvement alone in helping such

individuals attain and continue abstinence (Walsh et al. 1991). In some hospitals, AA members visit inpatients, and many general hospitals host AA meetings.

Other organizations have been modeled on AA. Narcotics Anonymous (NA), founded in 1947, and Cocaine Anonymous (CA), founded in 1982, are two examples. Contacts for AA, NA, and CA can usually be found in local telephone directories or on the organizations' respective Web sites. Patients should be told that some self-help groups address special issues for participants and that it may be necessary for them to attend several different meetings in their area before they find a group that suits them or they make a decision that self-help is not beneficial.

Patients with a substance-related disorder and another psychiatric disorder have better outcomes when both disorders are treated simultaneously and all stakeholders (patients, clinicians, families, and community leaders) are invested (Mueser et al. 1997; Nunes and Quitlin 1997; Torrey et al. 2002). Nevertheless, integrated long-term treatment programs for such patients can be difficult to find. Many psychiatric inpatient units, psychiatric halfway houses, outpatient clinics, and other mental health facilities in the community are unable or unwilling to treat psychiatric patients who also have SUDs. In many substance abuse treatment facilities, there is little if any contact with psychiatrists, and treatment is provided by counselors who have minimal psychiatric training. Integrated programs combine rehabilitation, psychiatric evaluation, and the appropriate use of other treatment modalities, such as psychotherapy and pharmacotherapy. AA, NA, and CA officially support the use of psychotropic medications when necessary. Dual-diagnosis or "double-trouble" groups also use a 12-step approach.

Recommendations for patients after a suicide attempt and a recent history of alcohol or drug use or abuse range from discharge with outpatient mental health and substance abuse follow-up to inpatient psychiatric involuntary commitment (i.e., if there is a strong suicidal risk). When ambivalence exists about the correct disposition, a brief inpatient psychiatric stay for further evaluation usually is prudent.

Patients with concomitant chronic medical illnesses that limit participation in formal substance treatment programs pose special problems. Patients, families, and medical staff may focus so much on the medical illness that substance use is neglected as an issue. Patients may encounter difficulties with transportation or difficulty sustaining the concentration necessary to take full advantage of formal rehabilitation programs. For example, a clinical trial of alcoholism treatment after liver transplantation failed in part because of the patients' infirmity and

need for intensive medical management (Weinrieb et al. 2001). Medically ill patients often feel estranged from the “world of the well.” Devising aftercare programs tailored to such patients’ needs is often difficult. Patients are sometimes seen individually and attend meetings of AA or professional groups as tolerated.

Additional difficulties occur when patients have spinal cord injuries, blindness, deafness, or other physical disabilities. For example, some caregivers involved in the treatment of paraplegic patients experience excessive sympathy that causes them to ignore significant substance abuse problems. However, it is possible to successfully integrate paraplegic patients into standard treatment programs. Deaf patients often need specialized services, such as sign language interpreters, to utilize standard rehabilitation services. Some communities have AA groups for deaf or blind people. Patients with significant cognitive limitations, including mental retardation, traumatic brain injury, and dementia, pose a difficult problem because they are not able to benefit from standard psychosocial treatment approaches, all of which rely on capacity to communicate and learn.

Patients in recovery from addiction and who are abstinent often face the dilemma of whether to take mood-altering substances (e.g., narcotics for pain or anxiolytics for sedation) in the course of the planned treatment. Recovery teaches people to avoid all mood-altering substances because use of these substances can lead to relapse or a substitute addiction. If the hospitalization is elective, such as for ambulatory surgery, the issue can be discussed with drug treatment staff members or AA sponsors. It may be possible to use pain management techniques that avoid the use of narcotics (see Chapter 36, “Pain”). When the issue is discussed in advance and adequate support is provided, most patients do not have relapses. The clinician should encourage AA members and sponsors to visit the patient and should halt treatment with mood-altering medication as soon as medically indicated. Continued or increased need for narcotic medications in the face of improving medical response to the treatment or the development of a pattern of continuing complications resulting in ongoing narcotic requests should lead to an evaluation for recurrence of a SUD.

## Treatment Outcome

Long-term studies have consistently shown that treatment of substance dependence is beneficial and cost-efficient from a public health or societal perspective (McLellan et al. 1996). Predicting which individual patients are more apt to benefit from which type of treatment has been a greater problem. Patients who are more compliant with

and receive more treatment generally do better, as do patients who receive additional treatment directed at specific ancillary problems, such as housing, employment, and comorbid psychiatric illness (McLellan et al. 1997). In Project Match, a large randomized trial of alcohol treatment modalities and predictive pretreatment variables, investigators did not find a robust association between specific treatments and specific indicators (Project Match Research Group 1998). In a similar study, the COMBINE study, investigators are evaluating the efficacy of naltrexone and acamprosate alone or together in combination with different intensities of behavioral therapy (COMBINE Study Research Group 2003). Other potential predictors, such as severity of addiction, social status, number of previous treatment attempts, coping style, family history, and patient self-selection of treatment type, have not been shown to have consistent associations with treatment outcome.

Relapse prevention is essential in treating substance dependence. The goals of relapse prevention are to address ambivalence, reduce drug or alcohol availability, minimize high-risk situations, develop coping strategies, recognize conditioned cues to craving and decision patterns that lead to use, establish alternatives to drug or alcohol use, and avoid the attitude that all is lost if drug use occurs in the context of treatment (Carroll et al. 1991).

## Alcohol-Related Disorders

---

Workers in the addiction field have attempted to more clearly define alcohol use problems, and accuracy is especially important for making a diagnosis in a medical setting. Several hospitalizations for alcohol-related illness can occur before a direct connection is made between a patient’s alcohol use and medical problems. Alcoholic patients tend to experience many alcohol-related problems before seeking professional help or attending AA meetings (Bucholz and Homan 1992). Stigma associated with the term *alcoholism* frequently inhibits physicians and patients from exploring the connections between abuse and biopsychosocial consequences. Psychiatrists participating in a hospital survey positively identified alcohol abuse two-thirds of the time, whereas physicians treating gynecology patients diagnosed the disorder only 10% of the time (Moore et al. 1989). In primary care settings similar underdiagnosis is common; however, in studies that rely on chart review or screening instruments, investigators may underestimate what physicians really suspect to be the case (Rumpf et al. 2001; Rydon et al. 1992).

The official psychiatric nomenclature for alcohol abuse and dependence evolved from the view of alcohol-

ism as a personality disorder (American Psychiatric Association 1952), through recognition of episodic, habitual abuse (American Psychiatric Association 1968), to the more recent definitions in DSM-III (American Psychiatric Association 1980), DSM-III-R (American Psychiatric Association 1987), DSM-IV (American Psychiatric Association 1994), and DSM-IV-TR (American Psychiatric Association 2000). The newer definitions emphasize the complex of psychosocial consequences as well as physiological tolerance and withdrawal as hallmarks of the disease process. The diagnosis of alcohol dependence has been shown over 5 years to be predictive of a chronic, significant course of illness (Schuckit et al. 2001). The National Council on Alcoholism and Drug Dependence and the American Society of Addiction Medicine define alcoholism as a disease process (Morse and Flavin 1992) and disease as an involuntary disability. This definition states that alcoholism is a primary, chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. The disease is often progressive and fatal. It is characterized by impaired control over drinking, preoccupation with alcohol, use of alcohol despite adverse consequences, and distortions in thinking, most notably denial. Each of these symptoms may be continuous or periodic (Morse and Flavin 1992).

## Epidemiological Characteristics

The Epidemiologic Catchment Area study showed that the lifetime prevalence of alcohol abuse or dependence in the general population was 13.6% (Robins et al. 1984). Follow-up data from the same Epidemiologic Catchment Area population revealed a 1-year prevalence for alcohol disorders of 7.4%. Only 22% of these people ever used any mental health or addiction services, and of those, approximately one-half were seen by specialty mental health or addiction professionals. The other half were examined by general medical professionals (Regier et al. 1993). In other words, people who seek consultation for alcohol problems are as likely to see general physicians as they are to see mental health or drug abuse specialists. The revised 1-year prevalence estimates for the 18–54 age group, based on both the Epidemiologic Catchment Area and the National Comorbidity Survey and focusing more on clinical significance, are 6.5% for alcohol use disorders and 2.4% for drug abuse disorders (Narrow et al. 2002). Binge drinking is on the rise among adults and is associated with impaired driving (Naimi et al. 2003).

Alcohol-related problems usually begin between the ages of 16 and 30 years. Data suggest that sales to underage drinkers and adult heavy drinkers account for 50% of alcoholic beverages sold (Foster et al. 2003). Regier et al.

(1990) reported that 53% of persons with an alcohol or drug abuse disorder also have a comorbid psychiatric disorder. Women are more likely than men to present for treatment in mental health or medical settings (Weisner and Schmidt 1992). Men are more likely than women to receive treatment in jails and drug treatment programs. Alcoholism among elderly individuals is increasing and is often difficult to diagnose because the symptoms are often less dramatic than they are among younger persons.

A conservative estimate is that 25% of general hospital inpatients and 20% of medical outpatients have alcohol-related disorders (Cleary et al. 1988; Moore et al. 1989). Diagnosis of these disorders in patients in general hospitals is challenging. For example, a patient may present with cirrhosis and severe gastritis after several years of “moderate” alcohol intake, but no psychosocial sequelae are reported. Detailed, repeated, or collateral history is necessary before the diagnosis of alcohol dependence becomes clear.

Patients with alcoholism usually resist and avoid doctors because of denial, embarrassment, stigma, problems with authority figures, or poor self-care. The medical condition occasionally is the only apparent indication of alcohol abuse. Results of a seminal study by Vaillant (1995) highlighted the fact that medical complications sometimes are the main reason for abstinence, as when alcohol use precipitates gastrointestinal bleeding, a traumatic injury, a sickle-cell crisis, or a seizure.

## Medical and Other Complications

Common alcohol-related medical conditions include gastritis and peptic ulcer, pneumonia, alcoholic hepatitis and cirrhosis, trauma (e.g., traumatic brain injury, subdural hematoma, fractures), pancreatitis, cardiomyopathy, hemorrhagic stroke, labile hypertension, anemia, peripheral neuropathy, fetal alcohol syndrome, amnesic syndrome (Korsakoff’s psychosis), and alcoholic dementia (Lieber 1995; Rehm and Bondy 1998; Reynolds et al. 2003).

Liver disease is the ninth leading cause of death, and alcoholism is a major cause of liver disease. It has been estimated that 75% of patients with chronic pancreatitis are alcohol dependent (Van Thiel et al. 1981). Alcohol use also contributes to increased rates of oral cavity, laryngeal, esophageal, liver, and breast cancers (Cole and Rodu 2001; Singletary and Gapstur 2001). Heavy alcohol use adversely affects the natural course of chronic hepatitis C (Bhattacharya and Shuhart 2003). Women experience increased mortality risk at a lower level of alcohol intake than men. Although in some epidemiological studies limited alcohol consumption, compared with abstinence, has been associated with lower risk of myocardial infarction, ischemic cerebrovascular disease, and

dementia (Mukamal et al. 2003a, 2003b, 2003c), such correlations require replication and may not be simply causal. More important, these results are based on samples from the general population, not the medically ill, and may be misused by alcohol-dependent patients to rationalize continued use of alcohol. The goal for patients with substance abuse and medical conditions should be abstinence, and patients benefit most from integrated primary care and addiction treatment (Weisner et al. 2001).

The total spending for health care services to manage alcohol problems and the medical consequences of alcohol consumption was estimated at \$22.5 billion for 1995, with a total economic cost of \$166.5 billion (National Institute on Drug Abuse and National Institute on Alcohol Abuse and Alcoholism 2001). There is an association between alcohol use and violent crime, including assault, rape, child molestation, and murder. In one study involving 2,095 trauma victims, Meyers et al. (1990) found that 41% of the patients were drinking before sustaining the injuries. In a more recent study, Schermer et al. (2003a) found that 45% of trauma surgery patients had positive screening results for problem alcohol use. Alcohol problems are underrecognized and undertreated on trauma services and burn units (Bernstein et al. 1992; Schermer et al. 2003b) (see Chapter 30, "Surgery"). Orthopedic injuries in alcohol and drug users are more severe and require longer hospitalizations than in nonusers (Levy et al. 1996).

Alcoholism, which is strongly associated with suicide, increases the suicide rate 60–120 times compared with the rate in the nonalcoholic population, particularly in synergy with other predisposing factors such as unemployment, impulsivity, and aggression (Caces and Harford 1998; Mann et al. 1999). The lifetime risk of suicide among alcoholic patients is estimated to be 2.0%–3.4% (Murphy and Wetzel 1990). Alcoholic patients who attempt suicide may have more severe alcohol problems and greater comorbidity than those who do not attempt suicide (Murphy et al. 1992).

## Predisposition and Risk Factors

Alcoholism probably results from a complex interaction among biological vulnerability, family, environment, and culture. Studies involving men and women showed that genetic variables significantly influence incidence, although the mechanism of genetic transmission is unknown (Johnson et al. 1998; Merikangas et al. 1998b). Hypothesized heritable factors include abnormalities in the serotonergic (Lappalainen et al. 1998; Mantere et al. 2002), dopaminergic (Edenberg et al. 1998), and opioid

systems (Camí and Farré 2003; Wand et al. 1998). Functional neuroimaging points to particular areas of the brain associated with craving, intoxication, and withdrawal (Tapert et al. 2003). Inherited variations in alcohol-metabolizing enzymes, such as those common in Asian populations, confer reduced risk of alcoholism (Schuckit 1999). Genotypic variation in neurotransmitter alleles may effect vulnerability to alcohol dependence and its phenotypes (Enoch et al. 2003; Nurnberger et al. 2001). The P300 component of the event-related potential continues to be investigated as a marker of alcoholism (Justus et al. 2001; Suresh et al. 2003).

In a prospective study, Vaillant (1995) found no personality style to be predictive of alcoholism; however, alcoholism occurs more commonly when other psychiatric disorders are present. Neurobehavioral disinhibition in childhood and conduct disorder in adolescence may be risk factors (Tarter et al. 2003), and increased tolerance of alcohol during the teen years may be a marker for future dependence (Schuckit and Smith 2001). There is a rich literature on the relationship between alcohol use and depression (Hasin et al. 2002) and on the shared genetic vulnerability between alcohol dependence and other psychiatric disorders (de Graaf et al. 2002; Fu et al. 2002; Hasin and Grant 2002; Hasin et al. 2002). Alcoholic patients are at increased risk of bipolar disorder, panic disorder, and social phobia but not of non-substance-induced major depressive disorder (Schuckit et al. 1997). In a study involving general hospital patients with borderline personality disorder, 67% of the patients had an SUD (Dulit et al. 1990). Antisocial personality disorder also is associated with alcohol use disorders and with poorer treatment outcome (Kranzler et al. 1996). Debate continues over the explanations for these associations (Jacobsen et al. 2001; Kopelman 1995; Merikangas et al. 1998a). Alcohol use is common in patients with schizophrenia, in whom such use may transiently decrease social anxiety, dysphoria, insomnia, and other nonpsychotic but unpleasant experiences. Alcohol use may also contribute to poor outcome in this population (Cantor-Graae et al. 2001; Drake et al. 1989; Noordsy et al. 1991).

## Specific Disorders

### *Intoxication*

The effects of alcohol intoxication range from mild inebriation to respiratory depression, coma, and, rarely, death. Gamma-aminobutyric acid (GABA), *N*-methyl-D-aspartate (NMDA), and second-messenger systems all mediate physiological effects (Nestler and Self 1997). Alcohol activates GABA-mediated chloride ion channels,

inhibits NMDA-activated ion channels, and potentiates serotonin 5-HT<sub>3</sub> receptor-activated ion channels. GABA subunits may change structurally as tolerance and dependence develop. Alcohol may combine with endogenous and exogenous chemicals such as dopamine and cocaine to produce toxic metabolites (McCance-Katz et al. 1995, 1998).

The body metabolizes alcohol at the rate of approximately 100 mg/kg/hour. Approximately 1.5 hours are required to metabolize 1 ounce (30 mL) of whiskey. Among individuals who have not developed tolerance, a blood alcohol concentration of 0.03 mg% can lead to euphoria, 0.05 mg% can cause mild coordination problems, and 0.1 mg% usually causes ataxia. Anesthesia, coma, and death are associated with a blood alcohol concentration greater than 0.4 mg% (Adams et al. 1997). In patients who engage in chronic heavy drinking and have developed tolerance, high blood levels are reached with fewer of these effects. The first-pass metabolism of alcohol is lower in women because they have lower amounts of gastric alcohol dehydrogenase than do men. This phenomenon may explain the increased bioavailability of alcohol, higher rates of cirrhosis, and lower thresholds for intoxication among women (Frezza et al. 1990).

### *Uncomplicated Withdrawal*

In individuals who have developed tolerance, alcohol withdrawal symptoms develop when a relative decrease in blood alcohol level occurs; therefore, symptoms can occur while drinking continues. A coarse, high-frequency generalized tremor may appear that increases during motor activity or stress (e.g., when the hand or the tongue is extended). The tremor typically peaks 24–48 hours after the last drink and subsides after 5–7 days of abstinence. Patients also often have signs of autonomic hyperactivity, including hypertension, tachycardia, sweating, malaise, nausea, vomiting, anxiety, and disturbed sleep.

Histories can be difficult to obtain during medical emergencies. A patient who is not believed to have alcohol dependence often suddenly develops withdrawal symptoms 1–3 days after surgery. It is often difficult to differentiate withdrawal from other causes of postoperative delirium (see Chapter 30, “Surgery”). Changes in vital signs may have many other explanations in acute medical illness, and concurrent medications (e.g., sedative-hypnotics, beta-blockers, and anticonvulsants) may partially obscure or suppress signs of withdrawal, seriously delaying recognition and full appropriate treatment of withdrawal. The diagnosis is particularly at risk of being missed in patients who are critically ill. The Clinical Institute Withdrawal Assessment for Alcohol—Revised

(CIWA-Ar) is a valuable clinical scale for quantifying withdrawal and following symptoms over time (Sullivan et al. 1991). The CIWA-Ar must be carefully interpreted in the medically ill, because symptoms of other systemic disease may overlap with symptoms of withdrawal (Lambert 2003; Lapid and Bostwick 2002).

### *Withdrawal Seizures*

Withdrawal seizures typically occur 7–38 hours after last alcohol use, peak frequency occurring at approximately 24 hours after last use (Adams et al. 1997). However, a significant fraction (16%) of first seizures in drinkers fall outside the conventionally defined withdrawal period, coming while the person is still drinking or as long as a week after the last drink (Ng et al. 1988). Although the relation of seizures to alcohol use is dose dependent and appears to be causal, the timing of seizures is seemingly random (Ng et al. 1988). Among patients with chronic alcoholism, 10% experience multiple seizures (Espir and Rose 1987). Hypomagnesemia, hypokalemia, respiratory alkalosis, and hypoglycemia all potentially contribute to alcohol withdrawal seizures. As many as one-third of patients who experience withdrawal seizures develop alcohol withdrawal delirium.

### *Withdrawal Delirium (Delirium Tremens)*

Delirium tremens (DT) is characterized by confusion, disorientation, fluctuating or clouded consciousness, and perceptual disturbances. Typical signs and symptoms include delusions, hallucinations, agitation, insomnia, mild fever, and marked autonomic arousal. Patients frequently report vivid visual hallucinations of insects or small animals or other perceptual distortions. These hallucinations are typically (but not invariably) associated with feelings of terror and agitation. Symptoms of DT usually appear 2–3 days after cessation of heavy drinking, peak intensity occurring on the fourth to fifth day. Patients often have a repetitive pattern of DT each time they withdraw from alcohol (Turner et al. 1989). Withdrawal symptoms, which can wax and wane, usually subside after 3 days of adequate treatment, but even well-managed DT can continue to wax and wane for several weeks (Hersh et al. 1997). Untreated DT can last as long as 4–5 weeks. Compared with other alcoholic patients, those with a history of DT or withdrawal seizures report a greater maximum number of drinks per day, more lifetime withdrawal episodes, more sedative-hypnotic abuse, and a greater number of medical problems (Schuckit et al. 1995). DT occurs more frequently and is particularly dangerous in patients who have infections, subdural hematomas, trauma, liver disease, or metabolic disorders. In earlier literature, mortality rates of 15%–20% among patients

with DT were cited, but deaths have become uncommon with adequate treatment (Foy et al. 1997). One study showed that of 334 alcohol-dependent patients presenting with alcohol withdrawal, 6.9% developed DT despite benzodiazepine treatment (Palmstierna 2001). All of the patients with DT had the following five risk factors: 1) current infectious disease, 2) heart rate greater than 120 beats/minute on admission, 3) withdrawal symptoms despite an alcohol concentration greater than 1 g/L body fluid by Breathalyzer test, 4) history of seizures, and 5) history of delirious withdrawal episodes. In a case-control study, Fiellin et al. (2002) identified elevated blood pressure, previous DT or withdrawal seizure, and medical comorbidity as contributing to the risk of DT. In the hospital, physical restraints and 24-hour sitters are sometimes needed to protect the patient and to ensure that intravenous lines are maintained.

### ***Alcohol-Induced Psychotic Disorder***

*Alcoholic hallucinosis*, designated *alcohol-induced psychotic disorder* in DSM-IV-TR, is defined as vivid auditory hallucinations that last at least 1 week and occur soon after the cessation or reduction of heavy alcohol ingestion. The hallucinosis presents with a relatively clear sensorium and few autonomic signs or symptoms. As many as 10%–20% of cases may become chronic (Soyka 1996). The hallucinations sometimes include familiar noises or clear voices. The patient usually responds to these hallucinations with fear, anxiety, and agitation (Victor 1992). Diagnosis is based on a history of recent heavy alcohol use and the absence of schizophrenia or mania. Auditory hallucinations and delusions in alcoholic hallucinosis can closely resemble those in schizophrenia and can make differential diagnosis difficult in the absence of adequate historical findings (Soyka 1990).

### ***Alcohol-Induced Amnestic Disorder***

Persisting alcohol-induced amnestic disorder (Wernicke-Korsakoff syndrome) often begins with an abrupt onset of truncal ataxia, ophthalmoplegia, and delirium (Wernicke's encephalopathy), but it can occur in the absence of the classic symptom constellation (Brew 1986). The etiology of the disorder is thiamine deficiency due to poor nutritional, medical, or other factors. Thiamine deficiency can cause death or, more commonly, persisting, severe, anterograde amnesia (Korsakoff's psychosis) in which memory is not transferred from immediate to long-term memory storage. Approximately 80% of patients with Wernicke's encephalopathy who are treated and survive develop this persisting amnesia (Reuler et al. 1985). Post-mortem examinations show lesions in the brainstem,

diencephalon, and frontal lobes (Kopelman 1995) (see also Chapter 7, "Dementia"; Chapter 23, "Endocrine and Metabolic Disorders"; and Chapter 32, "Neurology and Neurosurgery").

### ***Neurological Disease***

Alcohol-induced dementia is another example of a neuropsychiatric disorder found in patients with chronic alcoholism (see Chapter 7, "Dementia"). Because alcoholic patients have complicated medical histories and are often poor historians, the diagnosis is often presumptive. Other disorders affecting the nervous system associated with chronic alcoholism include polyneuropathy, hepatic encephalopathy, acute or chronic subdural hematoma, and cerebellar degeneration with truncal ataxia. Rare conditions such as central pontine myelinolysis, Marchiafava-Bignami disease, and nutritional amblyopia also occur.

### ***Liver Disease***

Alcohol has direct toxic effects on the liver (Lieber 1988). Alcohol dehydrogenase, a liver enzyme, metabolizes alcohol to toxic acetaldehyde. Aldehyde dehydrogenase catalyzes the transformation of acetaldehyde. Acetic acid, lactic acid, uric acid, and fat are by-products of this process. The first stage of alcoholic liver injury is mild alcoholic hepatitis, which is reversible with abstinence but with continued drinking progresses to cirrhosis. Severe alcoholic hepatitis has a mortality approaching 50% (Haber et al. 2003). Cirrhosis is irreversible and results in hepatic encephalopathy (see Chapter 6, "Delirium"), liver failure, portal hypertension, ascites, and gastrointestinal bleeding. The only definitive way to diagnose alcohol-induced cirrhosis is by liver biopsy. Hepatitis C can accelerate liver damage caused by alcohol consumption, and vice versa.

Cirrhosis decreases the activity and levels of hepatic enzymes, including the cytochrome P450 system. Decreased albumin concentration, common in alcoholic patients with liver disease, increases the bioavailability of most psychotropic drugs. In patients with impaired liver function, the doses of hepatically metabolized medications may have to be reduced. Blood levels of the drugs should be monitored when possible (see Chapter 37, "Psychopharmacology").

### ***Liver Transplantation***

Despite early reluctance to perform liver transplantation on alcoholic patients, approximately 30% of the 3,000 orthotopic liver transplantations in the United States each year are performed on patients with alcoholism. There is reliable evidence that properly screened alcoholic patients rarely return to drinking and that they have rates of

survival and a quality of life comparable with those of nonalcoholic patients (DiMartini et al. 1998, 2002; Lucey et al. 1997). The psychiatric evaluation should include consideration of history of drinking, insight into illness, family insight and support, willingness to consider treatment, social stability, and long-term sobriety predictors such as substitute activities, a sense of hope, and comorbidity with drug use or antisocial personality (DiMartini et al. 2002; Franklin and Paine 2003; Roggla et al. 1996; Tringali et al. 1996). Transplantation and substance abuse are discussed in detail in Chapter 31 (“Organ Transplantation”).

### ***Interaction Between Alcohol and Medications***

The interaction between alcohol and medications can have a wide range of effects (i.e., from lethal overdoses to undermedication) (Table 18–3). Alcohol is partly metabolized through the hepatic microsomal enzyme system that metabolizes other drugs. In the acute phase, alcohol can slow metabolism and increase blood levels of medications, such as oral anticoagulants, diazepam, and phenytoin, which compete for cytochrome P450 enzymes. In the chronic phase, because of cytochrome P450 enzyme induction, alcohol can lead to increased metabolism and decreased blood levels of these medications. Chronic alcohol intake with associated cytochrome P450 enzyme induction can also promote acetaminophen toxicity as a result of the accumulation of toxic metabolites

Conversely, some medications can influence the metabolism of alcohol. For example, chlorpromazine, chloral

hydrate, and cimetidine increase blood alcohol levels by inhibiting alcohol dehydrogenase. Alcohol enhances diazepam absorption, which decreases its safety margin and increases the possibility of overdose. In addition, alcohol increases the potency of other central nervous system (CNS) depressants and has unpredictable effects when used with CNS stimulants. Mild disulfiram-like reactions can occur with oral hypoglycemics (e.g., tolbutamide and chlorpropamide), griseofulvin, metronidazole, and quinacrine. Long-term use of salicylates or nonsteroidal anti-inflammatory drugs and alcohol can lead to gastrointestinal bleeding. Because some alcoholic beverages contain tyramine, monoamine oxidase inhibitors are best avoided in the treatment of active or recovering alcoholic patients.

### **Physical Examination and Laboratory Testing**

Spider nevi, palmar erythema, cigarette burns between the index and middle fingers, poor dental care, jaundice, enlarged liver, abdominal pain, peripheral neuropathy, and muscle weakness are clinical signs of alcoholism. When alcoholic patients present as severely intoxicated, semicomatose, or comatose, complications of alcoholism must be considered, including head injury (e.g., subdural hematoma), stroke, metabolic derangements (e.g., hypoglycemia), hepatic encephalopathy, postictal state, aspiration, and cardiac arrhythmia as well as the possibility of polydrug intoxication.

**TABLE 18–3. Medication interactions with alcohol**

<b>Medication</b>	<b>Effects</b>
Disulfiram (Antabuse)	Flushing, diaphoresis, vomiting, pounding headache, anxiety, confusion
Anticoagulants (oral)	Increased anticoagulation effect with acute alcohol intoxication, decreased effect after chronic alcohol use
Griseofulvin	Minor disulfiram-alcohol-like reaction
Metronidazole	Minor disulfiram-alcohol-like reaction
Oral hypoglycemics	Minor disulfiram-alcohol-like reaction
Tranquilizers, narcotics, antihistamines	Increased central nervous system (CNS) depression
Diazepam	Increased absorption of diazepam, synergistic CNS depression
Phenytoin	Increased anticonvulsant effect with acute intoxication; with chronic alcohol use, alcohol intoxication or withdrawal may lower seizure threshold
Salicylates, nonsteroidal anti-inflammatory drugs	Gastrointestinal bleeding
Chlorpromazine	Increased levels of alcohol
Cimetidine	Increased levels of alcohol
Monoamine oxidase inhibitors	Hypertensive crisis possibly due to adverse reaction to tyramine in some alcoholic beverages

For years investigators have searched for reliable laboratory markers of recent heavy alcohol use (see Table 18–4). Serum gamma-glutamyltransferase (SGGT) levels are increased in more than 50% of patients who have an alcohol problem and in 80% of alcoholic patients with liver dysfunction (Trell et al. 1984). Aspartate aminotransferase (AST) levels are increased in 46% of patients with alcoholism. Decreased white blood cell count and increased mean corpuscular volume and uric acid, triglyceride, alanine aminotransferase (ALT), and blood urea nitrogen (BUN) levels are also common in alcoholism. However, in patients with advanced cirrhosis, liver enzyme levels are sometimes normal, but prothrombin time is increased, and BUN level may be low. One-third of patients with alcoholism have increased blood glucose levels, but it is not uncommon for alcoholic patients with inadequate calorie intake to have hypoglycemia and hypoalbuminemia.

Both the total amount of carbohydrate-deficient transferrin and the ratio of carbohydrate-deficient transferrin to total serum transferrin can help identify heavy alcohol use over time. Stowell et al. (1997) found the test to be approximately 80% sensitive and 90% specific in the detection of chronic consumption of more than 60 g of alcohol daily in a population of male drinkers. Although results may be influenced by tobacco use, age, cirrhosis, sex, and other factors (Stowell et al. 1997; Whitfield et al. 1998), the test may be useful for monitoring for relapse in men and women, particularly when combined with measurement of SGGT concentration (Allen et al. 1999, 2001; Anton et al. 1998). However, no single test or combination of laboratory measures has been found sufficiently sensitive and specific for identification of occult alcohol dependence.

**TABLE 18–4. Laboratory findings associated with alcohol abuse**

Increased mean corpuscular volume
Increased AST, ALT, and lactate dehydrogenase levels
Increased SGGT level (particularly sensitive)
Increased serum carbohydrate-deficient transferrin level
Decreased albumin, vitamin B <sub>12</sub> , and folic acid levels
Increased uric acid and amylase levels, evidence of bone marrow suppression
Prolonged prothrombin time (cirrhosis)

*Note.* ALT=alanine aminotransferase; AST=aspartate aminotransferase; SGGT=serum gamma-glutamyltransferase.

## Screening Tests

Two widely used brief screening tests for the detection of alcoholism are the self-administered Michigan Alcoholism Screening Test (MAST) and the clinician-administered CAGE questionnaire (Table 18–5). The MAST is a 25-question form that is 90% sensitive; the CAGE is a four-item test. The CAGE has been studied in a variety of populations. In a study of pretraumatic and posttraumatic brain injury, sensitivity and specificity both were more than 90% (Ashman et al. 2004). The four-question Rapid Alcohol Problems Screen, the five-question TWEAK test, and the 10-question Alcohol Use Disorders Identification Test have been found more useful than the CAGE in women and ethnically diverse populations (Bradley et al. 1998; Cherpitel 2002; Steinbauer et al. 1998). The Alcohol Use Disorders Identification Test is more sensitive than the CAGE for identification of nondependent hazardous drinking (McCusker et al. 2002). The Patient Health Questionnaire, a brief self-administered screen for psychiatric disorders designed for primary care, also helps identify alcohol use disorders (Spitzer et al. 1999). A single positive response is reasonably effective in identifying problem drinking (Hodgson et al. 2003). The addiction severity index is a treatment planning assessment tool that examines seven areas of patient functioning, including drug and alcohol abuse (McLellan et al. 1980). A review of the various screening instruments is available online through the Center for Substance Abuse Treatment, Treatment Improvement Protocol series (Center for Substance Abuse Treatment 2004).

## Acute Management and Treatment

### *Intoxication*

Intoxicated behavior is managed by decreasing external stimuli, interrupting alcohol ingestion, and protecting

**TABLE 18–5. CAGE questionnaire for the diagnosis of alcoholism**

Have you ever...
<b>C</b> Thought you should CUT back on your drinking?
<b>A</b> Felt ANNOYED by people criticizing your drinking?
<b>G</b> Felt GUILTY or bad about your drinking?
<b>E</b> Had a morning EYE-OPENER to relieve hangover or nerves?

*Note.* Two or three positive responses=high index of suspicion; four positive responses=pathognomonic.

*Source.* Reprinted from Ewing JA: "Detecting Alcoholism: The CAGE Questionnaire." *Journal of the American Medical Association* 252:1905–1907, 1984. Copyright 1984, American Medical Association. Used with permission.

individuals from harming themselves and others until the toxic effects of alcohol disappear. Psychiatrists most often encounter acutely intoxicated patients in the emergency department. No antidote is available in the United States, but elsewhere metadoxine has been found safe and effective in accelerating elimination of alcohol and reducing signs of intoxication (Addolorato et al. 2003). In cases of potentially fatal overdoses, hemodialysis is sometimes attempted.

### *Withdrawal*

The choice of inpatient versus outpatient treatment of withdrawal usually depends on the severity of symptoms, the stage of withdrawal, the presence of medical and psychiatric comorbidity, the presence of polysubstance abuse, patient cooperation, ability to follow instructions, social support systems, patient history, and, increasingly, insurance reimbursement policies. Consultation requests often involve patients whose withdrawal symptoms have been only partially eliminated during detoxification or patients who are not yet beyond danger of serious medical complications.

Not all alcohol-dependent patients need medication for detoxification. Benzer (1990) found that only 10.6% of hospitalized alcohol-dependent patients had withdrawal symptoms severe enough to necessitate medication. Full detoxification, a modified detoxification schedule, or as-needed medication is used depending on the severity of dependence, medical condition, detoxification history, vital signs, and mental status. For routine cases, as-needed (symptom-triggered) oxazepam was found as safe and effective as a fixed-schedule protocol (Daepfen et al. 2002). In alcoholic patients with histories of withdrawal seizures, DT, or otherwise complicated withdrawals or with other serious medical conditions (e.g., coronary artery disease), full medical detoxification should proceed; one should not rely on as-needed medications alone. Safe detoxification occurs when autonomic signs and symptoms are adequately controlled. Sedation is a clinically useful indicator of adequate treatment in early withdrawal.

Benzodiazepines are recommended for the treatment and prevention of withdrawal symptoms (Mayo-Smith 1997). Benzodiazepines are safe, easy to administer, have anticonvulsant properties, and are efficacious. Chlordiazepoxide is commonly used because of its long-acting metabolites. Benzodiazepines such as lorazepam (the only one that can reliably be given orally, intramuscularly, or intravenously) and oxazepam should be used in the treatment of patients with severe liver disease and of elderly patients, because these drugs are metabolized via conjugation rather than oxidation. Otherwise, no clear differ-

ences in efficacy have been found among benzodiazepines. Diazepam is less frequently used in detoxification because of its reported euphorogenic properties in some patients. The benzodiazepines with longer half-lives, such as chlordiazepoxide and clonazepam, may require less frequent administration. Anticonvulsants are being used increasingly in the treatment of alcohol withdrawal and have been shown in a number of studies to be as efficacious as benzodiazepines (Malcolm et al. 2001). A few consultants prefer to use phenobarbital because of its very long half-life, which offers some degree of protection in patients who leave a facility before completing detoxification. Despite the evidence that administration of ethanol is a poor choice for treating alcohol withdrawal in the hospital, the practice continues, primarily among surgeons (Rosenbaum and McCarty 2002). A survey showed that 91% of hospitals still had alcohol in their formularies and that most ethanol was dispensed for alcohol withdrawal (Blondell et al. 2003). Use of alcohol for alcohol detoxification is not considered standard-of-care treatment.

Ideal candidates for outpatient detoxification have good social supports, are highly motivated, and need to be able to make daily clinic visits during the withdrawal period. Furthermore, they have CIWA-Ar scores of 10 or less (Table 18-6), have no history of withdrawal seizures or DT, and do not have medical illnesses that may complicate the withdrawal process (e.g., history of gastrointestinal bleeding or cirrhosis). Optimal inpatient withdrawal follows a symptom-triggered medication protocol with a standardized withdrawal rating scale, such as the CIWA-Ar (Table 18-6). Ward staff must be trained in using such scales, but withdrawal generally is faster and requires less medication with use of the scales (Saitz et al. 1994). Patients initially found to need withdrawal medication on the basis of CIWA-Ar results should be considered for a medication-tapering schedule for safe detoxification.

Nutritional deficiencies of thiamine, vitamin B<sub>12</sub>, and folic acid should be corrected with oral thiamine (100 mg/day), folic acid (1 mg/day orally), daily multivitamins, and adequate nutrition. It is uncertain how long vitamin supplementation should be continued, but because vitamins are inexpensive and harmless, some clinicians recommend continuing them indefinitely. Thiamine 100–200 mg should be given intramuscularly or intravenously to patients with very poor nutrition or who are unable to tolerate oral intake. Intravenous thiamine should be given before glucose infusion, because glucose depletes thiamine stores, which can precipitate acute Wernicke's encephalopathy. Magnesium, potassium, and phosphate all may have to be repleted.

**TABLE 18–6. Pharmacological management of alcohol withdrawal**

<b>Symptom-triggered medication regimens</b>
Administer one of the following medications every 2–4 hours when the CIWA-Ar score is $\geq 10$ : Consider the patient's history, recent alcohol intake, and weight in determining dosage Chlordiazepoxide (50–100 mg orally) Oxazepam (30–60 mg orally) Lorazepam (1–2 mg orally)
Repeat the CIWA-Ar 2–4 hours after every dose to assess the need for further medication
<b>Structured medication regimens</b>
Chlordiazepoxide 50 mg orally every 6 hours for four doses, then 50 mg every 12 hours for two doses, then 25 mg orally every 12 hours for 2 doses, then one dose of 25 mg and discontinue
Lorazepam 2 mg orally every 6 hours for four doses, then 1 mg every 6 hours for eight doses
For severe withdrawal (CIWA-Ar $> 20$ ), lorazepam up to 2–4 mg every 6 hours may be necessary with taper based on symptoms over several days

*Note.* CIWA-Ar=Clinical Institute Withdrawal Assessment for Alcohol—Revised.

Individuals with a history of epilepsy may need additional anticonvulsant medication. For uncomplicated withdrawal seizures, the addition of anticonvulsants to benzodiazepines is not always necessary (D'Onofrio et al. 1999); however, for those who experience a seizure or who have a history of alcohol withdrawal seizures, the addition of carbamazepine or valproate, tapered over 1–2 weeks, can be helpful. Diazepam, 10 mg intravenously, usually aborts status epilepticus; however, the addition of phenytoin is occasionally necessary. Lorazepam has been found to be effective in the emergency setting (Alldredge et al. 2001).

### ***Alcohol-Induced Psychotic Disorder***

When patients experience alcoholic hallucinosis during detoxification, a potent antipsychotic such as haloperidol, 2–5 mg orally twice a day, is typically needed to control agitation and hallucinations, but newer atypical antipsychotics may be efficacious. Although there is a theoretical concern that antipsychotics lower the seizure threshold, this problem is unlikely as long as the patient also is receiving a benzodiazepine. The clinician should reassess the use of antipsychotic medication soon after cessation of symptoms. Continued administration of antipsychotics is seldom needed unless the patient has a chronic alcoholic psychosis (Korsakoff's psychosis).

### ***Delirium Tremens***

The best treatment of DT is prevention through careful assessment and aggressive treatment of significant signs and symptoms of withdrawal. Once it is evident, DT may follow a course of its own. The first principle of management is protection of patients from themselves and others. Sedation and reduced stimulation are needed, and physical restraints may be necessary. Large doses of benzodiazepines usually are required but occasionally are ineffective. A switch to phenobarbital has proved effective in some cases. Propofol has been reported effective in cases of DT refractory to high doses of benzodiazepines (McCowan and Marik 2000). Patients in danger of severe damage due to muscular agitation may need to be pharmacologically paralyzed for their protection and receive mechanical ventilation.

### **Long-Term Medication Management**

Although disulfiram (Antabuse) has not been shown to be generally effective in controlled trials in which adherence has not been monitored (Fuller et al. 1986), this agent may be a useful adjunct for some patients with alcoholism. However, disulfiram therapy should be used only in patients who have made a commitment to long-term treatment, so administration of the drug is rarely initiated in the treatment of general hospital inpatients. Contraindications to disulfiram treatment include severe liver disease, pregnancy, heart disease, and psychosis. Disulfiram also is associated with important drug–drug interactions (e.g., increased levels of phenytoin and isoniazid).

Naltrexone has been shown to reduce the risk of relapse to heavy drinking in alcohol-dependent patients (Garbutt et al. 1999; Volpicelli et al. 1992). The usual dosage is 50 mg orally once a day. In patients with polysubstance dependence, the dose may have to be increased (Oslin et al. 1999). Side effects include headache, nausea, and mild dysphoria. These effects can be minimized if administration is initiated at a dose of 25 mg. Because it is an opioid antagonist, naltrexone cannot be used in the treatment of patients receiving opioid analgesics. Medication compliance significantly affects efficacy. Kranzler et al. (1998) performed preliminary investigations of an injectable, sustained-release form of naltrexone. Large, double-blind, placebo-controlled trials of oral naltrexone have produced mixed results in different populations (Guardia et al. 2002; Krystal et al. 2001; Morris et al. 2001).

### **Treatment Outcome**

Approximately 33% of patients with alcoholism stop drinking without formal treatment intervention, 33% im-

prove with treatment, and 33% never achieve sobriety. Patients who are simply handed lists of community-based substance abuse programs rarely follow through with treatment. Motivational interviewing techniques are important skills that help guide patients to recognize their addiction, resolve ambivalence about changing behaviors, and instill patient ownership of the change process (Miller et al. 2003).

## **Sedative-, Hypnotic-, and Anxiolytic-Related Disorders**

---

### **Abuse and Dependence**

Sedative-hypnotic and alcohol intoxications are similar in symptoms and complications. Because sedative-hypnotic use is so frequent in hospitalized patients, the detection of sedative abuse can be difficult. Abuse rarely starts as a result of treatment of acute anxiety or insomnia in a hospitalized patient. The risk of sedative abuse in chronically medically ill outpatients is far greater. There are three major classes of benzodiazepine abusers: polysubstance abusers, pure sedative abusers, and therapeutic users who have lost control. Individuals prone to polysubstance abuse tend to use sedatives for their calming effects (i.e., to come down after use of a stimulant such as cocaine) and for their ability to decrease dysphoric affects, including anxiety, or to potentiate euphoric effects of other drug classes (e.g., benzodiazepines in combination with methadone to boost euphoria).

Pure sedative abusers usually have significant underlying psychopathological conditions (Martinez-Cano et al. 1999), and relapse is common. In a long-term follow-up study involving subjects with primary sedative-hypnotic dependence, 46% of the subjects continued to abuse drugs after in-hospital rehabilitation treatment (Allgulander et al. 1987). Anyone can develop physiological dependence with low-dose use over several years or high-dose use over weeks to months (Dietch 1983). Patients with a history of other SUDs are at increased risk of benzodiazepine abuse (Ross and Darke 2000). In addition, children of alcoholic individuals may respond differently to benzodiazepines than others and may be more prone to benzodiazepine abuse (Ciraulo et al. 1996).

In general, drugs with short half-lives are more likely to cause abuse, withdrawal, dependence, and addiction than are similar drugs with long half-lives, such as alprazolam versus clonazepam and butalbital versus phenobarbital. However, despite their short half-lives, the non-benzodiazepine hypnotics zolpidem and zopiclone are reported to cause much less abuse and dependence than

benzodiazepines, although they both pose risk in patients with prior substance abuse (Hajak et al. 2003). Rarely prescribed older sedatives such as carisoprodol (Soma), chloral hydrate (Noctec), ethchlorvynol (Placidyl), glutethimide (Doriden), meprobamate (Miltown), methaqualone (Quaalude), and methyprylon (Noludar) have high abuse liability and are associated with severe withdrawal syndromes.

### **Complications**

Most cases of gross benzodiazepine intoxication are self-limiting and are best treated supportively. In severe cases and in overdose, the benzodiazepine antagonist flumazenil can reverse coma (Basile et al. 1991), but use of this agent may be associated with seizures, especially if the patient is benzodiazepine dependent. Elderly patients taking even low-dose sedative-hypnotics are at increased risk of confusion, loss of balance, and falls (Frels et al. 2002). Cognitive deficits are not uncommon with benzodiazepine abuse. These deficits may improve or persist for months after detoxification (Tonne et al. 1995). In one study involving more than 4,000 elderly patients, more than 9% of the patients had been treated with benzodiazepines in the preceding year, and benzodiazepine use was associated with impaired functional status independent of age and other medical conditions (Ried et al. 1998).

The high-potency benzodiazepine flunitrazepam (Rohypnol) has been used illegally to incapacitate women for the purpose of sexual assault and can induce anterograde amnesia. Covert flunitrazepam intoxication should be suspected in sexual assault victims who are amnesic for the assault (Anglin et al. 1997).

### **Withdrawal**

The length of time between last use of a drug and onset of withdrawal is a function of the elimination half-life of the drug. For example, withdrawal symptoms occur 7–10 days after abrupt cessation of diazepam but 1–2 days after cessation of alprazolam. Withdrawal symptoms are similar to those produced by alcohol. Seizures may herald withdrawal and are a potential complication of high-dose, unexpected, or poorly managed benzodiazepine withdrawal. Severe withdrawal can produce psychosis and may result in death.

Treatment of sedative-hypnotic withdrawal is similar to that of withdrawal from alcohol. Because of the high prevalence of polysubstance abuse, a detailed substance use history should be obtained to determine the likelihood of polysubstance withdrawal (Busto et al. 1996). A cross-tolerant sedative is given to prevent benzodiazepine

withdrawal symptoms, and the daily dose is gradually decreased; long-acting benzodiazepines are recommended. Alprazolam is particularly difficult to taper after long-term use or high-dose abuse, and it is usually best to convert treatment to a longer-acting benzodiazepine such as clonazepam, which can be easily withdrawn. For some high-dose abusers, particularly those with serious medical comorbidity, inpatient detoxification may be necessary. Addition of an anticonvulsant (e.g., carbamazepine or valproate) can add an additional margin of safety over the course of a difficult withdrawal process.

The most important factor in minimizing complications during benzodiazepine withdrawal is to decrease the dose by approximately 10% per day; the terminal 10% should be tapered slowly to zero over a 3- to 4-day period. In general, detoxification is accomplished within a 10- to 14-day period, but certain individuals need longer detoxification. Tapering may take weeks or months when patients have been taking benzodiazepines for many years or when the drug is resistant to tapering (e.g., alprazolam).

Certain personality traits, such as dependency and passivity, are associated with higher daily doses, more severe withdrawal symptoms, and treatment failure (Schweizer et al. 1998). Detoxification with shorter-acting benzodiazepines, such as oxazepam or lorazepam, often is used in the treatment of elderly patients and patients with liver or pulmonary disease. Anticonvulsants and propranolol are reportedly useful adjuncts in treating prolonged withdrawal symptoms when long-term benzodiazepine therapy is discontinued (Schweizer et al. 1991).

## Prevention and Acute Management

Preventing habituation to sedative-hypnotic drugs is the best prevention of abuse and dependence. Limited prescriptions, single-source policies (i.e., obtaining prescriptions from one provider), and appropriate follow-up all are helpful. General guidelines for anxiolytic treatment are reviewed in Chapter 12 (“Anxiety Disorders”) and hypnotic use in Chapter 16 (“Sleep Disorders”). Sedative-hypnotics should usually be avoided in the treatment of patients with alcoholism and those with a history of substance abuse.

## Opioid-Related Disorders

---

Opioid abuse manifests in various ways in patients in medical settings. Psychiatrists are frequently consulted regarding opioid therapy for patients who are prescribed methadone, are thought or known to be dependent on prescription or illicit narcotics, engage in drug-seeking

behavior, exhibit personality problems that interfere with medical care, or have overdosed. Suspicion is heightened by exaggerated pain complaints, by visits to multiple providers for multiple pain complaints requiring a narcotic prescription (e.g., migraine, back pain, dental pain, fibromyalgia, and endometriosis), and by claims to be “allergic” to every analgesic except for particular opioids (e.g., hydrocodone or oxycodone).

Opioid-dependent patients often provoke angry reactions from staff, which can result in discharging a patient prematurely or underprescribing pain medications. Chronic pain patients who develop tolerance to opioids and experience opiate withdrawal on cessation of use are often mislabeled addicts (see Chapter 36, “Pain”). Tolerance and withdrawal alone are not sufficient for the diagnosis of either substance abuse or dependence. For example, cancer patients with painful bone metastatic lesions may need high doses of narcotics and are unlikely to become psychologically dependent or engage in addictive behaviors.

Deaths related to heroin overdose are common and recently have been on the rise, resulting from variations in purity and the presence of contaminants (Office of Applied Studies 2003). Although most heroin is taken intravenously, snorting has become more popular among users who fear contracting HIV infection or hepatitis C. Poly-substance abuse is extremely common among people addicted to opiates. The combination of heroin and cocaine (“speedballing”) is one of the most frequent combinations, and concomitant alcohol use is common. Heroin abuse exists among working middle- and upper-class individuals as well as the poor. Rates of misuse of, and death from, use of controlled-release oxycodone and similar prescription drugs doubled between 1992 and 2000 (Office of Applied Studies 2004). Synthetic opioids such as fentanyl are abused by individuals who have easy access, such as nurses, physicians, and especially anesthesiologists.

## Epidemiological Characteristics

Estimates of opioid abuse derive from overdose reports, surveys, the prevalence of medical complications, reports of arrests, and data on admissions into treatment programs. In the United States most of the approximately 1 million individuals with chronic opioid dependence are not in treatment. Difficult-to-reach addicts are an intense focus for HIV and tuberculosis education programs and intervention.

## Pathophysiological Mechanism

There are three major subtypes of opioid receptors: mu, sigma, and kappa. Opioids that bind at the mu receptor

produce analgesia, altered mood (often euphoria), sedation, respiratory depression, reduced gastrointestinal motility, inhibition of certain spinal polysynaptic reflexes, cough suppression, suppression of corticotropin-releasing factor and adrenocorticotrophic hormone, miosis, pruritis, and nausea and vomiting. Certain individuals may be prone to addiction because of a hypothesized hypoactivity of the endogenous opioid system. In one study of 3,372 male twin pairs, genetic factors were calculated to account for 38% of the variance in heroin abuse (Tsuang et al. 1998).

## Comorbidity

Among people addicted to opiates, the prevalence of other psychiatric disorders is high (Frei and Rehm 2002; Rounsaville et al. 1982). However, it is often difficult to separate the symptoms of chronic intoxication and withdrawal from those of preexisting Axis I and II pathological conditions. During initial rehabilitation, symptoms of depression are not as likely to remit as they are in alcoholic patients. Rounsaville and Kleber (1985) found that opiate-dependent people who sought treatment in community programs were more often depressed than an untreated community sample and had poorer social functioning, increased nonspecific anxiety symptoms, and more drug-related legal problems. These factors probably facilitate crises that lead patients to treatment.

Contaminated needles and impure drugs can cause endocarditis, septicemia, pulmonary emboli, pulmonary hypertension, skin infections, hepatitis C and B, and HIV infection. Of persons injecting drugs for at least 5 years, 60%–80% are infected with hepatitis C (Centers for Disease Control and Prevention 2002). Intravenous drug use and sexual contact with those who use are major routes of transmission of HIV in the United States and elsewhere (see Chapter 28, “HIV/AIDS”). Chronic constipation is common in chronic opioid users and can cause recurrent abdominal pain simulating intestinal obstruction (Rogers and Cerda 1989).

## Intoxication and Withdrawal

Physical signs of intoxication include pupillary constriction (so-called pinpoint pupils), decreased gastrointestinal motility, marked sedation, slurred speech, and impairment in attention and memory. Daily use of opioids for days to weeks, depending on the dosage and potency of the drug, can produce intensely uncomfortable but non-life-threatening withdrawal syndromes after cessation.

The onset of opioid withdrawal depends on the half-life of the opioid and the chronicity of use; symptoms be-

gin approximately 8–10 hours after the last dose of short-acting opioids such as morphine and heroin. Opioid withdrawal presents as a flulike syndrome. The symptoms include anxiety, dysphoria, yawning, sweating, rhinorrhea, lacrimation, pupillary dilatation, piloerection (the origin of the term “cold turkey”), mild hypertension, tachycardia, disruption of sleep, hot and cold flashes, deep muscle and joint pain, nausea, vomiting, diarrhea, abdominal pain, weight loss, and fever. Subacute, protracted withdrawal symptoms can last for several weeks.

Urine toxicological screening should be performed whenever opioid abuse is suspected. In many hospital toxicological screens, synthetic opioids are not detected as part of the initial screen, so specific testing may be needed if this problem is suspected. Quinolone antibiotics can produce false positive opiate results (Baden et al. 2001).

An opioid overdose should be considered in any patient who presents in a coma, especially when respiratory depression, pupillary constriction, or needle marks are present. Naloxone (0.4 mg) should be given immediately, even without certainty that the coma is due to opioids, because this drug is harmless (except for the risk that excessive naloxone can precipitate severe withdrawal in opioid-dependent individuals). In cases in which it does appear that an opioid overdose is the cause of coma, administration of naloxone is repeated because the drug has a short duration of action. In overdose of long-acting opioids such as methadone, treatment in an intensive care unit and a naloxone intravenous drip may be instituted.

In pregnant women, methadone doses of more than 20 mg/day are associated with moderate to severe withdrawal in newborns (Ostrea and Welch 1991). However, in the care of pregnant women already receiving methadone treatment, opioid withdrawal is not recommended (Center for Substance Abuse Treatment 1993). In the United States the standard of care for the treatment of pregnant women found to be heroin addicted is methadone therapy. The outcome of infant withdrawal improves when mothers are supervised in methadone maintenance programs (Harris-Allen 1991) compared with when mothers are opiate addicted but are not in methadone maintenance programs.

## Acute Management and Treatment

Two methods of treatment are available for actively using opioid-dependent individuals in a general hospital—detoxification and agonist maintenance. Detoxification is often needed for general hospital patients who are abusing street drugs such as heroin or prescription drugs such as oxycodone, meperidine, and codeine. Agonist mainte-

nance is rarely initiated in the general hospital unless it is part of pain management; more often, the consulting psychiatrist is asked to advise on the continuation or modification of ongoing outpatient maintenance. When opioid dependence is questionable, the consultant can perform a naloxone challenge test by administering naloxone 0.4 mg intravenously. Abrupt onset or worsening of withdrawal symptoms strongly supports a diagnosis of opioid dependence.

### *Agonist Maintenance*

Dole and Nyswander in 1965 first postulated that methadone would diminish drug-seeking behavior, increase personal productivity, and decrease illicit activities because wide fluctuations in opioid blood levels would cease. In "hard-core addicts" (i.e., opioid-addicted patients who have been using drugs two or more times per day for more than a year or who are continuously involved in drug street life), methadone therapy continues to contribute to improved health, decreased crime, increased employment, and decreased risk of HIV infection (Office of National Drug Control Policy 2001).

Methadone is relatively long acting with a half-life of 24–36 hours. The long half-life prevents extreme fluctuation in opioid blood levels. Methadone, at doses of approximately 80 mg daily, also blunts the euphoric response to heroin. Unlike heroin, which has a half-life of 8–12 hours, methadone is taken once daily, usually orally, but it can be given intramuscularly (in divided doses) or intravenously (one-third of oral maintenance dose). Once-daily administration provides a structure for rehabilitation and is superior to drug-free treatment of hard-core addicts (Sees et al. 2000). With ongoing participation in psychosocial therapies in addition to methadone maintenance, the goal of treatment is that the addicted person no longer engages in illegal activities to support a costly habit and is able to successfully obtain and keep gainful employment and attend to family and social responsibilities. Common side effects of methadone are sedation, mild euphoria, constipation, and reduced sweating.

A frequent mistake made by medical staff is to base an initial methadone dose solely on how a patient looks, how a patient says he or she feels, and vital signs. The Clinical Opiate Withdrawal Scale is a useful, standardized, clinician-administered rating scale that combines signs and symptoms for assessment of severity of withdrawal (Wesson and Ling 2003). Hospitalized patients receiving methadone maintenance should continue to receive methadone on the basis of their preadmission dose, which should be verified with the methadone clinic, unless methadone is medically contraindicated. An average maintenance dos-

age is 80 mg/day, but occasionally higher maintenance doses are given.

Several medications, including rifampin, phenobarbital, phenytoin, and carbamazepine (Gourevitch and Friedland 2000), efavirenz (McCance-Katz et al. 2002), and lopinavir/ritonavir (McCance-Katz et al. 2003), increase methadone metabolism, placing patients at risk of opiate withdrawal. Methadone also increases plasma desipramine concentration (Kosten et al. 1990). Methadone should not be combined with monoamine oxidase inhibitors. Methadone maintenance is possible in patients with liver disease until late stages of the disease. The dose should be reduced by at least one-half in patients with impaired hepatic function.

Buprenorphine, a long-acting mu opioid receptor partial agonist, was approved by the U.S. Food and Drug Administration in 2003 as a Schedule III narcotic for the treatment of opioid dependence. At lower doses buprenorphine functions as an opioid agonist, but at higher doses it has antagonist properties. This drug has shown promise in clinical trials for use in outpatient maintenance therapy for opioid dependence, with sublingual administration daily to three times a week, at an average dosage of 9 mg/day (Ling et al. 1998). However, the average clinical dosage is 16 mg/day and ranges from 8 to 32 mg/day. Clinical trials support the feasibility and effectiveness of having trained primary care physicians in private offices prescribe buprenorphine or buprenorphine/naloxone administered sublingually for the treatment of opioid dependence (Fudala et al. 2003). Prescribing physicians must apply for and receive a waiver from the Center for Substance Abuse Treatment. A physician can obtain the waiver by meeting one of the qualifications listed in the enabling legislation or by participating in an 8-hour training program. Buprenorphine/naloxone in a 4:1 ratio is the formulation to be used for maintenance therapy (e.g., 8/2 mg is 8 mg of buprenorphine and 2 mg of naloxone). The addition of naloxone prevents diversion of the drug to injected use by those who are opioid dependent. Because of the partial agonist properties of buprenorphine, opioid-dependent patients must show objective signs of opiate withdrawal before dosing. This requirement usually means that at least 6 hours have elapsed since the previous dose of opioid was self-administered. Induction is conducted over several hours on day 1, with patients receiving up to 4/1 mg initially and observation. The initial dose is followed by another 4/1 mg if opioid withdrawal symptoms persist after 2 hours for a total dose on day 1 not to exceed 8/2 mg. This dose can be increased to 16/4 mg if needed on day 2. Most patients need 16/4 mg daily (R.E. Johnson et al. 2003). The hope is that this approach will increase access to treatment not only for

heroin addicts but also for persons addicted to prescription opioids, because the office setting is less stigmatizing and more anonymous than that of methadone clinics. The utility of buprenorphine for short-term detoxification in medical or psychiatric settings is receiving study in the National Drug Abuse Treatment Clinical Trials Network (see [http://www.nida.nih.gov/CTN/brochures/pat\\_info\\_ctn\\_001.html](http://www.nida.nih.gov/CTN/brochures/pat_info_ctn_001.html)). Buprenorphine is new, and many details of how to best use it require further investigation (Gowing et al. 2000).

### ***Methadone Detoxification***

Methadone detoxification is a viable option for patients who have good pretreatment functioning, have long-term success with a low dose of methadone, are less connected to “street culture,” or are addicted to opioids other than heroin. Slow outpatient detoxification (i.e., decreasing by 10% per week until the daily dose is 10–20 mg and then decreasing by 3% per week) reduces relapse rates. Clonidine or buprenorphine can be substituted toward the end of methadone detoxification, when the methadone dose is 20 mg or less

## **Detoxification From Heroin and Other Opiates**

For opioid-dependent patients hospitalized on a general medical unit who are not already taking methadone, 30–40 mg/day in divided doses over the first 24 hours is a reasonable methadone detoxification dosage. Agonist detoxification from heroin, morphine, meperidine, and weaker opioids (e.g., codeine and oxycodone) is generally accomplished by giving sufficient methadone to reduce withdrawal symptoms and then decreasing the dose by 20% each day over a 5- to 7-day period. Patients may need other medications for symptoms of opiate withdrawal, including diarrhea, muscle and stomach cramps, and insomnia (e.g., dicyclomine, ibuprofen, atropine [Kaopectate], and lorazepam).

### ***Detoxification With Clonidine***

Clonidine blocks the autonomic manifestations of opioid withdrawal. Results of several studies have confirmed the usefulness of clonidine for inpatient detoxification from opioids (Charney et al. 1981). A clinical trial in hospitalized heroin-dependent patients with HIV infection showed clonidine to be as effective as methadone or buprenorphine. Results have been less impressive in outpatient trials (Kleber et al. 1985, McCann et al. 1997). In clinical trials in which the subjects were outpatients, clonidine was inferior to buprenorphine (Fingerhood et al. 2001;

Gowing et al. 2000; O’Connor et al. 1997). Although it suppresses autonomic signs of withdrawal, clonidine is less effective in relieving subjective discomfort (Jasinski et al. 1985). Clonidine may be administered orally, transdermally (via the Catapres TTS-1, -2, or -3 patch), or in combination. The advantage of the patch is once-a-week application, which is usually adequate. The patch is more difficult to use in the care of elderly patients because it can cause orthostasis. In addition, the patch can have adverse interactions with other drugs and may not be effective in cases of severe dependence. Sedation and hypotension are common side effects and limit the dose of clonidine. Although clonidine is widely used, U.S. Food and Drug Administration has not approved it for the management of opioid detoxification. As with agonist detoxification, patients detoxified with clonidine may need adjunctive medications for reduction of auxiliary withdrawal symptoms.

### ***Detoxification With Clonidine and Naltrexone***

A combination of clonidine and low-dose naltrexone can be used for opiate detoxification. Detoxification with this combination is more effective than detoxification with clonidine alone (O’Connor et al. 1997). The combination may shorten the withdrawal period to 3 or 4 days, clonidine diminishing the naltrexone-associated withdrawal. Higher doses of clonidine often are necessary for successful use of this combination in outpatients (Stine and Kosten 1992).

## **Opiate Addiction and Pain**

The general principles of evaluation and treatment of pain in opioid-dependent individuals are similar to those for other patients with pain and are reviewed in Chapter 36 (“Pain”). However, treatment complexities can arise when opioid-addicted patients develop acute or chronic pain syndromes. The consultant must ensure that adequate pain medications are prescribed and that as-needed medication schedules are avoided. Opioid-dependent patients need higher doses of narcotics for acute pain control as a result of tolerance. When given only standard doses, addicted patients legitimately state they need more narcotic, but the staff may misinterpret this request as drug seeking. On the other hand, some opioid-dependent patients are inappropriately demanding and truly drug seeking. Explicit expectations and behavioral limits must be established early and ideally by means of a written contract with the patient. When they are used for analgesia, such as for postoperative pain, opioids should be tapered at the same percentage rate in both non-opioid-dependent and opioid-dependent patients.

## Cocaine-Related Disorders

---

DSM-IV-TR describes both *cocaine use disorders* (cocaine dependence and cocaine abuse) and *cocaine-induced disorders* (cocaine intoxication, cocaine withdrawal, cocaine intoxication delirium, cocaine-induced sexual dysfunction, cocaine-induced psychotic, mood, anxiety, and sleep disorders).

### Epidemiological Characteristics

An estimated 193,034 U.S. emergency department visits solely for cocaine use were documented in the 2001 Drug Abuse Warning Network (Office of Applied Studies 2003), and cocaine is the most frequently reported drug in emergency department visits. Frequent reasons for psychiatric consultation in the medical setting are cocaine overdose, positive results of a urine toxicological screen, cocaine-induced depression, cocaine-induced cardiac problems, and cocaine-induced psychosis. According to the 1998 National Household Survey on Drug Abuse, 1.8 million individuals in the United States had used cocaine during a 1-month period (Office of Applied Studies 1999). Use of crack cocaine is especially high in poor urban areas (Rees Davis et al. 2003), but its use is widespread among other populations, such as rural migrant workers. Many cocaine users are polysubstance abusers (Community Epidemiology Working Group 2001).

### Pharmacological Characteristics

Cocaine hydrochloride is a white crystalline powder derived from the coca plant. It is usually diluted to 20% purity by mixing with other local anesthetics, such as lidocaine or procaine, or various sugars. Freebase cocaine is prepared from the hydrochloride salt by alkalization and extraction with organic solvents. Crack or rock cocaine is a prepackaged freebase form of cocaine that is ready for smoking. "Freebasing" is smoking freebase cocaine; intense euphoria begins within seconds. Because freebased cocaine is absorbed directly from the lungs, it goes immediately to the brain, bypassing the liver. Euphoric effects depend on blood levels and on the slope to peak concentration. Most cocaine is hydrolyzed in the body to benzoylecgonine, which is detectable in the urine up to 36 hours after use. High doses are detectable for up to 3 weeks. Rapid tolerance develops to the euphoric effects of cocaine. Cocaine and alcohol may combine to make a toxic metabolite called *cocaethylene*, which is potentially quite cardiotoxic (McCance-Katz et al. 1995, 1998).

### Pathophysiological Mechanism

Cocaine blocks reuptake of neuronal dopamine, serotonin, and norepinephrine. With repeated cocaine use, tolerance develops rapidly as a result of decreased reuptake inhibition and release of catecholamines and altered receptor sensitivity. Hypotheses to explain the severe craving associated with cocaine dependence have included cortical kindling (Halikas et al. 1991), altered opioid receptor binding (Zubieta et al. 1996), altered dopaminergic or serotonergic function (Satel et al. 1995), and hedonistic deregulation (Koob et al. 1997). Neuropsychological deficits and cortical tissue loss (measured by magnetic resonance imaging) are reported (Franklin et al. 2002; Gottschalk et al. 2001). Functional neuroimaging is focusing on dysfunction of dopaminergic systems in the orbitofrontal and memory circuits (Goldstein and Volkow 2002, Volkow et al. 2002), and genetic risk factors may also be important in determining cocaine abuse (Kendler et al. 2003a, 2003b).

### Intoxication

Intoxication is characterized by euphoria, hyperalertness, grandiosity, and impaired judgment. Individuals are more gregarious or withdrawn; may have increased anxiety, restlessness, and vigilance; and exhibit stereotypical behavior. Maladaptive behavior includes fighting, psychomotor agitation, and impaired social or occupational functioning.

Cocaine binges can last for a few hours to several days. Tolerance to the euphoric effects develops during the course of a binge. Physical signs of use include tachycardia, pupillary dilation, increased blood pressure, perspiration, chills, nausea and vomiting, and visual and tactile hallucinations. Paranoia occurs with high doses and chronic or binge use of cocaine and is usually of brief duration. In one study, experienced cocaine users given intravenous cocaine became uniformly paranoid (Sherer et al. 1988). These symptoms usually remit, but heavy, prolonged use or a preexisting psychopathological disorder may result in persistent psychosis. Bizarre obsessive and ritualistic behaviors, such as skin picking, are reported.

### Withdrawal or Abstinence

Medically uncomplicated withdrawal occurs with cessation of or decreases in cocaine use after regular, high doses.

### Medical and Other Complications

Cocaine use is associated with acute and chronic medical ailments (e.g., chronic intranasal use leads to septal necro-

sis). Anesthetic properties of cocaine can lead to oral numbness and dental neglect. Cocaine binges can cause malnutrition, severe weight loss, and dehydration. Intravenous cocaine use, because of contaminants, can result in endocarditis, septicemia, HIV infection, local vasculitis, hepatitis B and C, emphysema, pulmonary emboli, and granuloma. Freebasing of cocaine is associated with decreased pulmonary gas exchange, and pulmonary dysfunction can persist (Itkomen et al. 1984).

In New York City, one of every five individuals who committed suicide during a 1-year period used cocaine immediately before his or her death (Marzuk et al. 1992). Congenital deficiency of pseudocholinesterase slows metabolism of cocaine, and the slowed metabolism can result in toxic levels, sudden delirium, and hyperthermia. Cocaine can cause acute agitation, diaphoresis, tachycardia, metabolic and respiratory acidosis, cardiac dysrhythmia, grand mal seizures, and, ultimately, respiratory arrest. Cardiac complications include acute chest pain, myocardial infarction, congestive heart failure, arrhythmias, endocarditis, aortic dissection, and cardiomyopathy. Approximately 25% of cases of myocardial infarction in adults younger than 45 years are attributable to cocaine (Qureshi et al. 2001). Cardiac disease has been found commonly (38%), even in young asymptomatic chronic cocaine users (Roldan et al. 2001). Cocaine is associated with increased risk of hemorrhagic and ischemic stroke (Pettiti et al. 1998) as well as acute rhabdomyolysis (Ruttenber et al. 1999). Neuropsychological deficits may persist after 1 year of abstinence (Toomey et al. 2003). Death from cocaine toxicity is not linearly correlated with dose, and deaths have occurred among recreational, low-dose users. Pregnant women who use cocaine are at increased risk of abruptio placentae. A “crack baby” syndrome including both physical and psychological abnormalities was widely described in offspring of mothers who used cocaine during pregnancy (Eyler et al. 1998a, 1998b). However, authors of a systematic literature review concluded that “there is no convincing evidence that prenatal cocaine exposure is associated with developmental toxic effects that are different in severity, scope, or kind from the sequelae of multiple other risk factors..., including prenatal exposure to tobacco, marijuana, or alcohol, and the quality of the child’s environment” (Frank et al. 2001, p. 1614).

### Acute Management and Referral

Agitation and anxiety associated with cocaine intoxication are treated with benzodiazepines. Beta-blockers are contraindicated for this purpose because they cause unop-

posed alpha-adrenergic stimulation. Dihydropyridine-class calcium channel antagonists have been proposed for the treatment of cocaine-induced stroke (Johnson et al. 2001). Patients with cocaine-associated chest pain who do not have acute cardiac complications after 9–12 hours may require only a brief observation period in the hospital (Weber et al. 2003). Haloperidol is usually effective in the treatment of cocaine-associated psychosis. Withdrawal depression generally does not necessitate use of antidepressant medication. McCance (1997) noted that although more than 30 medications have undergone clinical trials, no medication has shown consistent efficacy in the treatment of cocaine dependence or in the reduction of craving for the drug. Medications investigated include tricyclic antidepressants, selective serotonin reuptake inhibitors, anticonvulsants, dopamine agonists and antagonists, and miscellaneous agents such as bupropion, naltrexone, methylphenidate, and tyrosine. Baclofen, a GABAergic agent, has shown promise as a treatment for cocaine dependence and is undergoing clinical trials (Shoptaw et al. 2003). When a comorbid psychiatric disorder, such as major depression, bipolar disorder, or schizophrenia, is present, optimal concurrent treatment of that disorder is essential to rehabilitation of cocaine users.

### Treatment Outcome

Treatment outcome is affected by severity of psychosocial problems, family support, intensity of withdrawal, and degree of antisocial features in addition to initial motivation for treatment. In a randomized multicenter trial Crits-Christoph et al. (1999) compared four manual-guided psychotherapeutic treatments of cocaine dependence. Individual drug counseling combined with group drug counseling proved more effective in reducing cocaine use than cognitive psychotherapy, supportive-expressive psychotherapy, or group drug counseling alone. Positive and community reinforcement therapy with vouchers is also promising (Higgins et al. 2003). Not surprisingly, relapse rates after treatment are lowest among patients with the fewest psychosocial problems (Simpson et al. 1999). People who abuse cocaine must avoid alcohol and other mood-altering drugs, which disinhibit behavior and lead to relapse. This concept is difficult for cocaine-dependent individuals to accept, because they merely want to quit cocaine use. Treatment of clearly defined attention-deficit/hyperactivity disorder (Levin et al. 1998) should proceed in concert with treatment of cocaine dependence, but methylphenidate has not been proved to have any effect on cocaine use itself (Schubiner et al. 2002), and stimulants carry their own risk of abuse.

## Amphetamine-Related Disorders

---

Amphetamines (speed) have stimulant and reinforcing properties similar to those of cocaine. Amphetamines cause catecholamine release, especially of dopamine. The signs and symptoms of amphetamine intoxication include tachycardia, increased blood pressure, pupillary dilatation, agitation, elation, loquacity, and hypervigilance. In contrast to cocaine, amphetamines rarely cause myocardial infarction (Costa et al. 2001). Amphetamine psychosis can resemble acute paranoid schizophrenia. Visual hallucinations are common. Binge episodes (“runs”), which are similar to those experienced with cocaine use, often alternate with symptoms of a severe crash. Polysubstance use is common.

CNS stimulants, such as dextroamphetamine and methylphenidate, are prescribed for the treatment of narcolepsy, attention-deficit/hyperactivity disorder, and fatigue in multiple sclerosis, but the doses used infrequently cause adverse effects such as insomnia, irritability, confusion, and hostility. Amphetamine abuse can start in an attempt to lose weight or to enhance energy.

### Epidemiological Characteristics and Complications

Abuse of methamphetamine (“ice”) is a particular problem in the midwestern, western, and southwestern United States but has been spreading into other parts of the country (Community Epidemiology Working Group 2001)—2.1% of the population has tried methamphetamine at least once. Among the so-called club drugs, methamphetamine abuse accounted for the largest share of reported emergency visits 15,000 in the United States in 2001 (Ball and Kissin 2002, 2003). Methamphetamine can be readily manufactured (“cooked”) in small kitchen or bathroom “labs,” and the process can result in explosions, fires, and exposure of household residents to toxic chemicals. The effects include increases in blood pressure, body temperature, activity, alertness, and risky sexual behaviors (Frosch et al. 1996). Toxicity can include stroke, seizures, arrhythmias, coma, and death. Methamphetamine has a relatively long half-life, and chronic methamphetamine users can exhibit prolonged psychosis. Evidence suggests the presence of long-term neurotoxicity in methamphetamine abusers after they become abstinent (Ernst et al. 2000). Withdrawal can produce a “crash” similar to cocaine withdrawal and accompanied by depression and anergia. Intravenous amphetamine abuse can present with the same complications as those of intravenous use of other illicit substances.

### Acute Management

Treatment of individuals who abuse amphetamines is similar to that of cocaine users. However, the effects of amphetamine may last longer. The consultant may be asked to assist with management of psychosis, aggressive behavior, or withdrawal depression and suicidality. Acidification of urine speeds elimination. Antipsychotic medications should be used to treat paranoid or delusional symptoms, which can continue for days to weeks after the drug is no longer present in the urine. Rehabilitation requires a comprehensive treatment approach, as described for other substances earlier (see section “General Principles” earlier in this chapter).

## Phencyclidine-Related Disorders

---

Phencyclidine (PCP) is an anesthetic agent that first appeared as a street drug in the 1960s; PCP abuse peaked between 1978 and 1980. In 2002, 3.2% of the population 12 years or older had used PCP at least once and 1.1% of high school seniors had used PCP within the past year (Johnston et al. 2004). Current street samples sold as PCP vary greatly in purity. Smoking marijuana cigarettes laced with PCP is the most common form of administration. PCP is a noncompetitive NMDA/glutamate receptor antagonist and has effects on serotonergic and dopaminergic systems as well (Jentsch and Roth 1999; Nabeshima et al. 1996).

### Medical and Other Complications

The psychoactive effects of PCP generally begin within 5 minutes and plateau 30 minutes after use. Volatile emotionality is the predominant behavioral presentation. PCP clinical effects are unpredictable, and people who repeatedly seek these experiences may have an underlying psychiatric disorder. Affects range from intense euphoria to anxiety, and behavior can include stereotypical repetitive activities and bizarre aggression. Distorted perceptions, numbness, and confusion are also common. Associated physical signs include hypertension, muscle rigidity, ataxia, and nystagmus (particularly vertical nystagmus). At higher doses, dilated pupils, hypersalivation, hyperthermia, involuntary movements, and coma can occur (Davis 1982; Deutsch et al. 1998).

### Acute Management

Acute reactions generally require pharmacological intervention. Intravenous diazepam is the drug of first choice; antipsychotics are occasionally necessary. Because supportive treatment may also be needed, management in a

medical setting is preferred. After ingestion of PCP, the urine test result may be positive for 7 days; false-negative results can occur. PCP elimination is initially enhanced by ammonium chloride and subsequently by ascorbic acid or cranberry juice (Aronow et al. 1980).

## Club Drugs and Hallucinogens

The term *club drugs* comes from the association of several drugs with use in dance clubs or all night dance parties ("raves"). Popular club drugs are methamphetamine (see earlier section, "Amphetamine-Related Disorders"), lysergic acid diethylamide (LSD; "acid"), 3,4-methylenedioxymethamphetamine (MDMA; "Ecstasy" or "X"), gamma-hydroxybutyrate (GHB; "liquid X"), ketamine ("special K"), Rohypnol ("roofies"), and dextromethorphan ("DMX") (Bialer 2002). Emergency department visits due to MDMA and GHB use increased dramatically starting in the late 1990s. In the United States in 2002, emergency department visits for MDMA-related disorders numbered 4,026 and for GHB-related disorders numbered 3,330 (Ball and Kissin 2002). Hallucinogenic drugs include LSD, mescaline, psilocybin, and synthetic derivatives such as 3,4-methylenedioxyamphetamine (MDA). The popularity of hallucinogens began to wane in the mid-1970s, but a modest resurgence in use occurred in the early 1990s, particularly among youth.

### MDMA ("Ecstasy")

MDMA, called "Ecstasy," was promoted in the 1960s and 1970s as a "mood drug" without the distracting perceptual changes of other hallucinogens (Grinspoon and Bakalar 1986). MDMA is usually taken orally but can be taken intranasally (snorted). The purity of the drug in tablets or pills can vary dramatically, and it is often "cut" with numerous stimulants. Desired effects include feelings of empathy, connectedness, extroversion, euphoria, and self-confidence. MDMA is thought to cause increased release of serotonin as well as serotonin reuptake inhibition. Serotonin neurotoxicity and parkinsonian syndromes have occurred in association with MDMA use, and neuropsychological deficits may persist; however, the actual relationship to drug use is hotly debated (Daumann et al. 2003; Halpern and Pope 1999; Reneman et al. 2001; Ricaurte et al. 2002; Rickert et al. 1999; Simon and Mattick 2002). MDMA use has been associated with derealization, depersonalization, and racing thoughts. Serious medical complications have included hyperthermia, seizures, cardiac arrhythmias, myocardial infarction, hyponatremia, fulminant liver failure (necessitating transplantation in several cases), and death (Burgess et al. 2000; Caballero et al. 2002; Kunitz et al.

2003; Qasim et al. 2001; Schifano et al. 2003; Shannon 2000; Vollenweider et al. 2002).

### GHB

GHB is a CNS depressant that is increasingly being used for recreational purposes. As recently as 1990, GHB was sold in health food stores as an antianxiety agent. On the street GHB is usually sold as a liquid. GHB users describe pleasurable effects similar to those of alcohol, and the adverse CNS effects of GHB are also similar to those of alcohol. After recognition of the toxicity of GHB, the U.S. government restricted access to this agent; however, this prohibition was followed by the appearance of 1,4-butanediol and gamma-butyrolactone, industrial solvents that are precursors of GHB. These substances began to be marketed as dietary supplements and have been taken recreationally, to enhance bodybuilding, and to treat depression or insomnia (Zvosec et al. 2001). Serious cases of toxicity with GHB and these two precursor solvents have included vomiting, incontinence, agitation, fluctuating consciousness, respiratory depression, and death (Zvosec et al. 2001). Regular daily GHB use can produce tolerance, physiological dependence, and addiction. The signs and symptoms of GHB withdrawal are similar to those of alcohol and benzodiazepine withdrawal (Dyer et al. 2001; Rosenberg et al. 2003). Treatment of GHB withdrawal and delirium is approached similarly to that of alcohol withdrawal with supportive care and high-dose sedatives (McDaniel et al. 2001).

### Ketamine

Ketamine hydrochloride was originally used as a human and animal anesthetic but recently has become part of the rave scene. Much of the ketamine sold on the street is diverted from veterinarians' offices. Ketamine is odorless and flavorless, so it can be added to beverages without detection. The drug also is a potent NMDA antagonist (Haas and Harper 1992). Ketamine produces dissociative feelings and sedation, immobility, amnesia, increase in body temperature, and analgesia (Dillon et al. 2003; Freese et al. 2002). Ketamine can be taken orally, smoked, snorted, or injected but generally is snorted or swallowed. Most of the effects of ketamine are dose-related. When taken at higher doses, ketamine can cause vomiting, amnesia, slurred speech, incoordination, agitation, delirium, and out-of-body experiences. Ketamine flashbacks, similar to flashbacks with hallucinogens, are common. Treatment is supportive.

### LSD and Other Hallucinogens

LSD is derived from ergot, a fungus, and is a potent mood-altering drug. Studies in the United States have shown a 5.9% annual prevalence of use by 12th graders

(Johnston et al. 2004), and 13% of women ages 14–26 years (Rickert et al. 2003) report ever having used LSD. LSD is sold on the street in capsules, tablets, and occasionally in liquid form.

LSD induces intense changes in perception of time, space, and body image. Physical signs of intoxication include tachycardia, dilatation of pupils, and sweating. An individual's response to LSD, mescaline, and related drugs varies greatly with the user's expectations and the circumstances of use. Individuals having "bad trips" can present with severe anxiety or paranoia. The chance of a bad trip is increased by emotional distress before use, reluctant use, or an aversive setting. Flashbacks, usually visual, occasionally occur after cessation of hallucinogenic drug use.

## Management

Hallucinogen-intoxicated patients should be placed in a quiet setting with minimal stimuli. Spoken to in a soft, calm voice, the individual is then "talked down" from frightening experiences. Diazepam sometimes is needed as an adjunct. Antipsychotics are rarely necessary. In studies involving small numbers of patients, clonidine, naltrexone, and sertraline have been used successfully to treat flashbacks (Lerner et al. 1998, 2000), but risperidone reportedly worsens symptoms (Morehead 1997).

## Cannabis-Related Disorders

---

The main psychoactive constituent in marijuana is delta-9-tetrahydrocannabinol ( $\Delta^9$ -THC), one of 60 cannabinoids. Marijuana sold on the street contains 5%–17%  $\Delta^9$ -THC (Drug Enforcement Administration 2001). Hashish is a resin from the cannabis plant that contains a higher percentage of  $\Delta^9$ -THC than does marijuana.  $\Delta^9$ -THC binds to cannabinoid receptors, located primarily in hippocampal and striatal regions. An endogenous ligand for these receptors, anandamide, has been identified (Ameri 1999). Results of several studies suggested that there is a genetic vulnerability to cannabis use and dependence (Kendler et al. 2002; Merikangas et al. 1998b; Tsuang et al. 1998). Medical use of marijuana is still a hotly debated scientific and political issue (Watson et al. 2000).

## Laboratory Findings

Cannabinoids can be detected in the urine of chronic abusers 21 days or more after cessation of chronic, heavy use, because of slow release from fat stores. In most occa-

sional users, urine drug screen results remain positive for 1–5 days (Schwartz and Hawks 1985).

## Intoxication

Peak intoxication after smoking cannabis generally occurs in 10–30 minutes. Intoxication usually lasts 2–4 hours, depending on the dose; however, behavioral and psychomotor impairment may continue several hours longer.  $\Delta^9$ -THC and its metabolites, which are highly liquid soluble, tend to accumulate in fat cells. This phenomenon extends the half-life to approximately 50 hours. Personality, past experience with the drug, and setting can alter the experience dramatically, although higher doses of  $\Delta^9$ -THC increase the chances of a toxic reaction. Users experience slowed sense of time, increased appetite and thirst, and a keener sense in all modes of perception. They also experience euphoria, heightened introspection, absorbing sensual experiences, feelings of relaxation and floating, and increased self-confidence. Psychosis, derealization, and aggression occur rarely. Conjunctivitis, a strong odor of cannabis, dilated pupils, tachycardia, dry mouth, and coughing are physical signs of recent use.

## Withdrawal

In chronic high-dose users, reported withdrawal symptoms from cannabis include anxiety, irritability, insomnia, anorexia, and myalgia, but no stereotypic syndrome has been described (Haney et al. 1999).

## Long-Term Use

Controversy surrounds the existence of an "amotivational syndrome" associated with chronic cannabis use. This syndrome is characterized by passivity, decreased drive, diminished goal-directed activity, fatigue, and apathy. Research into this amotivational syndrome is plagued by methodological problems, including selection bias and lack of control subjects. Long-term marijuana users may have residual cognitive deficits (Pope et al. 2001; Solowij et al. 2002) and other comorbid psychiatric symptoms (Troisi et al. 1998). There is little evidence that cannabis causes chronic psychosis in individuals who do not have symptoms (Gruber and Pope 1994).

$\Delta^9$ -THC is used in some medical settings to control severe nausea and vomiting, mainly in association with AIDS, cancer chemotherapy, and bone marrow transplantation.  $\Delta^9$ -THC is no longer an approved treatment of glaucoma, because more effective treatments are available. Other medical use remains highly controversial (Joy et al. 1999). A report by the Institute of Medicine com-

prehensively evaluated the scientific evidence for benefits and risks of using marijuana as a medicine (Watson et al. 2000).

## Acute Management

Marijuana intoxication does not usually require professional attention. Anxiolytic agents are occasionally needed, and neuroleptics are used in rare cases of protracted paranoia. Patients with cardiovascular disease may not tolerate the increased heart rate and blood pressure that are caused by marijuana.

## Long-Term Management

Treatment of people who abuse marijuana follows the general principles established for other substances, but special attention is paid to developmental issues in adolescent abusers. Adolescent drug programs typically focus on promoting age-appropriate behavior and communication skills.

## Nicotine-Related Disorders

---

Tobacco addiction is the most preventable health problem in the United States. In 1993, approximately 60 million Americans smoked tobacco, and 400,000 deaths and \$50 billion in direct medical-care expenditures were attributable to tobacco (Medical-Care Expenditures Attributable to Cigarette Smoking 1994). In the United States, approximately 30% of men and 26% of women smoke cigarettes. The percentage of young adults smoking cigarettes significantly increased between 1994 (35%) and 1998 (42%) (Office of Applied Studies 1999). Since 1965, the prevalence of cigarette smoking among adults in the United States has declined almost half. Cigarette smoking prevalence declined in the late 1970s, leveled off in the 1980s, and increased in the 1990s (Giovino 2002). Similar trends have occurred in other Western countries, but the prevalence of smoking has been increasing in Asia.

Nicotine is a psychoactive substance with euphoric and positive reinforcement properties, similar to those of cocaine and opiates (Benowitz 1988; Henningfield 1984). The individual develops tolerance to nicotine and experiences significant withdrawal symptoms, including craving for tobacco, irritability, anxiety, difficulty concentrating, restlessness, decreased heart rate, increased eating with a weight gain of 5–10 pounds (2.3–4.5 kg), and sleep disturbance. Subjects with higher nicotine tolerance have more withdrawal discomfort. Because most general hospitals

are smoke-free, nicotine withdrawal should be considered in the differential diagnosis of any anxious or dysphoric inpatient.

## Predisposition or Risk Factors and Comorbidity

Cigarette smokers generally begin smoking as teenagers, because of peer tobacco use, parental tobacco use, and symptoms of anxiety, depression, or conduct disorder. A strong association exists between smoking and other drug abuse, especially alcohol abuse. However, alcoholic patients stop smoking at the same rate as do nonalcoholic patients.

Genetic factors play a major role in the initiation of smoking and the transition to nicotine dependence (Sullivan and Kendler 1999). There is a well-established relationship between nicotine dependence and major depressive disorder. For example, Kendler et al. (1993) found a strong association between average lifetime daily cigarette smoking and lifetime prevalence of depression. Nicotine withdrawal is typically more severe in persons with histories of major depression or anxiety disorders. Patients with histories of major depressive disorder are prone to recurrence of depression after smoking cessation (Covey et al. 1997) and should therefore be more closely monitored.

## Effects

The adverse health effects of both active and passive smoking, as well as intrauterine exposure, are well-known and documented extensively in the literature. Tobacco use can produce a calming, euphoric effect in chronic users. This effect is more pronounced after a period of tobacco deprivation. Symptoms of acute nicotine poisoning include nausea, salivation, abdominal pain, vomiting and diarrhea, headaches, dizziness, and sweating. Inability to concentrate, confusion, and tachycardia also can occur (Hughes and Hatsukami 1986).

Tobacco smoke also contains polycyclic hydrocarbons that alter hepatic metabolism of many drugs (Carrillo et al. 1996; Hughes 1993). Patients who resume smoking after prolonged stays in smoke-free hospitals may experience clinically significant alterations in therapeutic blood levels of prescribed medications (Zevin and Benowitz 1999).

## Management

The success rate with every attempt to stop smoking is 5%, and 50% of individuals eventually stop. Behavioral,

cognitive, educational, self-help, and pharmacological approaches are all used to treat nicotine dependence (American Psychiatric Association 1996). Cognitive-behavioral treatments may be particularly suitable for patients with histories of depression (Hall et al. 1998). However, 95% of individuals who stop smoking receive no formal intervention; research is needed to clarify how and why these individuals discontinue use. Fear of weight gain frequently delays smoking cessation. Cognitive-behavioral strategies, pharmacological strategies, or exercise regimens are sometimes used to treat weight gain associated with cessation.

Nicotine replacement therapy should be considered for medically ill hospitalized patients with heavy nicotine addiction, because 50% experience marked withdrawal. Most general hospitals have antismoking rules, but it is unfortunate that few have adequate smoking cessation programs. Nicotine replacement is available in a number of forms, including gum, transdermal patch, intranasal spray, and inhaler.

Bupropion improves abstinence rates independently of its antidepressant effect (Hayford et al. 1999). Jorenby et al. (1999) found that combining bupropion with the transdermal patch further improves abstinence rates while reducing weight gain. The efficacy of bupropion is modest, and probably not unique, although not all antidepressants provide benefit in smoking cessation. Earlier smaller controlled trials showed beneficial effects of nortriptyline, doxepin, and cognitive behavioral therapy. The results of large controlled trials of fluoxetine and sertraline were never published. In a multiple-arm clinical trial Hall et al. (2002) found nortriptyline, bupropion, and psychological intervention each produced better abstinence rates than simple medical management, but all three had limited efficacy in producing sustained abstinence.

## Inhalant-Related Disorders

Inhalants are a diverse group of chemicals and include gasoline, airplane glue, aerosols (e.g., spray paint), lighter fluid, fingernail polish remover, typewriter correction fluid, a variety of solvents, amyl and butyl nitrites, and nitrous oxide. Inhalant use has been increasing among both male and female adolescents (Neumark et al. 1998). A high rate of abuse has also been found among Native Americans (Reed and May 1984). Nitrous oxide abuse occurs among medical and dental personnel. Inhalants are inexpensive and easily obtained. Fumes of glues and paint products are usually inhaled from bags or rags.

## Intoxication

Typical signs and symptoms of inhalant intoxication include grandiosity, a sense of invulnerability and immense strength, euphoria, slurred speech, and ataxia. Visual distortions and faulty space perception are also common. Inhalant intoxication is associated with aggressive, disruptive, and antisocial behavior. Among adolescents, inhalant abuse is associated with arrests, poor school performance, increased family disruption, and other drug abuse (Santos de Barona and Simpson 1984).

Intoxication can last from a few minutes to as long as 2 hours. Impaired judgment, poor insight, violence, and psychosis are common sequelae (Cohen 1984). Paint stains around the face are a clear indication of inhalant abuse. Central respiratory depression, cardiac arrhythmia, and accidents can cause death, and long-term damage to bone marrow, kidneys, liver, muscles, and the nervous system has been reported (Brouette and Anton 2001; Espeland 1995). The lifetime course of an inhalant abuser is not clear. Reports suggest that inhalants are primarily abused by youths. Inhalant abusers are likely to move on to other substances in later life.
